# FOREWORD

A comprehensive reference work on learning and memory could not be better timed than this. During the second half of the twentieth century, the study of learning and memory moved from a descriptive science largely based on the pioneering behavioral analyses of Pavlov, Thorndike, Watson, Skinner, Kamin, Rescorla, and Wagner to a new mechanistic science of mind that combines these brilliant behavioral studies with an analysis of the underlying neural mechanisms, first in a regional manner by Milner, Tulving, Mishkin, Squire, Schachter, and Morris, then on the cellular level, and finally on the molecular level.

The challenges that now face the field are outlined by the five great pioneers in the study of memory – the editor-in-chief Jack Byrne and the editors of these four extraordinary volumes: *Learning Theory and Behavior*, edited by Randolf Menzel; *Cognitive Psychology of Memory*, edited by Henry Roediger; *Memory Systems*, edited by Howard Eichenbaum; and *Molecular Mechanisms of Memory*, edited by David Sweatt. The challenge faced by the contributors to these volumes was to combine the molecular mechanisms with the other three levels in order to provide a coherent, systematically and intellectually satisfying understanding of learning and memory. This is central to the new science of mind. Since memory is the glue that holds our mental life together, the topics covered by these four volumes are central to and paradigmatic for all aspects of the neurobiology of mental life, which has as its goal the understanding of all mental processes in neurobiological terms. Indeed, it is the plasticity of the brain that is the key to understanding the continuity of all mental function. The goal for each of these four volumes was to bridge the subdisciplines concerned with the various forms of memory into a coherent science. The chapters of each of these volumes succeed admirably in doing just that. As a result, this rich and rewarding reference work will serve as a superb framework for the decades ahead, a reference that will provide both the student and the working scientist with the intellectual background necessary to understand and function effectively in the study of learning and memory.

# PREFACE

*Learning and Memory: A Comprehensive Reference* is the most authoritative set of volumes ever produced on learning and memory and represents the state of the science in the early 21st century. The study of learning (the process of acquiring new information) and memory (retention of that information for future use) has intrigued philosophers and writers for centuries because our memories and plans for the future consolidate who we are, and disruption of these processes dramatically interferes with our daily lives. The fascination with learning and memory is not limited to the humanities, but has been the subject of intense scientific research. Psychologists are concerned with elucidating the features of learning and memory processes and systems, neurobiologists seek to determine the neuronal mechanisms of learning and memory, and neurologists and psychiatrists focus on research and treatment of failures or disruptions in learning and memory.

The study of learning and memory represents a scientific field that has matured at all levels – from the discovery of the protein chemistry and molecular biology of the cellular events underlying learning and memory, through the delineations of the properties and functions of neuronal networks, to formulating and testing the psychological and behavioral neuroscientific theories of learning and memory. In addition, many basic research findings have applied implications on such diverse fronts as education, legal issues hinging on eyewitness testimony, learning disorders in children, memory disorders following brain damage, and declines in memory in older adults.

The volumes in this *Comprehensive Reference* are the result of a meeting in London in July of 2005 where the editors planned the massive work of consolidating all facets of the study of learning and memory. We collected nearly all the topics (albeit from many different disciplines and directions) that we considered constituted scientific approaches to learning and memory and proceeded to parcel the topics into four volumes, resulting in *Learning Theory and Behavior* edited by Randolf Menzel; *Cognitive Psychology of Memory* edited by Henry Roediger III; *Memory Systems* edited by Howard Eichenbaum; and *Molecular Mechanisms of Memory* edited by David Sweatt. This was a formidable task, not only because of the richness and diversity of the subject matter, but also because we needed to logically place topics in the appropriate volume. Although some of the decisions may seem arbitrary, and indeed there is overlap both within and between volumes, each editor ended up with a set of coherent topics that they could organize and introduce in a logical manner.

With approximately 40 chapters per volume, it is no surprise that the editors cover an unusually wide range of intellectual territory or that there is a difference in interpretation by some authors. The organization is a significant editorial challenge and investment in and of itself. However, it is the editor's selection of authors, and the ensuing scholarship on learning and memory from different perspectives, that make this series unique. Authors were identified and invited based on their expertise on a particular topic, and their contributions represent a marvelous compendium of research in learning and memory. The chapters in this series not only represent scientific strength and breadth, but also range from learning at the synaptic level to a systems level approach, and include studies of remarkable learning capabilities in a variety of invertebrates and vertebrates, including human beings.

The first volume in the series, *Learning Theory and Behavior* edited by Randolf Menzel, consists of 38 chapters and sets the tone for the interdisciplinary and comparative approach to the study of learning and memory. He introduces the volume by emphasizing both the value and the limitation of the comparative approach in natural and laboratory settings, stressing that we need information from the behaving animal as well as the neuronal structures in order to understand the processes involved in information storage and retrieval. Several chapters review progress from using animal models, including worms, molluscs, insects, rodents, birds, and nonhuman and human primates. In addition, concepts such as planning, decision-making, self-awareness and episodic-like memory, usually reserved for human beings, are discussed at several taxonomic levels. The final chapters take an engineering perspective and describe synthetic approaches, including modeling neuronal function and developing a concise theory of the brain.

The second volume, *Cognitive Psychology of Learning* edited by H. Roediger, is comprised of 48 chapters on various aspects of cognitive ability and the underlying neuroscience. The basics of attention, working memory, forgetting, false memories, remembering vs. knowing, the process of recognition, and episodic memory are covered. In addition, topics that are often not included in "memory" volumes deservedly receive attention here, e.g., learning of concepts and categories, learning of perceptual and motor skills, language learning, and implicit learning. This volume also covers memory processes throughout the human lifespan and includes chapters on individual differences in memory ability, both subnormal (learning disabilities) and supranormal (performance of mnemonists and experts in particular domains). Finally, chapters on applied aspects of memory research, dealing with such topics as eyewitness identification in the legal system and applications of research to educational issues, are included.

Volume 3, edited by H. Eichenbaum, consists of 29 chapters which represent a "progress report" on what we know about memory systems and their relationship to different parts of the brain. *Memory Systems* returns to a comparative approach of learning and memory. This volume introduces the concepts of multiple memory systems, and many chapters discuss in extensive detail the different features of declarative memory and their underlying brain structures. Procedural learning in humans and other animals is addressed, and a short section details the involvement of hormones and emotions on memory retention or loss. Finally, changes in memory systems associated with aging, disease processes, and drug use are addressed.

The final 42 chapters in Volume 4, *Molecular and Cellular Mechanisms of Memory* edited by J.D. Sweatt, represent a review of the state of the science of what we know at the systems, cell, and molecular levels on learning and memory formation, as well as providing a look at the emerging and future areas of investigation. Once again, this volume covers an impressive amount of information derived from studies at many taxonomic levels, from molecular associative learning mechanisms, through an array of studies on synaptic plasticity, to the cell level of fear conditioning.

The centrality of learning and memory to our daily lives has led to intense analysis by psychologists and neurobiologists for the past century, and it will undoubtedly remain at the forefront of research throughout this new century as well. It is our intention that this set of volumes will contribute significantly to the consolidation of this field, and it is meant as a resource for scientists and students interested in all facets of learning and memory. No other reference work covers so wide a territory and in so much depth.

*Learning and Memory: A Comprehensive Reference* would not have been possible without the tremendous work of the Editorial Board, who identified the topics and their authors, and reviewed each contribution. Special thanks also go to Johannes Menzel, Senior Acquisitions Editor at Elsevier, for supporting the project and Andrew Lowe and Laura Jackson, Production Project Managers, and Joanna De Souza, Developmental Editor, for ensuring that the production schedule was maintained.

# 2.01 Introduction and Overview

**H. L. Roediger III**, Washington University in St. Louis, St. Louis, MO, USA

## 2.01.1 The Cognitive Psychology of Memory: Introduction

The main problem in the scientific study of memory is that it proceeds on many different fronts. Neurochemical and neurobiological approaches propel some researchers; systems neuroscientists examine changes in larger pathways in the nervous system; animal behaviorists examine learning and memory as reflected in behavior of (mostly) infrahuman animals, such as birds finding caches of seed; cognitive psychologists study human memory through behavioral means using measures such as recall and recognition; computer scientists endorse computational approaches to memory that sometimes pay little attention to behavioral or neuroscience constraints; and, of course, the study of memory has been the topic of discourse by philosophers for over 2000 years. This four-volume series covers a huge selection of topics that are central to the scientific study of memory. In a different edited volume, Roediger et al. (2007) considered 16 critical concepts in the science of memory from the various viewpoints described above.

## 2.01.2 Cognitive Approaches to Memory

Practitioners of what is today called cognitive psychology have a long tradition of the experimental study of various aspects of memory. Experimental psychology is often dated from the founding of Wilhelm Wundt's laboratory in Leipzig in 1879. Coincidentally, that same year marks the year that Hermann Ebbinghaus (1850–1909) began his painstaking research that led to his great book, *Über das Gedächtnis (On Memory)* in 1885 (Ebbinghaus, 1885). Ebbinghaus conducted meticulous experiments that asked many fundamental questions about learning and memory, and virtually all his results have stood the test of time in that they have been widely replicated. His work dates the start of the cognitive/behavioral study of learning and memory in humans, although of course centuries of speculation and theorizing (particularly by the British empiricist philosophers) preceded and informed his first experimental efforts. Bower (2000) provides a brief historical overview of this approach to studying learning and memory.

Cognitive psychologists approach the problem of memory through careful experimentation to examine theories that vary in their levels of specification. Some theories (say, transfer-appropriate processing) are broad and seek to capture a wide range of performance across many situations, whereas other approaches (such as mathematical models of performance in specific tasks) are more formal and often attempt to capture memory performance only in tightly structured paradigms.

Traditionally, up until perhaps 30 years ago, cognitive psychologists paid little attention to neuroscience discoveries, and likewise, neuroscientists paid little attention to the experimental work of the cognitive psychologists. Although this division of labor is honored to some degree in the separate volumes of this work, the interests of scientists are clearly broader today. Unlike the case 30 years ago, cognitive psychologists today follow advances in neuroscience with great interest, and many of the concepts and tasks used by neuroscientists were originally developed by psychologists (either those studying animal learning and memory or those applying cognitive methods to these topics in humans). Although this volume is largely devoted to the cognitive/behavioral study of memory, many chapters lean heavily on neuroscience findings. The authors were given leeway to cover their particular topic from the vantage they deemed most appropriate, bringing in the types of evidence they considered most relevant. Some chapters rely heavily on neuroscience evidence, whereas others refer to purely behavioral experimentation. I see this as perfectly appropriate for the various topics covered in this volume.

## 2.01.3 Organization of the Volume

One time-honored procedure in the study of cognitive processes is sorting (e.g., Mandler, 1967). An experimenter can give a subject a set of concepts and ask him or her to sort them into groups. The hope is to discover something about how the subject's mind organizes experiences into concepts or categories. The titles of chapters for this volume were originally listed alphabetically, but then the editors of each volume were asked to organize them in some meaningful way, which corresponds reasonably well to a sorting task. I took several trials to reach criterion on this task and can still quibble with myself on various decisions. Luckily, the editors were not asked to create sections of the volume and to label our categories. Here I provide some rationale for the ordering of the chapters and, at the same time, outline the contents of the volume.

The volume begins with a chapter on attention and memory by Neil Mulligan (*See* Chapter 2.02). After all, events in the world that are not attended will not be encoded well and cannot be remembered later, so this seemed a logical starting point. Nelson Cowan's chapter on sensory memory (*See* Chapter 2.03) follows this one. Sensory memory (iconic storage, echoic storage, and similar processes in other modalities) lies at the borderline between perceiving and remembering. No one has ever proposed a good solution to the question of where perceiving ends and remembering begins, and ideas about sensory storage bridge this gap. Susan Gathercole's chapter on working memory comes next (*See* Chapter 2.04). The topic of how people hold information in mind while manipulating it in reasoning and solving problems represents a huge topic in cognitive psychology over the past 40 years. The next chapter is on serial learning by Alice Healy and William Bonk (*See* Chapter 2.05). Most research on serial learning uses paradigms requiring short-term recall (such as digit span and similar procedures), so placing it after the working memory chapter seems reasonable. However, the chapter also covers long-term processes in serial organization.

Robert Greene provides a chapter on the fundamental topic of repetition and spacing effects (*See* Chapter 2.06). Perhaps the first principle of learning and memory is that repeated experiences are (almost) always better remembered than single experiences; further, having two experiences distributed in time (up to some limit that differs for various tasks and retention intervals) leads to greater performance. Another fundamental principle, dating at least to George Miller's (1956) pioneering work on recoding in memory, is that events are not remembered as they are presented in the outside world (events do not somehow leap into the brain as veridical copies of experience), but, rather, events are coded (or recoded) as they are filtered through an individual's personal experiences (or apperceptive mass, to bring back a useful term from early in psychology). Events are remembered as they are coded and not as they necessarily 'are' in the environment. Reed Hunt's chapter on coding processes brings out this important point and shows how recoding can improve retention in some cases but in other cases can lead to errors (*See* Chapter 2.07). Mental imagery is one type of code that has received great attention in the literature, and Cesare Cornoldi, Rossana DeBeni, and Irene Mammarella review this literature in the next chapter (*See* Chapter 2.08).

An event that differs dramatically from many other events that are themselves similar is usually well remembered, which constitutes a distinctiveness effect. For example, a picture of a horse embedded in the middle of a 99-word list of other concrete nouns is much better remembered than if the word 'horse' is presented in a uniform list of 100 words (with 'horse' embedded in the analogous position in the list). This outcome occurs even if the mode of recall is verbal (i.e., people must recall the word 'horse' both when it is presented as a picture and as a word). Distinctiveness effects are ubiquitous in memory research, and Stephen Schmidt provides a review of what is known about this topic in his chapter 'A Theoretical and Empirical Review of the Concept of Distinctiveness in Memory Research' (*See* Chapter 2.09). The next chapter, 'Mnemonic Devices: Underlying Processes and Practical Applications,' by James Worthen and Reed Hunt, brings together the chapters on recoding, imagery, and distinctiveness by reviewing techniques for memory improvement that have been developed over the years (*See* Chapter 2.10). Some of these techniques date back to the ancient Greeks, but modern research has helped to uncover the reasons for their effectiveness. Many of these techniques depend on imagery, and some (such as the method of loci) rely on humans' ability to remember routes and spatial layouts well, especially ones experienced repeatedly. Timothy McNamara, Julia Sluzenski, and Bjorn Rump review the interesting topic of human spatial memory and navigation (*See* Chapter 2.11).

The next chapters in the volume have to do with memory losses and errors. Forgetting refers to the loss of information over time, and James Nairne and Josefa Pandeirada review the topic in their chapter by that name (*See* Chapter 2.12). A complementary topic is on inhibitory processes, a chapter by Karl-Heinz Bauml (*See* Chapter 2.13). Inhibitory processes are concerned with another set of phenomena that have to do with forgetting. The basic idea is that forgetting may result from an active process of memories being inhibited and therefore forgotten, at least temporarily. Forgetting is often considered an error of omission – information does not come to mind when we try to retrieve it – but errors of commission are of great interest, too. False memories arise when we retrieve information differently from the way it was experienced or, in the most dramatic cases, when we retrieve confident memories of events that never happened at all. Elizabeth Marsh, Andrea Eslick, and Lisa Fazio review this topic in their chapter titled 'False Memories' (*See* Chapter 2.14). Eric Eich, Elke Geraerts, Jonathan Schooler, and Joseph Forgas provide a chapter on mood and emotion in memory, titled 'Memory in and About Affect' (*See* Chapter 2.15). When people are in different moods when they experience events and then try to retrieve them later, they often remember more poorly than if the moods are the same between encoding and retrieval (the phenomenon of mood-congruent memory). However, when people experience greater emotional states during encoding (e.g., strong fear), they often remember events well.

The next few chapters have to do with retrieval of information from memory, as well as associated states of consciousness and processes during this process. Suparna Rajaram and Sarah Barber provide an overview of retrieval processes in memory (*See* Chapter 2.16). John Gardiner writes on the distinction between remembering and knowing, which are responses representing two states of conscious awareness during retrieval (*See* Chapter 2.17). Asher Koriat, Morris Goldsmith, and Vered Halamish discuss control processes in voluntary remembering, dealing with issues such as the criterion people use when deciding that recovered information should be reported as a memory and the factors affecting memory reports (*See* Chapter 2.18). Stephen Lindsay writes on the related topic of source monitoring, or the issue of how people recollect the source of information they report as a memory – did I read the fact in the newspaper, did a friend tell me, or was it learned from television (*See* Chapter 2.19)? Janet Metcalfe and John Dunlosky write on the issue of metamemory, or what people know about their own memories and the strategic processes used in regulating encoding and retrieval of information (*See* Chapter 2.20). Alan S. Brown has provided two chapters on puzzling phenomena of memory retrieval, the experience of déjà vu (when a person has the strange sensation that an event or scene has been experienced previously), and the tip-of-the-tongue phenomenon (the annoying experience when a desired bit of information can almost, but not quite, be retrieved) (*See* Chapters 2.21, 2.22).

Colleen Parks and Andrew Yonelinas provide the chapter 'Theories of Recognition Memory' (*See* Chapter 2.23), with particular emphasis on whether a single-factor or two-factor theory best accounts for the data. William Hockley writes about the related topic of memory search in various types of memory tests, including short-term recognition (S. Sternberg's (1966) item recognition test), long-term recognition, free recall, and other tasks (*See* Chapter 2.24). Both the chapter on recognition and the chapter on memory search involve considerations of mathematical modeling, and the next chapter by Jeroen Raaijmakers explicitly considers mathematical models of human memory (*See* Chapter 2.25). His chapter is followed by a related one by Michael Kahana, Marc Howard, and Sean Polyn on associative retrieval processes in episodic memory (*See* Chapter 2.26). Karl Szpunar and Kathleen McDermott provide an overview on the concept of episodic memory as it has developed since Tulving's seminal chapter in 1972 (Tulving, 1972) (*See* Chapter 2.27). They discuss how neural processes involved in episodic memory may also subserve a person's envisioning the future as well as recollecting the past.

The next series of chapters involves memory of a different kind from episodic memory. David Balota and Jennifer Coane's chapter on semantic memory concerns representation of well-learned information such as words and their meanings (*See* Chapter 2.28). Brian Ross, Eric Taylor, Erica Middleton, and Timothy Nokes survey the related field of how humans learn concepts and categories in 'Concept and Category Learning in Humans' (*See* Chapter 2.29). Gideon Deák and Anna Holt describe research on the critical issue of language learning and report how theories have advanced over the years (*See*

Chapter 2.30). Peter Frensch and Hilde Haider discuss research on the venerable topic of transfer and expertise (*See* Chapter 2.31), a topic that really runs throughout the book in many ways.

Pierre Perruchet reviews the evidence concerning implicit learning, which uses transfer designs as a major tool for understanding (*See* Chapter 2.32). Dale Stevens, Gagan Wig, and Daniel Schacter then review recent evidence on the related topic of implicit memory and priming (*See* Chapter 2.33). Timothy Lee and Richard Schmidt provide an overview on the topic of motor learning and memory, which is related to implicit learning in some ways (*See* Chapter 2.34). Much recent work has shown that procedural and motor skills (as well as some other forms of learning) consolidate while people sleep. Jessica Payne, Jeffrey Ellenbogen, Matthew Walker, and Robert Stickgold review this exciting frontier in memory research in 'The Role of Sleep in Memory Consolidation' (*See* Chapter 2.35).

The next group of chapters is concerned with development of memory across the lifespan, as well as individual differences among people in memory ability. Carolyn Rovee-Collier and Kimberly Cuevas review evidence about infant memory (*See* Chapter 2.36), and then Peter Ornstein, Catherine Haden, and Priscilla SanSouci consider the development of skilled remembering in children (*See* Chapter 2.37). Elena Grigorenko discusses developmental disorders of learning (*See* Chapter 2.38), and Michelle Dawson, Laurent Mottron, and Morton Gernsbacher describe learning in autism (*See* Chapter 2.39). Michael Kane and Tina Miyake write about individual differences in episodic memory among adults (*See* Chapter 2.40), and Moshe Naveh-Benjamin and Susan Old discuss aging and memory (*See* Chapter 2.41). Finally, Anders Ericsson describes research on superior memory of mnemonists and experts in various domains (*See* Chapter 2.42).

The next few chapters of the book focus on more applied aspects of learning and memory research. Mark McDaniel and Aimee Callendar discuss work on cognition, memory, and education, focusing on applying principles from learning and memory research to educational practice (*See* Chapter 2.43). Jeffrey Neuschatz and Brian Cutler discuss the important issue of eyewitness identification (*See* Chapter 2.44). Since the advent of DNA evidence, over 200 people convicted of crimes – often on the basis of eyewitness evidence - have been released from prison, exonerated by DNA evidence. This state of affairs has caused a searching examination of the typical methods used by police to conduct eyewitness identifications. Gilles Einstein, Mark McDaniel, Richard Marsh, and Robert West discuss another popular topic in recent research – how people remember to do things in the future, such as taking an antibiotic pill four times a day when fighting an infection. Their chapter, 'Prospective Memory: Processes, Lifespan Changes, and Neuroscience,' discusses this interesting line of research (*See* Chapter 2.45).

The last three chapters of the volume examine memory from a broader perspective. Most chapters previously described are based on laboratory tasks concerned with learning and memory. Martin Conway and Helen Williams write on the nature of autobiographical memory, which is concerned with how people recollect the events of their lives (*See* Chapter 2.46). Michael Ross, Craig Blatz, and Emily Schryer discuss social memory processes, which includes the issue of how people influence one another as they remember (as well as other topics) (*See* Chapter 2.47). Finally, James Wertsch discusses the emerging topic of collective memory (*See* Chapter 2.48), which is a representation of the past that is shared by members of a group. The group might be people in a nation recollecting an important historical event, such as how people in the United States remember the Revolutionary War. Different groups may see the past in different ways, as Wertsch brings out in his chapter. The empirical study of collective memory is an emerging topic but one that is sure to be more important in the future.

## 2.01.4 Conclusion

The 47 substantive chapters in this volume represent a marvelous, state-of-the art digest by leading scholars as they summarize what is known about many of the critical topics in the cognitive psychology of learning and memory. The entries range from topics that have a long history (e.g., transfer) to those that have emerged only recently (prospective memory, collective memory). Editing the volume has caused me to learn much, and I believe every reader of this volume will share this experience.

# 2.02 Attention and Memory

**N. W. Mulligan**, University of North Carolina, Chapel Hill, NC, USA

> Very great is the dependence of retention and reproduction upon the intensity of the *attention* and *interest* which were attached to the mental states the first time they were present. [italics in original] (Ebbinghaus, 1885: 3)

> Whatever future conclusions we may reach as to this, we cannot deny that *an object once attended to will remain in the memory,* whilst one inattentively allowed to pass will leave no traces behind. [italics in original] (James, 1890: 427)

## 2.02.1 Introduction

This chapter provides a brief overview of the relationship between attention and memory. The above quotations, although specifically written about the relationship between attention and long-term memory, provide a traditional viewpoint articulating the intimate connection between these constructs. Indeed, as Norman (1969) notes, a researcher would have little difficulty finding similar speculations in the earliest surviving writings in philosophy of mind. Ancient practical manuals on memory and rhetoric begin with the fundamental assumption that successful memory starts with attention (Yates, 1966). Modern researchers in cognitive psychology are likewise interested in attention and memory, but typically for theoretical reasons rather than the practical demands of the rhetorician's 'art of memory.' We shall see that, despite disputes about the details, these quotations remain quite apt regarding many aspects of the relationship between attention and memory.

At the outset, it should be noted that there is a tremendous amount of research under the general heading of 'attention and memory,' enough to require a book-length review even in the early days of the 'cognitive revolution' (Norman, 1969), and even more so in later eras (Cowan, 1995). Consequently, this short review is necessarily selective and incomplete. My goal is simply to describe some of the most important trends and results and to point the interested reader in the direction of additional resources. To begin, we briefly discuss the varieties of memory and the varieties of attention before proceeding to discuss the relationship between the two.

### 2.02.1.1 Varieties of Memory

Psychologists have long found it useful to differentiate among forms or aspects of memory. The most basic distinction is based on duration, the difference between immediate, fleeting retention of recently presented material and longer-lasting, more permanent aspects of memory. This distinction was captured early on in James's distinction between primary and secondary memory and was similarly delineated in the modal model of Atkinson and Shiffrin (1968), with its distinction between the short-term and long-term stores. Contemporary psychology continues to distinguish between shorter-term and longer-term memory, as well as among different forms of long-term memory, based on neuropsychological, neuroscientific, and behavioral evidence (e.g., Schacter et al., 2000).

Working memory is the current term for short-term or primary memory, although this conception is more complicated than the unitary short-term store envisaged in the modal model. Working memory is the system responsible for the short-term storage and manipulation of mental representations and contains three primary components, the phonological loop, the visuospatial sketchpad, and the central executive (Baddeley, 1986). The phonological loop is the mechanism responsible for the storage and rehearsal of phonological/verbal information. In a similar way, the visuospatial sketchpad provides temporary maintenance of visual and spatial patterns. The central executive coordinates the operation of these two subsidiary components and mediates the manipulation and transformation of information in these subsystems. The central executive is often associated with limited-capacity attentional resources (Engle, 2002), as discussed later. Finally, a recent version of the working memory model (Baddeley, 2002) proposes an additional component, the episodic buffer, responsible for binding together information represented in different forms or codes (**Figure 1**).

As short-term memory has been fractionated into multiple components, recent theorizing also distinguishes among multiple forms of long-term memory. These distinctions are based on several dimensions, key among them differences in phenomenology and differences in informational (or representational) content. First, it is common to differentiate among varieties of long-term memory based on phenomenology at retrieval, that is, whether the retrieval produces conscious recollection or not. This is critical to the distinction between explicit memory, which refers to conscious, intentional recollection of the past, and implicit memory, which refers to unconscious or unintentional influences of the past. Numerous differences (or dissociations) between explicit and implicit memory lend credence to the importance of this distinction (e.g., *See* Chapter 2.33; Mulligan, 2003b). The distinction between recollection and familiarity made in dual-process models of memory similarly relies on differences in the phenomenology of retrieval (Yonelinas, 2002).

Distinctions based on informational content are important to the multiple systems view of long-term memory (e.g., Schacter et al., 2000), a view that overlaps with distinctions based on phenomenology. First, and most important for our present purposes, is episodic memory, long-term memory for personally experienced events. This form of memory records autobiographical experiences that occurred at a specific time in a specific place. As noted by Tulving (2002), this form of memory permits 'mental time travel,' allowing a person to reexperience an event from the first-person perspective. Episodic memory overlaps with the concept of explicit memory because it supports the conscious and intentional recollection of the past. Semantic memory refers to the organized body of general knowledge about the world. This form of memory includes concepts, categories, vocabulary, and so on. This form of memory is distinguished from episodic memory by its depersonalized nature. Retrieving information from semantic memory is tantamount to retrieving facts rather than reexperiencing prior episodes.

The perceptual representation system (PRS) is

> a collection of domain-specific modules that operate on perceptual information about the form and structure of words and objects. (Schacter et al., 2000: 635–636)

This system represents long-term knowledge of perceptual objects in the modality in which they are processed. Finally, procedural memory is the system that represents skilled behaviors, including perceptual and motor skills, as well as more abstract cognitive skills. This system is marked by slow, incremental strengthening of representations through repeated practice. Procedural memory encompasses the learning of motor skills, such as riding a bike or

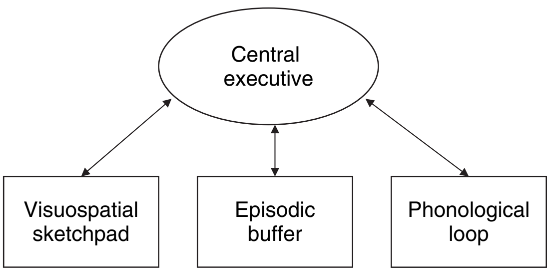

**Figure 1** The working memory model. Adapted from Baddeley AD (2002) Is working memory still working? *Eur. Psychol.* 7: 85–97, with permission.

swinging a golf club, as well as cognitive skills, such as learning to read.

Conscious recollection (explicit memory) is associated with the episodic system. Implicit memory is more various, forms of which appear to be mediated by each of the other nonepisodic systems. For example, perceptual priming (one manifestation of implicit memory) is attributed to the PRS, whereas conceptual priming is attributed to the operation of the semantic system. Finally, the expression of procedural skills is also associated with implicit memory.

### 2.02.1.2 Varieties of Attention

Just as memory is multifaceted, so too is attention. To begin, let us examine James' classic definition of attention:

> It is the taking possession by the mind, in clear and vivid form, of one out of what seems several simultaneously possible objects or trains of thought. Focalization, concentration of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others. (James, 1890: 403)

From such a description, researchers have typically teased out several aspects or dimensions of attention. First, attention is used for selection among the multitude of stimuli that impinge on our senses at any given moment. Perception would lack coherence if we attempted extensive analysis of every stimulus in the perceptual field. Second, attention implies a limited ability to process information. This is often characterized as a limited pool of attentional resources. Third, attention pertains to control in several ways: control of the flow of information, control of ongoing behavioral responses, and control of prepotent responses (e.g., inhibition).

The dominant distinction in recent research is between peripheral (or modality-specific) aspects of attention (such as visual attention) and central (or modality-independent) aspects of attention. For example, Johnston et al. (1995) propose a distinction between input and central attention, which distinguishes two limited-capacity mechanisms: one responsible for selective aspects of attention, and the other involved in higher-level mental functions (decision making, response selection, etc.). The distinction between selective and central attention corresponds quite closely to similar distinctions made in the literature on attention systems (Wickens, 1984; Duncan et al., 1997; Duncan, 1999), such as the distinction between perceptual and decisional attention (Ashby et al., 1998; Maddox, 2002), the distinction between perceptual and executive attention (Pashler, 1998; Engle, 2002), and the distinction raised in the neuroscience literature between the posterior and the anterior attention systems (Posner and Peterson, 1990; see also Freiwald and Kanwisher, 2004; Humphreys and Samson, 2004). Finally, the concept of central attention is often associated with the central executive component of Baddeley's (1986) model of working memory (e.g., Engle, 2002).

Studies of selective attention and central attention have typically used different experimental paradigms. In the typical experiment on selective attention, multiple stimuli are presented in the same modality, and the participant's attention is either directed at a critical stimulus or directed away from the critical stimulus by requiring the participant to respond to other (distracter) stimuli. Studies of central aspects of attention typically use divided-attention (or dual-task) paradigms. In these experiments, the participant is presented with two streams of stimuli in different modalities (e.g., visual and audition) and required to divide attention across the two sets. This is usually done by requiring the participant to respond to both streams of stimuli and by instructing the participant that both types of responses are important (i.e., encouraging the participant to divide attention equally over both tasks).

## 2.02.2 Attention, Memory, and the Beginnings of the 'Cognitive Revolution'

### 2.02.2.1 Cherry's Dichotic Listening Studies

Many of the landmark studies of the studies of the modern era of cognitive psychology focused on attention and memory. Specifically, studies of dichotic listening sought to analyze the role of selective attention in perception and memory. The initial study was that of Cherry (1953), who pioneered the experimental paradigm that would have such profound effect on later empirical and theoretical work. Cherry and the other early researchers were taken by the 'cocktail party problem,' which serves as a natural example of selective attention. At a cocktail party, there may be numerous conversations occurring all around the listener, any one of which could, in principle, be comprehended if attention were so directed.

A person in a conversation must attend to one speaker (and filter out all of the competing messages) to successfully take part in the conversation. How does this occur, and what is the fate of the unattended message(s)? To study this problem, Cherry developed an experimental analogue that would set the agenda for much of the early research on attention and memory. In this experimental technique, participants attended to one of two simultaneously presented messages. The messages were presented over different tracks of a stereo headset so that one message was presented to one ear, and a different message was presented to the other ear. The attended message was human speech, and the ignored message might consist of other human speech (in English or in another language), reversed speech, music, a steady tone, and so on. To ensure that subjects were attending to the correct message, the message was repeated by the subject as it was heard – a task called shadowing. The message that was not shadowed can be characterized as ignored or irrelevant rather than unattended. Although the goal of the dichotic listening task is to render the irrelevant message unattended, this may not always happen. It is possible that subjects might shift their attention on occasion to the nonshadowed message, undermining the goal of the experimental technique. This possibility makes a more neutral term (ignored or irrelevant) a better designation for the nonshadowed input.

Cherry found that subjects were successful in the shadowing task when the two messages differed in terms of their physical properties. The typical physical difference between the messages was spatial location, with one message presented to one ear and the competing message presented to the other. The messages could also be successfully segregated (and one successfully shadowed) when both messages were presented on the same track, provided the messages differed on another physical dimension, such as a male versus a female voice. However, if the two messages were physically similar (e.g., same location, or input ear, and same or similar voices), then the shadowing task became extremely difficult even if the messages differed in other ways, such as the topic or meaning of the messages. Cherry concluded that selection could only operate on the physical characteristics of the message and not on their content.

Most important for the present purposes was the memorial fate of the ignored message. Consistent with his conclusions about selection, Cherry (1953) found that only the physical properties of the ignored message were later remembered. After the shadowing task was over, subjects were asked what they remembered of the ignored message. Typically, subjects could remember whether it was human speech as opposed to a tone or music. Furthermore, they could recall whether it was a male or female voice. However, the subjects showed very little memory for the content of the unattended speech. That is, they showed little memory for words or phrases in the unattended message. Moray (1959) showed that, even when the same word was presented repeatedly – as many as 35 times – in the ignored ear, there was no memory for the stimulus. Furthermore, subjects were not entirely certain that the language was English. Reversed speech and speech in other languages were rarely recognized as non-English. Cherry's broad conclusion was that the unattended material is analyzed at the level of gross perceptual characteristics, but that selective attention is required for the analysis of and long-term memory of detailed aspects of the message such as the language spoken, the identity of individual words, and semantic content.

#### 2.02.2.2 The Filter Model and the Debate between Early and Late Selection Theories

From research on dichotic listening, Broadbent (1958) developed an early, highly influential information processing account of attention, perception, and memory (**Figure 2**). In this model, Broadbent depicted cognition as a series of discrete, serial information-processing stages. Processing begins with sensory systems, which can process large amounts of raw sensory information in parallel. Other research (e.g., split-span studies) indicated that sensory information may be preserved for a short time prior to selection. Thus, Broadbent argued that the initial sensory processing of the perceptual characteristics of inputs was deposited into a short-term memory buffer. This is the point at which attention operates in Broadbent's model, acting as a selective filter. The filter blocks out unwanted inputs based on selection criteria that reflect the goals of the cognitive system. For example, given that the subject's goal is to succeed at the shadowing task, selection is based on the physical location of the to-be-attended message. The selection criteria operate on one of the perceptual characteristics of inputs in the memory buffer. The attended material gains access to a limited-capacity perceptual system (the P system in **Figure 2**), which allows analysis for content, conscious awareness, and ultimately, encoding into long-term memory.

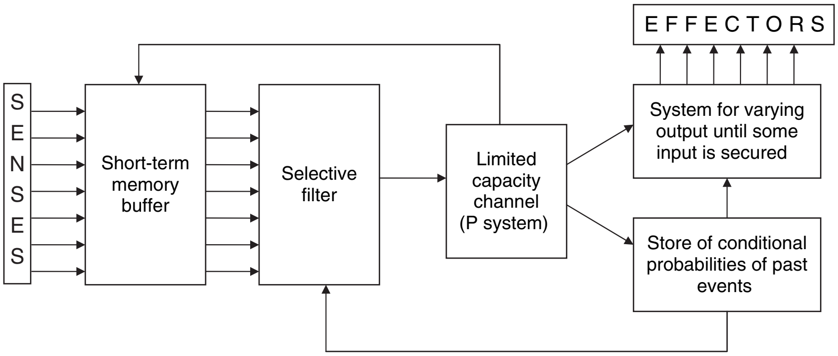

**Figure 2** The filter model. Adapted from Broadbent DE (1958) *Perception and Communication.* London: Pergamon Press, with permission.

It should be noted that Broadbent's model has many similarities to the Atkinson and Shiffrin (1968) modal model. The memory buffer in Broadbent's model corresponds to the sensory register of Atkinson and Shiffrin, in that both store raw sensory information prior to selective attention and refined perceptual analysis. The limited-capacity perceptual system of Broadbent is analogous to the short-term store of Atkinson and Shiffrin in terms of its limited capacity, its equation with the contents of awareness, and its role as a conduit to long-term storage.

Broadbent's model proposed that the selective filter operates on the basis of physical characteristics of the message and prior to the analysis of meaning. Consequently, this model is referred to as an early-selection model of attention. Subsequent research on the filter theory raised questions about early selection and gave rise to important competitor models. For example, Moray (1959) found that participants often noticed their own name when it was presented in the ignored channel. According to the filter model, detailed content such as the identity of a word or name should be unavailable from an unattended message. A converging result came from Treisman's (1960) study, in which one story was presented to the attended ear (and shadowed by the subject) and a second story was presented to the ignored ear. Partway through the study, the first story switched tracks and replaced the story in the ignored ear (the first story itself being replaced in the attended track with a new, third, story). According to the filter theory, if the subject is not attending to the irrelevant ear, then they should not process any of its content, and thus should have no awareness that the first story continued in the irrelevant channel. However, subjects typically continued to shadow the first story even after it switched ears. Neither of these results comports with Broadbent's original filter model.

Treisman (1964) handled these new findings by modifying Broadbent's theory. Treisman argued that selective attention does not operate as an all-or-none filter but, rather, operates like a gain control, attenuating unattended inputs. Such attenuated stimuli still might be recognized (i.e., their content fully analyzed) if the stimulus is very important (such as one's own name) or has been primed by attended semantic context. This attenuation view preserves the early placement of the selective filter (now an attenuator) as operating prior to semantic analysis and the processes required for encoding into long-term memory.

An alternate approach was adopted by late selection models (e.g., Deutsch and Deutsch, 1963; Norman, 1968). These models proposed that stimuli routinely undergo substantial analysis (up to identification processing), whether attended or not. The selective mechanism in these models operates after perceptual and content analysis but before response selection. Under this view, semantic analysis helps determine which stimulus is most relevant for current goals and should guide behavioral response.

A number of subsequent results were taken as supportive of late selection. For example, Lackner and Garret (1972) found that the interpretation of ambiguous sentences in the attended ear was biased by words presented in the ignored channel. The results of Corteen and associates (Corteen and Wood, 1972; Corteen and Dunn, 1974) were similarly interpreted as supporting late selection and memory access without attention. Participants in these studies initially underwent a learning phase in which a set of words was paired with electric shock. In a subsequent phase of the experiment, participants showed a heightened galvanic skin response (GSR) to the shock-paired words even when these words were presented to the ignored channel in a dichotic listening task.

Results such as these imply semantic analysis of unattended information (and late selection) but have been controversial because of the possibility of covert shifts of attention. It is possible in dichotic listening tasks (and in other selective attention tasks) that a subject's attention might wander to the nominally unattended ear. The critical question is whether results such as the above represent semantic analysis of unattended information or momentary shifts of attention to the ignored ear. As framed by Lachter et al. (2004), the issue is whether there is leakage (penetration of the selective filter by semantic content) or slippage (covert, perhaps unintentional, shifts of attention). In a review of the literature, Holender (1986) concluded that results that appear to support late selection in auditory selective attention are actually the result of such attentional slippage. A more recent review comes to the same conclusion for studies of both auditory and visual selective attention (Lachter et al., 2004). Furthermore, Lachter et al. (2004: 884–885) argue that the potential for slippage was underestimated in early research because estimates of the time necessary for attentional shifts were quite high (estimated to be 500 ms or longer in Broadbent (1958)). More modern estimates are as low as 150 ms for voluntary (endogenous) shifts of attention and 50 ms for involuntary (exogenous) shifts. If attention can be so rapidly shifted from one stimulus (or channel) to another, it raises the possibility that rapid shifts of attention might go unnoticed by the experimenter.

This issue has been raised regarding a number of studies. Following up on the results of Corteen and Dunn (1974), Dawson and Schell (1982) presented shock-associated words in the ignored channel of a dichotic listening task. Trials were separated based on evidence for attentional shifts to the ignored channel (based on on-line performance such as shadowing errors). The heightened GSR effect was much greater on trials exhibiting evidence of attention shifts than on trials exhibiting no such evidence. In a similar vein, Wood et al. (1997) varied the difficulty of the primary shadowing task (by increasing the rate of speech to be shadowed) under the assumption that, as the shadowing task becomes more demanding, covert attentional shifts to the ignored channel would be less likely. Evidence for semantic processing and long-term memory of the ignored channel was only found for easier shadowing tasks; no such evidence was found for the more demanding shadowing task, consistent with the idea that covert shifts of attention may give the appearance of semantic processing and long-term memory for unattended materials (for thorough review of these issues, see Holender, 1986; Lachter et al., 2004).

Finally, working memory resources, to be discussed in more detail next, may play a critical role in selective attention. For example, Conway et al. (2001) investigated the cocktail-party effect of Moray (1959), with participants of high and low working memory capacity. Prior research indicates that low working memory capacity is associated with distractibility. Conway et al. (2001) reasoned that more distractible subjects are more likely to allow their attention to shift to the irrelevant channel. This study found that the low-capacity subjects were much more likely to notice their name in the irrelevant channel. This result is consistent with the previous research suggesting that attention shifts may be responsible for the appearance of semantic processing of the ignored channel. In addition, this result indicates a close connection between working memory and selective attention. Similarly, deFockert et al. (2001) found that increasing a working memory load made subjects more susceptible to distraction in a visual selective-attention task. Several researchers have now suggested that selective attention processes are controlled by working memory resources (e.g., Engle, 2002; Lavie et al., 2004). That is, working memory capacity may dictate the extent to which we can successfully focus on one input in the face of distraction (as in dichotic listening). From a historical perspective, this is an interesting inversion. Psychology has traditionally described attention as controlling access to memory structures, but this view implies that a memory structure (working memory) controls the function of an attentional process (selective attention).

## 2.02.3 Working Memory and Attention

The concept of immediate or short-term memory has long been defined in terms associated with attention. For example, in the modal model of Atkinson and Shiffrin (1968), the presence of information in the short-term store rendered it available to consciousness and allowed the information to guide and control ongoing behavior. Attention is likewise associated with conscious awareness and control of behavior. The short-term store is defined as having a sharply limited capacity, as is attention when discussed in terms of processing resources. The same points could be made about the limited-capacity perceptual system in Broadbent's filter model. Of course, short-term memory is currently conceptualized in terms of the working-memory model (Baddeley, 1986), which contains specialized subsystems. However, the subsystems are similarly characterized as limited-capacity processing resources, although in the case of the phonological loop and visuospatial sketchpad, the resources are applied for specialized purposes.

In the modal model, the digit span task was the standard measure of the capacity of short-term memory, which along with numerous other assessments of capacity, yielded the famous estimate of $7 \pm 2$ (Miller, 1956). In the contemporary working memory model, digit span (along with other simple span tasks) is interpreted as a measure of the phonological loop. Analogous measures assess the capacity for storing visual and spatial information in the visuospatial sketchpad. For example, in one visual span task (Logie, 1996), a subject is presented with a matrix of blocks for a brief time. Some of the blocks are filled in, and others are unfilled. After a brief delay, the matrix is represented with one block changing from filled to unfilled (or vice versa). The participant's task is to identify the changed block. This task is relatively easy if the matrix consists of few blocks but becomes increasingly difficult as the size of the matrix increases. The matrix size at which the subject can no longer reliably identify the changed block is taken as the upper bound of the storage capacity of the visuospatial sketchpad.

The phonological loop and sketchpad are subject to dual-task interference, another of the ways in which the subsystems of working memory can be characterized as capacity-limited resources. In the case of these subsystems, the limitations are most clearly exhibited for distracter tasks requiring the same working memory resource. For example, if subjects simultaneously carry out a digit span task and a verbal distracter task (both tasks that draw on the phonological loop), the measure of capacity (i.e., digit span) is dramatically reduced relative to baseline. Alternatively, if digit span is carried out along with a distracter task requiring visual or spatial imagery (which should draw on the sketchpad and not the phonological loop), minimal reduction of digit span occurs. Visual span exhibits the opposite pattern of interference. A secondary task requiring visual or spatial imagery greatly reduces visual span, whereas a verbal secondary task produces much less of an effect. This pattern of selective interference provides part of the rationale for positing the two distinct storage systems (Logie, 1996). Furthermore, this demonstrates that the two subsystems are limited-capacity resources for specialized purposes or information types.

Although the phonological loop and visuospatial sketchpad can be related to the construct of attention via limited capacity, it is the central executive component of working memory that is most typically associated with attention. In contrast to the specialized subsystems, the central executive is a general, amodal processing resource that monitors and controls the actions of the working memory subsystems. Increasingly, the central executive is seen as playing the more general role of an attentional controller, prompting Baddeley (1993) to wonder whether working memory, particularly the central executive component, might be better labeled 'working attention.'

To assess the relationship between the central executive (and the entirety of working memory) and attentional control, it is useful to have a general measure of working memory capacity. These assessments do not solely measure the central executive, because the executive is assumed to regulate and control the other processes in the system rather than provide active storage of information itself. Measures of working memory are called complex span tasks because they seek to assess the joint processing and storage capacities of the whole system, in contrast with simple span tasks (like digit span) that predominantly measure passive storage of a single subsystem (such as the phonological loop). One example is the reading span task (Daneman and Carpenter, 1980) in which subjects read a series of sentences and simultaneously try to maintain the last word from each sentence. At the end of a set of sentences, the participant recalls the final words. The number of words recalled serves as the measure of working-memory span. This task requires both processing (for comprehension) and storage. A similar task is the operation span task (Engle, 2002), every trial of which consists of an equation and a word (e.g., "$4/2 - 3 = 6$? (yes or no) DOG"). The participant's task is to verify whether the equation is correct and remember the word for subsequent recall. At the end of a small set of trials (e.g., 2–7), the words are recalled (again serving as the measure of working memory span).

Working memory capacity, as measured in these tasks, correlates with a number of higher cognitive skills, such as language comprehension, reading ability, reasoning, and general intelligence (see Engle and Kane (2004), for a review). Importantly for the present purposes, working memory capacity also relates to the control of attention. As noted earlier, individuals with higher working memory spans are less distractible in dichotic listening tasks and exhibit greater control over inhibitory processes (e.g., Conway et al., 2001). Experimental manipulations of working memory capacity produce similar effects in selection and inhibition paradigms (deFockert et al., 2001; Engle and Kane, 2004; Lavie et al., 2004).

## 2.02.4 Attention and Episodic Memory

The preceding section focused on the relationship between attention and working memory. Returning to the quotations that began this chapter, we now turn to research on attention and long-term memory, beginning with episodic memory. The vast majority of research on long-term memory has focused on episodic (or explicit) memory, conscious recollection of the past on direct tests of memory such as recognition, free recall, and cued recall. Furthermore, most of this research on memory and attention examines the role of attention during encoding. The bulk of this research provides little challenge to the intuitive sense that attention is critical for long-term memory; that is, memory for a stimulus is negatively affected by manipulations of selective or divided attention. Rather, research in this domain typically examines whether some aspects of stimulus encoding might be less reliant on attention than others and whether any elements of episodic encoding can be thought of as being free of attentional influence. In addition, there has been recent interest in determining whether retrieval from episodic memory requires attention to the same degree as encoding.

### 2.02.4.1 Attention and Encoding

The deleterious effects of reduced attention during encoding have been amply documented from the earliest days of psychological research (Smith, 1895). This holds for manipulations of selective attention as well as dual-task manipulations meant to divide central attentional resources. Beginning with selective attention, the research on dichotic listening makes clear that memory for the content of material presented in the unattended channel is greatly diminished on explicit memory tests such as recognition and recall (Broadbent, 1971). Furthermore, it is often the case that there is no measurable episodic memory at all for ignored material. For example, Eich (1984) found that recognition memory was at chance for words presented in the ignored channel of a dichotic listening study. Of course, it is also clear from this early research that at least some rudimentary perceptual information about the unattended message persists. Even in studies with tight controls for covert attentional switching, subjects recall whether the ignored channel was human speech, a male or female voice, a tone, and so on, implying that some encoding of perceptual information occurs without selection (Lachter et al., 2004). On the other hand, it should also be noted that, even if perceptual information about ignored stimuli is encoded to some degree, the encoding of this information is enhanced by focused attention (Cowan, 1995).

Research on visual selective attention reveals similar results. For example, Wolford and Morrison (1980) developed a visual analogue to dichotic listening in which the study trials consisted of a word flanked by two digits (e.g., 3 DOG 5). In one condition, participants attended to the digits, judging if they were of the same parity (both odd or both even) or of different parity. Although the word was focally presented, it was not the object of attention. In another condition, participants attended to the word. Several blocks of trials were presented to fully accustom the participants to the encoding task. Later, participants were given a recognition test for the words. Not surprisingly, recognition memory was greater when participants attended to the words as opposed to the digits. In addition, when tested on words from the final study blocks (after practicing the parity judgment task over many trials), participants in the parity-judgment condition exhibited no recognition memory for the words. This is quite similar to dichotic listening results that imply that selective attention is critical for later long-term memory and may be absent in an unattended condition (Merikle and Reingold, 1991).

It is clear that selective attention to a stimulus enhances (and may be necessary for) long-term episodic memory for the stimulus. Substantial research has also been conducted to examine the role of central attentional resources in memory encoding, typically by using a dual-task paradigm (i.e., a divided-attention manipulation), in which encoding is carried out under full or divided attention conditions. For example, in the full attention condition, the participant might read a series of study words and attempt to memorize them for a later test. In the divided-attention condition, the participant attempts to read and memorize the study words while simultaneously carrying out a secondary task. The secondary tasks take on a number of forms but are all designed to compete for central attentional resources. For example, in the three-odd task, the participant hears a series of digits and signals whenever he/she detects a sequence of three odd numbers in a row. Alternatively, one might divide attention with a short-term memory load, in which the participant keeps in mind a set of digits or letters while reading and trying to memorize a set of study materials (the participant recalls the memory load at the end of the study trial to ensure that the material was kept in mind).

It is abundantly clear that dividing attention with tasks such as these degrades later memory on explicit tests, such as recognition or free and cued recall (e.g., Craik et al., 1996; Mulligan, 1998). It should be noted, however, that even quite demanding secondary tasks are unlikely to eliminate explicit memory (Mulligan, 1997, 1998). In addition, the effects of divided attention on encoding are graded: As the secondary task becomes more and more difficult, later memory for the study materials is reduced accordingly (e.g., Mulligan, 1997).

Much of the research in this area focuses on whether there are certain aspects of episodic memory that are more or less dependent on central attention. For example, Castel and Craik (2003) examined whether memory for item versus associative information has differential reliance on attention. Item memory refers to the recognition or recall of individual stimuli as having been present in some particular episode (e.g., the study phase of a memory experiment). Associative memory refers to memory for a newly formed association between stimuli. This goes beyond memory for which stimuli were present in a given context but requires remembering which stimuli were associated with one another. Castel and Craik argued that the formation of new associations requires binding processes that are carried out in prefrontal cortex and are highly dependent on central attention (e.g., Moscovitch, 2000). Consequently, these authors predicted that dividing attention during encoding should disrupt associative memory more than item memory. To test this prediction, participants were presented with pairs of study words under either full or divided attention (attention was divided with the three-odd task). Item memory was assessed by a recognition test for the second word of each pair. That is, participants merely had to remember whether the test word was presented during the study phase. Associative memory was assessed with a paired recognition test, using several types of test pairs. Some of the test pairs were identical to pairs on the study list (intact pairs), some test pairs consisted of two old words from different study pairs (rearranged pairs), and other test pairs contained one or two new words. On this test, participants try to recognize intact pairs from the study list, a discrimination requiring memory for a particular association formed during the encoding phase. Divided attention reduced accuracy in both of the item and associative tests, but as predicted, the deficit was substantially greater for associative recognition. Similar results are found on tests of context and order memory, tests that likewise require episodic binding of previously unrelated information (e.g., Troyer et al., 1999; Troyer and Craik, 2000).

Dual-process models of episodic memory, which propose two independent memory processes, recollection and familiarity (Jacoby, 1991; Yonelinas, 2002), are similar to the distinction between item and associative information. Recollection refers to consciously remembering both the specific test item and the context in which it occurred, whereas familiarity is an undifferentiated feeling that a stimulus was previously encountered. Recollection is assumed to entail a recall-like search process that is consciously controlled and intentional. Familiarity, however, is assumed to be unconscious and unintentional, reflecting processing fluency. Recollection is reliant on binding processes during encoding that associate items and their spatiotemporal context. This suggests that recollection should be quite sensitive to divided attention during encoding. Alternatively, familiarity is assumed to have much less reliance on associative processing, and consequently less reliance on attention. Several lines of research support these notions. First, different types of episodic tests show differential sensitivity to divided attention at encoding, with free recall being the most affected and recognition memory the least (e.g., Craik et al., 1996). Given that free recall is assumed to be heavily reliant on recollective search processes and recognition is more heavily influenced by familiarity, it makes sense that recall is more affected by divided attention than recognition. Second, methods used to tease apart recollection and familiarity within recognition memory (such as the process-dissociation and remember/know procedures) generally indicate that dividing attention during encoding has robust effects on later recollection but little effect on familiarity (see Yonelinas (2002) for a review).

### 2.02.4.2 Attention and Retrieval

Because the traditional view states that attention is critical for the *creation* of memory traces (e.g., James, 1890; Cherry, 1953; Broadbent, 1958; Norman, 1969), it is not surprising that the vast majority of the research on attention and episodic memory has focused on encoding. Interest in the role of attention in memory retrieval is a more recent development. In an early study on the topic, Baddeley et al. (1984) examined the effects of divided attention on both episodic encoding and retrieval using free-recall, cued-recall, and recognition memory tests. As one would expect, dividing attention during encoding decreased performance on all the memory tests. However, when attention was divided during retrieval there was little decrease in memory accuracy, leading Baddeley et al. to conclude that retrieval processes are relatively automatic.

Craik et al. (1996) likewise varied attention during encoding and during retrieval but came to somewhat different conclusions. Craik et al. used a secondary task that permitted two complementary assessments of the role of attention in memory retrieval. First, as in Baddeley et al. (1984), accuracy in the memory task was compared under the full and divided attention conditions. Second, performance on the secondary task in the divided-attention condition was compared with performance in this task when performed alone (in a baseline condition, in which the secondary task was the sole task). The first comparison indicates whether the secondary task has an effect on memory retrieval. The second comparison indicates whether memory retrieval has an effect on the secondary task. Such secondary task costs are a traditional way to measure whether a process (like memory retrieval) requires attention. The results of the first comparison were consistent with Baddeley et al. (1984): dividing attention during retrieval produced little decline in memory accuracy (of course, divided attention during encoding produced the typical reduction in memory performance, **Figure 3**). However, the second comparison indicated that performance in the secondary task was disrupted when paired with memory retrieval. This contradicts the proposal that retrieval processes are automatic. Rather, Craik et al. argued, retrieval processes make use of attentional resources (as evidenced by the secondary task costs) but proceed in an obligatory (or 'protected') manner (Naveh-Benjamin et al., 2000). Under this view, retrieval takes precedence over other ongoing activities, protecting retrieval accuracy from the deleterious effects of a secondary task.

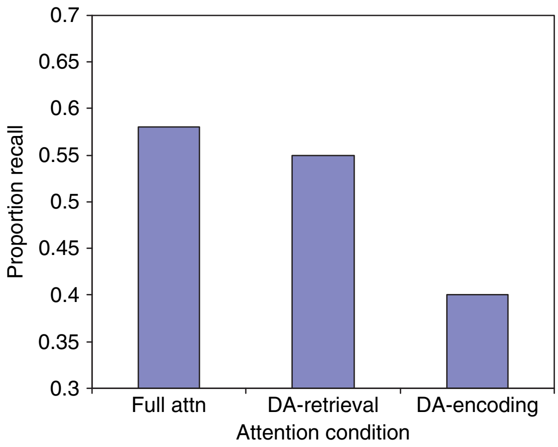

**Figure 3** Craik et al. (1996) found that dividing attention during encoding produced a substantial decrease in recall, whereas dividing attention during retrieval produced minimal effect. Full attn = full attention at both encoding and retrieval; DA-encoding = divided attention during encoding, full attention during retrieval; DA-retrieval = full attention during encoding, divided attention during retrieval.

Although Baddeley et al. (1984), Craik et al. (1996), and several other studies (see Craik (2001) for a review) found no effect of divided attention at retrieval on memory accuracy, such effects sometime emerge. Some studies report significant effects on free and cued recall without finding a comparable effect on recognition accuracy (e.g., Park et al., 1989; Anderson et al., 1998). In other studies, a significant decrement to recognition accuracy is reported (Fernandes and Moscovitch, 2000; Hicks and Marsh, 2000; Lozito and Mulligan, 2006). It is important to ascertain why such effects might be found.

Fernandes and Moscovitch (2000, 2003) have argued that memory retrieval is more likely to be disrupted when the secondary task and the memory task use the same type of materials. For example, Fernandes and Moscovitch (2000) used either a number-based or word-based secondary task as participants carried out a recall or recognition test for studied words. The number-based task did not disrupt test accuracy (consistent with Craik et al., 1996), whereas the word-based task significantly reduced memory accuracy. Although the results indicate a divided attention deficit in recognition, Fernandes and Moscovitch argued that decrements obtained were not caused by competition for central attentional resources but were, rather, a result of competition for word-specific representational systems. Fernandes and Moscovitch labeled this a material-specific interference effect.

Hicks and Marsh (2000), in contrast, posited that competition for central resources can also lead to a divided attention effect under certain conditions. They based this claim on the dual-process model described above, arguing that search-based recollection processes should be disrupted by a secondary task, whereas familiarity processes should be less susceptible. Consequently, encoding conditions that produce higher levels of recollection should exhibit divided-attention effects. Hicks and Marsh had participants either read or generate words during encoding under the standard assumption that generation enhances later recollection. During the recognition test, memory accuracy was reduced by divided attention in the generate condition but not in the read condition. Lozito and Mulligan (in press) also found significant divided-attention effects on both conceptual and perceptual recognition tests, converging on a similar conclusion: Memory retrieval that is recollective in nature is susceptible to divided-attention effects during retrieval. In light of the results of Fernandes and Moscovitch (2000), it is critical to note that the secondary tasks of Hicks and Marsh and of Lozito and Mulligan used numbers, whereas the memory test used words, implying that the divided-attention effect is general (i.e., implicating central attention), rather than material specific.

## 2.02.5 Attention and Other Forms of Long-Term Memory

### 2.02.5.1 Attention and Implicit Memory

At the outset of this chapter we differentiated between explicit (episodic, recollective, intentional, conscious) memory and implicit (unconscious, unintentional, nonepisodic) memory. Explicit memory is typically measured with traditional memory tests, such as recognition and free and cued recall, in which participants are directed to think back about a prior event and report on it. Implicit memory tests simply require participants to perform a task (e.g., completing word fragments, generating category examples) without reference to any prior experience. Memory for prior events is inferred from the increased ability to complete, generate, identify, or otherwise process recently presented stimuli. The enhanced processing is called priming.

The principles that govern implicit and explicit memory appear to differ in a number of ways, as evidenced by striking population and functional dissociations (*See* Chapter 2.33; Roediger and McDermott, 1993; Mulligan, 2003b). Coupled with neuroimaging evidence (e.g., Schacter and Badgaiyan, 2001), these dissociations indicate separable components of memory underlying implicit and explicit memory phenomena. Given the centrality of attention in theories of memory encoding and the rather uniform effects of divided attention on episodic memory, it is important to evaluate the role of attention in implicit memory.

With regard to manipulations of selective attention, the results are quite clear: Directing attention away from a stimulus diminishes the amount of priming detected (e.g., Eich, 1984; Bentin et al., 1998; Crabb and Dark, 1999; Mulligan and Hornstein, 2000). This implies that selective attention is necessary for robust levels of priming. A separate question is whether implicit memory can arise in the absence of attention. This question is a matter of some debate. A study by Eich (1984) indicated this possibility. In this dichotic listening experiment, subjects shadowed a prose passage presented to one ear while word pairs were presented in the other ear. Each word pair consisted of a homophone and a word biasing its less common meaning (e.g., taxi-FARE). Subjects showed no explicit recognition for these words. In an implicit test condition, subjects were given a spelling test for aurally presented words. This test contained the homophones presented during the shadowing task as well as a control set of homophones. The subjects were more likely to choose the uncommon spelling for homophones from the ignored channel than for the control homophones, demonstrating above-chance priming for the word pairs presented in the irrelevant channel. This has been taken as evidence of implicit memory for unattended stimuli. It should be noted that, when the word pairs were presented to the shadowed ear, even greater levels of priming resulted. So Eich's results demonstrate reduced priming for the ignored versus attended channel, coupled with above-chance priming for the material presented in the ignored ear. Merikle and Reingold (1991) showed a similar pattern of results for visual selective attention.

Although the results of Eich (1984) were impressive and indicate that implicit memory has less reliance on selective attention than does explicit memory, there is reason to wonder whether these results represent implicit memory for unattended material. Wood et al. (1997) suggested that the presentation rate of the material in Eich's (1984) study was too slow to preclude rapid, covert switches of attention. As noted in the earlier discussion of dichotic listening, there is always the concern of attentional slippage. Wood et al. investigated this issue by varying the speed with which the attended materials was presented. At the slower rate used by Eich, Wood et al. found the same results: chance-level recognition coupled with above-chance priming on the spelling task. However, at the faster rate (a rate at which subjects could still successfully shadow), priming in the spelling task was not above chance. Wood et al. argued that a faster rate in the attended channel renders the shadowing task more attention demanding and diminishes the likelihood of covert (and undetected) switches of attention to the putatively unattended channel. Consequently, even though the unattended materials were presented at the same slow rate as in the Eich study, no priming was found. This argues against the notion that implicit memory is found for unattended stimuli. Similarly, Berry et al. (2006) recently failed to replicate Merikle and Reingold's results with visual selective attention, strengthening the concern about implicit memory in the absence of attention.

A related line of research has used dual-task paradigms to examine the role of central attention resources in implicit memory. As with selection attention studies, initial studies implied important differences in the role of attention in implicit and explicit memory, with later studies modifying this conclusion. Consider an experiment by Parkin and Russo (1990), in which participants named pictures of everyday objects during the study phase. In the full-attention condition, this was the sole task. In the divided-attention condition, participants named the pictures and carried out a tone-monitoring task, in which a series of tones were categorized as high, medium, or low. Participants were later given an explicit test, in which they recalled the names of the pictures, or an implicit test, in which they identified fragmented pictures. Priming in this task is indicated by identification of studied (or old) pictures at lower levels of clarification than the new pictures. As would be expected, recall was greatly diminished by divided attention. However, the amount of priming on the picture-fragment task was essentially the same for the full- and divided-attention conditions. Several other studies produced similar results (see Jacoby et al., 1989; Parkin et al., 1990; Russo and Parkin, 1993; Mulligan and Hartman, 1996; Schmitter-Edgecombe, 1996a,b), giving rise to the claim that implicit memory has little reliance on attention and largely reflects automatic encoding processes (e.g., Jacoby et al., 1989, 1993; Parkin et al., 1990; Parkin and Russo, 1990; Bentin et al., 1995; Isingrini et al., 1995; Aloisi et al., 2004).

The notion that implicit memory reflects automatic encoding processes has not withstood subsequent research, however (see Mulligan and Brown (2003) for a review). First, this initial research focused on perceptually based priming tasks (such as perceptual identification and word and picture fragment completions), in which degraded or partial perceptual cues guide memory retrieval. Implicit memory may also be assessed with conceptually based tests in which memory retrieval is guided by conceptual cues, such as category names or associates. Mulligan and Hartman (1996; Mulligan, 1997, 1998) demonstrated that conceptual priming is quite sensitive to division of attention during encoding. Second, even perceptually based implicit tests have proven susceptible to divided-attention manipulation under some conditions. For example, Mulligan (2003a) found that a divided-attention task requiring frequent response selection affected perceptual priming, whereas a divided-attention task requiring less frequent response selection left priming unaffected.

To summarize the results, it is now clear that implicit memory is generally affected by a variety of selective- and divided-attention manipulations, indicating that implicit memory relies on both selective attention and central attentional resources. In addition, the effects of these attention manipulations are generally larger on explicit than implicit memory. At present, the results indicate that implicit and explicit memory differ quantitatively rather than qualitatively in terms of their reliance on attention. Both forms of memory rely on attention (in both the selective and central-resources senses), but explicit memory appears to rely on attention more heavily (see Mulligan, 2003a, for speculation as to why).

### 2.02.5.2 Attention and Procedural Learning

Procedural learning encompasses the acquisition of perceptual, motor, and cognitive skills and is another form of nonconscious memory. Skill acquisition is characterized by gradual improvements in performance over many sessions of practice. To isolate processes of procedural learning and make it amenable to experimental analysis, researchers have typically turned to a small set of laboratory tasks. The most prominent example is the serial reaction time (SRT) test. In this test, participants identify the location of a target as it moves among a fixed set of (usually four to seven) locations by pressing the key that corresponds to each new location. Embedded in the sequence of locations is a repeating pattern. Reaction times gradually decrease over hundreds or thousands of trials. Procedural learning is assessed in a transfer block in which the pattern is no longer present. An increase in reaction times indicates that something about the repeating pattern had been learned. Another commonly used task is the artificial grammar (AG) learning task developed by Reber (1967). In this task, participants are presented with strings of elements (e.g., letters) that were produced by a complex set of rules – the underlying grammar – that dictates the order in which the elements may occur. After exposure to the learning set, a new set of strings is presented, some of which are consistent with the grammar (i.e., these are strings generated by the grammar), and others that violate the grammar. The participant's task is to categorize the test strings as grammatical or nongrammatical. Above-chance accuracy on this test in the absence of verbalizable knowledge of the grammatical rules is usually taken as evidence of implicit learning of (at least some aspects of) the underlying grammar (see Dienes and Berry, 1997, for a review).

The bulk of the research on attention and procedural learning has examined the role of central attentional resources, using dual-task paradigms. In an early study, Nissen and Bullemer (1987) reported that dividing attention during learning eliminated procedural learning in the SRT task. The dual task used in that study was a tone counting task, in which participants heard high and low tones and kept a running count of the number of low tones. However, there is evidence that the tone-counting task may disrupt procedural learning by interfering with the timing or organization of responses in the SRT task rather than through its demands on central attention (e.g., Stadler, 1995). An arguably less problematic secondary task, the symbol counting task, produces similar effects, disrupting procedural learning relative to a full-attention condition (e.g., Shanks and Channon, 2002; Shanks et al., 2005). Research using the AG task produces similar results. Procedural learning in this task is reduced by a concurrent decision task (Dienes et al., 1991). The learning of complex motor skills has a similar reliance on attention (Wulf and Prinz, 2001). Thus, the acquisition of procedural skills appears to rely on central attentional mechanisms. However, the expression of highly learned skills may not. For example, Helman and Berry (2003) found that dividing attention during the final test in an AG task produced no effect on the expression of procedural information that was initially acquired in a full attention condition. Eversheim and Bock (2001) present a single study of procedural learning, which reveals the typical pattern of results across early acquisition trials and later expression of a practiced skill. These authors used a tracking task in which the visual feedback had been reversed. Over the early trials of the tracking task, performing a secondary task greatly diminished the rate of improvement. However, after extensive practice with the task, a dual-task condition produced little decrement in performance. That is, the acquisition of this new perceptual-motor skill was harmed by distraction, whereas the expression of the attained skill was little disrupted by divided attention.

Although the majority of the relevant studies examined central-attentional resources, a few have examined the relationship between selective attention and procedural learning. Perhaps not surprisingly, most have concluded that procedural learning requires selective attention to the stimuli of the learning task (e.g., Jiang and Chun, 2001; Turk-Browne et al., 2005; see also Wulf and Prinz, 2001).

## 2.02.6 Concluding Comments

This chapter began with quotations from James and Ebbinghaus articulating the traditional view that attention is critically important for memory. Modern researchers differentiate among multiple forms of both memory and attention, which has allowed a more fine-grained analysis of this relationship. We have seen the ways in which attention is intertwined with the concept of working memory, so much so that aspects of working memory (i.e., the central executive) are sometimes equated with central attention. It is also apparent that attention is critical for acquisition in long-term memory. This is especially clear with regard to episodic memory, although reliance on attention might be greater for certain aspects of episodic encoding (e.g., associative information) than for others (e.g., item information). Furthermore, recent research highlights the importance of attention during encoding for nonepisodic forms of memory, such as implicit and procedural memory phenomena. It is only in the case of long-term memory retrieval that the role of attention is debated. Retrieval from episodic memory appears to be attention demanding, albeit less so than memory encoding. In contrast, retrieval in procedural memory, especially of well-learned skills, is much less dependent on attention. Finally, there is little research on the role of attention in implicit memory, an area in need of systematic research.

# 2.03 Sensory Memory

**N. Cowan**, University of Missouri, Columbia, MO, USA

## 2.03.1 Introduction

Sensory memory refers to the short-lived memory for sensory details of events. This can include how things looked, sounded, felt, smelled, and tasted. To some extent, this type of information must persist in long-term memory. It allows us to recognize a familiar voice over the telephone or to recognize the taste of a favorite food. However, the human information processing system seems to be designed in such a way that the richness of sensory memories is quickly lost, leaving behind more categorized memories. For example, when one hears or reads a sentence, the gist is strongly saved but the exact manner in which the material was presented is more quickly lost; verbatim wording is readily accessible only for the most recent phrase, and it is incomplete even for that phrase (Sachs, 1967; Jarvella, 1970). Physical features of stimuli do leave long-term memory traces that influence later behavior (Kolers, 1974; Cowan, 1984; Weldon et al., 1995), but these may lack the fine-grained subtlety of short-lived sensory memories. Sensory memory is typically distinguished from mental imagery, which can include sensory-like qualities but is typically less detailed. For example, one may form an image of a U.S. penny (one-cent coin), but it is distinguished from a sensory memory in its vagueness, such as not really knowing which way Lincoln's head faces.

It has long been recognized that at least some sorts of sensory memory operate in a manner that is different from other forms of memory. In classic research on attention, subjects were asked to repeat a message presented to one ear and ignore a conflicting message presented to the other ear concurrently. Although they could recall little of the message presented to the ear to be ignored, when the task ended the last few words of that message often could be recalled (Broadbent, 1958). This suggested that the information in the unattended message was held temporarily in a form that soon would be lost if it were not attended. A natural way to understand that phenomenon is that the temporary storage consists of sensory information and a longer-lasting record can be saved only if that sensory information is attended before it fades away, which allows the formation of memory for the words that were spoken.

Sperling (1960) carried out a classic study that dramatically illustrated the difference between sensory and abstract forms of memory for a recent event. Subjects saw a briefly presented array with three rows of characters and then received a tone indicating whether the top, middle, or bottom row should be recalled (a partial-report cue). If the tone was presented soon enough, almost all characters in the designated row could be recalled, provided that there were four or fewer characters in the row. As the delay between the array and the tone cue was increased, performance diminished, quickly at first and then more slowly, curving down to a steady level (asymptote) within 1 s. By that point, the cue came too late to be of use, and subjects could remember only as many characters as one would expect if the limit were about four characters retained from the entire display. This pattern of results could be accounted for on the basis of two types of memory: a sensory memory that held the entire display like a snapshot for a very short time, even though the number of characters was far too large to be attended at once, and a more abstract memory that could hold only about four items. The partial-report cue could influence which part of the sensory memory was transferred to an abstract form and then reported, but the cue had to be presented before the sensory memory faded.

One can see from this finding that an understanding of sensory memory is critical for an understanding of performance on memory tests. Even if one is trying to assess the availability of abstract forms of memory, the contribution of sensory memory must be either eliminated or taken into account. Beyond that, sensory memory is an important aspect of our conscious experience of the outside world, as we will see.

One thing that makes sensory memory controversial is that the boundaries between it and other types of memory are debatable. By some accounts, there is a distinction between sensory storage that comes before perception and postperceptual storage (Massaro and Loftus, 1996). It does appear that there are two phases of temporary memory for stimulus qualities: a brief phase that seems like a continuation of the stimulus for about a quarter second, and a second phase that seems like a vivid recollection for some seconds (Massaro, 1975a; Cowan, 1984, 1988, 1995). However, one could argue that the process of perception begins quite rapidly in the brain, and that the first phase of memory for sensation is already part of perception. When this brief memory begins to fade away, it is not the same thing as a picture becoming hazy or indistinct, as if viewed through a fog. Instead, it is as if different features of each object can be lost separately. In Sperling's (1960) type of procedure, for example, the errors that crop up as the partial-report cue is delayed (or omitted) appear to be primarily location errors, in which a character is reported at the wrong location rather than forgotten completely (Townsend, 1973; Mewhort et al., 1981; Irwin and Yeomans, 1986). Consistent with this, a great deal of neurological research suggests that different features of an object, such as its identity versus its location, are perceived using different neural subsystems (in vision: Haxby et al., 1991; in hearing: Alain et al., 2001; in touch: Pons et al., 1992), and that perception of an object therefore requires a subsequent integration of these features. Sensory memory could include a constellation of features that have not necessarily been integrated. The full integration of these features into objects could require attention (Treisman and Gelade, 1980), which could result in a nonsensory type of memory.

It also may be that the brief sort of sensory memory is not truly a memory as such but, rather, a side effect of perceptual processing. The difference is that the neural effect of a stimulus giving rise to sensation begins before the stimulus ends and, for very brief stimuli, may not even reach a peak until some time after the stimulus has ended. The duration of this sensory memory appears longer for less intense stimuli. Such findings suggest that the sensory persistence of the stimulus may reflect conscious access to neural processes involved in perception (cf. Weichselgartner and Sperling, 1985; Dixon and Di Lollo, 1994; Massaro and Loftus, 1996; Loftus and Irwin, 1998).

Given such debates, it is important to back up and examine the distinctions regarding sensory memory that often are taken as its defining characteristics.

## 2.03.2 Defining Characteristics of Sensory Memory

### 2.03.2.1 Memory for Stimuli As Opposed to Ideas

Consider how the perception of a newborn infant must differ from that of an adult: it differs in many ways, but one important difference is as follows. The infant has a range of sensory experiences, but there is not yet any way to attach significance or meaning to most of those experiences. An adult does have meanings, or ideas, to attach to experiences. For example, if an American adult sees a red octagon, it may remind him or her of a traffic stop sign. Yet it seems reasonable to believe that there is perception and memory of the shape and color that can be separated from its meaning. That may not be exactly true, inasmuch as it is difficult for people to remember or perhaps even to perceive objects without some influence of their knowledge that apples are red, grass is green, and so on (Bartleson, 1960; Ratner and McCarthy, 1990). After identification of a stimulus and its meaning has taken place, there may be neural feedback to the parts of the brain that perceive sensations. Nevertheless, to a first approximation, we can think of sensory memory as the memory for the knowledge-free, sensation-based characteristics of stimuli that resemble what a newborn would perceive. If it turns out to be impossible to think of sensory memory in this way, the postulation of a distinction between sensory and nonsensory forms of memory may have to be weakened.

#### 2.03.2.2 Memory for Information More Fine-Grained Than a Familiar Category

A critical step in perception is categorization: gaining the knowledge that a particular stimulus is an example of items in a certain category, whether or not one knows a verbal label for that category. For example, one can perceive two successive piano notes as coming from different tone categories even if one does not know or remember the names of those categories. Sensory memory is typically viewed as coming before that step of categorization. As a result, it can include fine details that distinguish items within a category, such as differences in tone frequency too small to change the identity of the note, except to make it slightly out of tune (Keller et al., 1995), differences between two slightly different pronunciations of the same vowel (Pisoni, 1973), or differences between two slightly different shades of the same color (Massaro, 1975a). In each case, if slightly different stimuli are presented in close succession (ideally within about 250 ms of each other), the sensory memory of the first stimulus can be compared to the second stimulus with good acuity. This characteristic could be important, as when one is trying to learn exactly how to imitate a word spoken in an unfamiliar language or, in infants, learning language in the first place.

#### 2.03.2.3 Memory Even for Unattended Stimuli

As mentioned in the introduction, the concept of sensory memory arose to explain how people can briefly retain more information than they can process. The concept of a short-lived sensory memory for unattended information was present in the selective listening procedure (Broadbent, 1958) and the partial-report procedure using visual arrays (Sperling, 1960). Darwin et al. (1972) brought these two lines of research together by constructing an auditory analogue of Sperling's procedure. In this analogue, an array of three simultaneous spoken characters presented to left, center, and right spatial locations was followed by a second such array and then a test for the information presented at one location. Similar findings were obtained using arrays of tones (Treisman and Rostron, 1972; Rostron, 1974).

In the auditory studies, it was not possible to present 12 or more simultaneous stimuli as Sperling (1960) did in the visual modality. Consequently, it is possible that subjects were able to carry out a perceptual analysis of the sounds. Nevertheless, other evidence suggests that the perceptual analysis is incomplete and that the items need not have received full attention to have been remembered in the procedure of Darwin et al. (1972). Cowan et al. (1990) carried out a procedure in which nine syllables (*bee, bih, beh, dee, dih, deh, gee, gih, geh*) were presented at random intervals through headphones while the subject ignored them and silently read a novel. When a light signal occasionally appeared, the subject was to stop reading and identify the last spoken syllable, which occurred 1, 5, or 10 s ago. Generally, performance was good at a 1-s retention interval and decreased dramatically across the longer intervals. However, in an experiment in which subjects had to monitor the speech stream while reading (pushing a button if *dih* was presented), there was no forgetting across retention intervals, even though the monitoring task was performed correctly on only 60% of the trials. In another experiment, the reading was whispered by the subject and recorded so that diversions in attention away from the reading could be observed (as 1-s pauses in reading). It was found that consonant perception was much better on trials in which there were diversions of attention while the target syllable was presented. The sensory form of memory may only be adequate for vowel perception, and memory for consonants may be nonsensory in nature and may require attention to be formed. Vowels are more or less steady-state sounds, whereas stop consonants involve rapid acoustic changes that may be too complex to be maintained in a long form of sensory memory.

In sum, it seems apt to say that sensory memory is a special type of memory that may not require attention to be formed. It cannot hold all aspects of the environment; perhaps it comprises a snapshot of information or slice of time and is unable to hold much information that changes over time. Nevertheless, it is sufficient to save information about far more than one can attentively process at once and thereby serves as a sort of multichannel bulletin board helping the perceiver to shift attention from one sensory channel to another as the incoming information warrants.

## 2.03.3 Why Study Sensory Memory?

Cognitive psychologists and other students of human behavior have not been consistently enthralled by the concept of sensory memory. The majority of them are interested in learning how meaningful information is processed, and for that enterprise, the fate of sensory information seems to be of secondary interest. Taking this paucity of interest further, Haber (1983) asserted that sensory memory is a byproduct of processing that is not really of any use in ecologically relevant circumstances, with rare exceptions such as when one wants to read on a dark, rainy night by the light produced by flashes of lightning. However, there are several key reasons why sensory memory is of interest. Some important phenomena in the modern world make use of visual sensory memory; without its smearing of the effects of sensation, we would not perceive motion pictures as moving but, rather, as a rapid succession of still frames. It seems likely, as well, that there are analogous phenomena in the natural world. As one spots a deer running across the forest, the continual disappearance of parts of the animal behind trees and reappearance of those parts is reconstructed by one's perceptual system to form a continuous event, the deer running. Sensory memory may be critical in allowing this smooth percept to be formed. In audition, the case is straightforward, inasmuch as sounds inherently change over time. Some mental device must capture segments of the sounds in order to interpret them. For example, as we already have noted, language learning may depend on sensory memory for how words are pronounced. Some less obvious reasons to be interested in sensory memory are as follows.

### 2.03.3.1 Understanding Qualia and Consciousness

Philosophers speak of qualia, the essential mental states corresponding to experiences. These may be considered the building blocks of conscious experience. The equivalent notion within psychology is the study of subjective experience that can be traced back to the introspectionist method of Wilhelm Wundt, who founded the first laboratory of experimental psychology in 1879. Experimental methods related to introspection make use of similarities in the verbal descriptions of an event across individuals. Descriptions of fleeting events get at the smallest temporal unit of consciousness, or psychological moment, during which all events appear simultaneous even if they are not (e.g., Stroud, 1955; Lichtenstein, 1961; Allport, 1968; Eriksen and Collins, 1968; Creel et al., 1970; Robinson and Pollack, 1971). In the typical experiment to examine this concept, multiple visual displays (such as two sets of dots) are presented rapidly, and when they are presented in close enough temporal proximity, they are perceived as a single image that includes all of the presented items (e.g., all of the dots together). The presentation time within which there is perceived simultaneity depends on stimulus factors but is typically in the range of 100 to 200 ms. One account of the psychological moment states that the sensory memory of the first presentation still must be sufficiently active when the second presentation arrives, so that it becomes impossible to tell the difference between sensory memory and sensation, allowing them to be fused into an apparently simultaneous percept. On that basis one can explain, for example, why a loud noise and a closely following quieter noise can be perceptually fused into a single noise if the gap between them is no more than 100 ms or so (Plomp, 1964). The second noise must be mistaken for part of the decaying sensory trace of the first noise, and the chances of that happening increase as the gap between them gets shorter and the second noise gets quieter.

There were two competing hypotheses of the psychological moment, and only one of them is consistent with a sensory memory account. According to a continuous-moment hypothesis, the psychological moment is a sliding window of time. This is compatible with the notion that the sensory memory of each stimulus can be combined with immediately successive stimuli. In contrast, according to a discrete-moment hypothesis, there are successive windows defined by internal neural events (e.g., oscillation in the firing of neurons so as to collect incoming sensory signals). Two brief events occurring, say, 80 ms apart would fall in either the same psychological moment or in different moments, depending on when they happened to occur relative to the boundary between successive moments.

Allport (1968) carried out an experiment to decide between these hypotheses that seems especially elegant and decisive. On every trial, 12 horizontal lines were presented in rapid succession, over and over, progressing from a line high on the oscilloscope screen to lines lower and lower on the screen. Only one line was presented at a given time, but because of perceived simultaneity, multiple lines were visible at once. The rate of succession was adjusted for each subject until exactly 11 of the 12 lines were visible at once. At this rate, one could observe what was termed shadow movement as the remaining line that could not be seen changed over time. Now, according to a continuous-moment hypothesis, the shadow should move from top to bottom. While the 12th, lowest line is presented, the sensory afterimage of the 1st, highest line is the oldest and fades. While this line 1 is again presented, the sensory afterimage of line 2 becomes the oldest and fades; while line 2 is again presented, the sensory afterimage of line 3 becomes the oldest and fades; and so on. In contrast, according to a discrete moment hypothesis, the shadow should move from bottom to top. If lines 1–11 fit within one discrete perceptual moment, line 12 is not visible. Then line 12, along with the next presentation of lines 1–10, will all fit into the next moment, and line 11 will not be visible; then lines 11–12 along with the next presentation of lines 1–9 will all fit into the next moment, and line 10 will not be visible; and so on. The results consistently showed downward shadow movement, supporting a continuous psychological moment and a sensory memory explanation.

### 2.03.3.2 Understanding Group Differences in Information Processing

If the psychological moment is determined by sensory memory, then group differences in sensory memory have important implications for how the groups perceive the world. It determines which events will be grouped together within the duration of sensory memory and which will be separated, beyond that duration (e.g., Dixon and DiLollo, 1994; Loftus and Irwin, 1998).

A study by Cowan et al. (1982) suggested that 8- to 9-week-old infants have a longer first phase of sensory memory than adults do. The procedure that was used was one of auditory backward recognition masking (Massaro, 1975b). In that type of procedure in adults, two brief sounds are presented in rapid succession, and the subject is to identify the first sound in a multiple-choice test. Performance improves as the time between the onsets of the first and second sounds (the stimulus onset asynchrony or SOA) increases to about 250 ms. Even if the choices are so close that performance is substantially below 100%, performance levels off to an asymptotic level at about that SOA. The explanation (in concert with other, convergent procedures that we discuss later) is that information must be extracted over time from sensory memory into a more abstract form of memory until the second sound masks or overwrites the sensory memory of the first sound, interrupting the process of extracting information. By an SOA of 250 ms, the auditory sensory memory fades, so delays of the second, masking stimulus beyond that point would not help. For infant study, an *ah-ah* vowel pair was presented repeatedly, but with different SOAs among the pairs. Sometimes, an *eh-ah* pair was presented instead, but the access to this different pair was restricted to pairs with a particular SOA. The dependent measure of sound discrimination was how long and how vigorously infants were willing to suck on a pacifier that yielded not food but access to pairs that changed from *ah-ah* to *eh-ah,* rather than being stuck with a monotonous repetition of *ah-ah*. (For other infants, the assignment of the two vowels was reversed.) Higher sucking rates for this condition than for a condition in which there was no acoustic benefit of sucking yielded evidence of sound discrimination when the changes occurred within pairs with a 400-ms SOA, but not when the changes occurred within pairs with the 250-ms SOA that is sufficient for optimal performance in adult studies.

Various methods also have been used to show that the duration of sensory memory may differ from the norm in children with mental retardation (Campbell, and Meyer, 1981) or reading disability (Sipe and Engle, 1986) and in patients who have had unilateral temporal lobectomy (Efron et al., 1985). It is not known whether sensory memory abnormality contributes to cognitive disabilities in these groups.

### 2.03.3.3 Eliminating Contamination from Nonsensory Aspects of Cognition

Even if one is interested in abstract forms of memory, it is necessary to examine sensory memory in order to control its contribution in various test procedures. A good example is the procedure of Luck and Vogel (1997) to examine working memory. An array of simple, schematic objects is presented and then followed by a second array identical to the first or differing in the identity of one of the objects. In such procedures, people can remember about four items (cf. Sperling, 1960). If the interest is on that working memory limit, then one needs to be sure that sensory memory has faded away before the test. One could use a partial-report cue to determine when it has faded, as Sperling did. Another method is to mask the array with another, interfering array after various intervals and to determine how much information already has been transferred from sensory memory to working memory. Woodman and Vogel (2005) did that and suggested that sensory memory for items in an array was transferred to working memory at a rate of about 50 ms per item in the array.

A similar point could be made with respect to understanding attention. Imagine an experiment in which different word lists are presented simultaneously to the left and right ears. Suppose one has evidence suggesting that an individual can attend to both channels of speech at once. Such evidence may be misleading. If the speech is presented too slowly, there is the possibility of instead (1) attending to the word presented to one ear, and then (2) switching attention to the other ear in time to perceive the sensory memory of the word presented to that ear. If this is the case, speeding up the presentation may eliminate evidence that both channels are being perceived. For an example of this see Wood et al. (1997). In attention research, as in working memory research, the effect of sensory memory must be taken into account.

## 2.03.4 Techniques to Examine Sensory Memory

Of necessity, we already have discussed a number of techniques used to examine sensory memory. Now it should be helpful to take a brief inventory of these methods. In taking this inventory it is important to keep in mind that different methods disagree. Still, it may be proposed that different outcomes theoretically might result from a common sensory memory. For example, a subjective impression of the duration of a stimulus might result from the duration for which the sensory neural response exceeds a certain intensity, whereas a measure of information about the stimulus might result from an integration of the neural response intensity over time (cf. Cowan, 1987; Loftus and Irwin, 1998).

### 2.03.4.1 Sensory Persistence Procedures

In the most straightforward types of investigation, stimuli extended over time are perceived as being simultaneous, as in the investigations of the psychological moment described above. Johann Andreas Segner, a German physicist and mathematician living in the 1700s, attached a glowing coal to a cartwheel, rotating the wheel at various speeds. He found that a complete circle was perceived if the wheel was rotated at a rate of at least 100 ms per rotation. This implies that the sensory memory of the glowing coal fell below some minimal level of brightness by about 100 ms.

Efron (1970a,b,c) carried out quite a nice set of experiments to refine the sensory persistence procedure. An indicator (e.g., a click) stimulus was presented along with a target stimulus (e.g., a light flash), and the study estimated when the indicator sounded as if it occurred at the same time as the offset of the target (or, in a control condition, the onset of the target). The result was that the onset of the target was only very slightly overestimated, whereas the offset was overestimated by up to about 200 ms. The nature of the overestimation depended heavily on the duration of the target, such that the target appeared to have a minimal perceived duration of about 200 ms. Very similar results were obtained when the target was visual and when it was auditory. The duration of a perception appears to be the duration of the perceptual response, and if the target stimulus is brief, it reflects the duration of the target plus its perceptual afterimage or sensory memory.

### 2.03.4.2 Partial-Report Procedures

We already have described the procedures like that of Sperling (1960) and Darwin et al. (1972), in which an array of items is followed by a partial-report cue that allows part of the sensory memory representation to be transferred to a more abstract, categorized, reportable state, working memory. One enigma worthy of consideration is that, whereas persistence procedures have produced similar results for vision and audition, partial-report procedures seem to produce much shorter periods of cue utility for vision (under 1 s) than for audition (about 4 s). We return to this enigma when discussing theories of forgetting from sensory memory.

#### 2.03.4.3 Selective-Attention Procedures

We have touched upon procedures in which an auditory stimulus is ignored at the time of its presentation and only subsequently receives the benefit of attention applied to the sensory memory (Broadbent, 1958; Cowan et al., 1990; there are various other examples such as Treisman, 1964; Norman, 1969; Glucksberg and Cowen, 1970).

It is possible also to examine memory for unattended material in the visual modality. Various techniques can be used to get the subject to contract or expand the focus of visual attention (Eriksen and St. James, 1986; LaBerge and Brown, 1989), and one can then examine memory for information inside or outside of the attentional focus. One difficulty is that there is poorer perceptual analysis of information in the periphery of the visual field, regardless of whether that part of the field is the focus of attention. Usually, the center of the visual field of gaze is also the focus of attention, so attention and visual acuity are confounded. (That is not the case in audition, for which there is no change in the effectors accompanying attention.) Luckily, it is possible to direct a subject's attention to an area outside of the center of gaze (e.g., Brefczynski and DeYoe, 1999). For this reason, it is theoretically possible to determine the effects of attention on visual perception and examine memory for centrally presented but unattended stimuli. It does seem clear that visual attention affects perception, but more research is needed to reveal the details of unattended sensory images in the center of gaze.

#### 2.03.4.4 Backward-Masking Procedures

We already have touched upon the technique of backward masking, in which a brief target stimulus is followed by a mask and impedes recognition of the target. Notably, little masking occurs if the mask precedes the target (Massaro, 1973). This confirms that the critical aspect of backward masking is overwriting of the target's sensory memory by the mask, not the mere proximity of target and mask. It is also noteworthy that the period of backward masking obtained in the auditory modality is quite similar to the visual modality (Turvey, 1973). That appears to be true also in persistence procedures, but not in partial-report or selective-attention procedures, a point to which we return shortly.

One benefit of the masking procedure is that it can be used to show that the neural locus of sensory memory is not entirely peripheral. Turvey (1973) showed that substantial backward masking occurs even when the target was presented to one ear and the mask was presented to the other ear. (For convergent evidence of a central locus of the visual afterimage using a persistence technique, see Haber and Standing, 1969, 1970.) Kallman and Morris (1984) showed something similar in audition, though the opposite conclusion is often cited (Hawkins and Presson, 1977). Cowan (1995, Section 2.5) cited physiological studies supporting the notion that auditory sensory memory has a central locus.

## 2.03.5 Theories of Forgetting From Sensory Memory

### 2.03.5.1 Modality-Specific Rates of Decay

It is interesting to see how a scientific field responds to inconsistency. Although the methods described above have been present for quite some time, most theoretical mentions of sensory memory in textbooks seem to go along with the conclusion that auditory memory outlasts visual memory. That could account for the findings of partial-report and selective-attention procedures, but not the findings of persistence and backward-masking procedures. An alternative view is described in the sections that follow.

### 2.03.5.2 Two Phases of Sensory Memory with Different Rates of Decay

The study of Sperling (1960) was truly seminal in the field. When Darwin et al. (1972) found that sensory memory appeared to be useful for a much longer period in audition (about 4 s) than Sperling found in vision (less than 1 s), it led to the belief that auditory memory lasts longer than visual memory. However, Massaro (1976) offered a different interpretation. Whereas Sperling's experiments used a large number of simultaneous characters (e.g., 12), the smaller number of simultaneous characters used by Darwin et al. (1972) allowed perceptual analysis. According to this view, the sensory memory observed by Sperling was preperceptual, whereas that was not true of the memory observed in the auditory studies. Consistent with Massaro's view, Cowan (1984, 1988, 1995) summarized evidence from various procedures that there are two phases of sensory memory in both the visual and auditory modalities (as well as in other modalities): a short, literal phase lasting about 250 ms and a longer, second phase lasting several seconds. The second phase was said to comprise temporarily activated sensory features in long-term memory and was said to be both functionally similar to temporarily activated semantic features in long-term memory and much more processed than the first phase.

A couple of studies, one in vision and one in audition, provide striking evidence that there are two types of sensory memory. Phillips (1974) presented two spatial patterns of black and white squares that differed in at most the fill of one square. At short interpattern delays, performance was excellent but was harmed if there was a displacement of the screen location from the first pattern to the second. It was as if the subject actually could see the superimposition of the patterns. In contrast, at longer delays, performance was poorer, and displacement of the screen location did not matter. This suggests that the longer representation was more abstract than the shorter representation.

Kallman and Massaro (1979) carried out a backward-masking procedure in which a standard tone had to be compared to a subsequent comparison tone. Either the standard or the comparison tone was followed by a masking tone. At issue in this experiment was the effect of the similarity between the mask and the tone it masked. When the mask followed the standard tone, it could result in either interference with extraction of information from the sensory trace, which could be termed Masking Type 1, or overwriting of information about the tone even after it has been extracted from the sensory trace, which could be termed Masking Type 2. As the interval between the standard tone and the mask increased, Masking Type 1 presumably disappeared, whereas Masking Type 2 remained. On other trials, it was the comparison tone that was masked, and therefore, only Masking Type 1 was possible; a judgment could be made as soon as information was extracted from that comparison tone. Given that similarity effects were obtained only for Masking Type 2, it was possible to distinguish two phases of auditory memory with different properties. These were termed preperceptual auditory storage and synthesized auditory memory, respectively. These terms correspond to the short and long auditory stores of Cowan (1984).

### 2.03.5.3 No-Decay Theories

Last, it must be mentioned that some investigators have proposed that there are no decaying memories, including no decaying sensory memory. These investigators view the decline in performance with increasing retention intervals as a matter of a loss of temporal distinctiveness of the items at the end of the list (Neath and Crowder, 1990; Crowder, 1993; Nairne, 2002). That type of theory, combined with the notion that there is better temporal distinctiveness in the auditory modality (e.g., Glenberg and Swanson, 1986), could help to explain why there is an advantage for items at the end of a verbal list presented in the auditory as opposed to the visual modality (cf. Penney, 1989; Marks and Crowder, 1997; Beaman and Morton, 2000; Cowan et al., 2004). However, it is not an easy matter to distinguish between decay and distinctiveness accounts.

Cowan et al. (1997) considered that there might be a distinctiveness explanation for performance in two-tone comparison procedures, in which performance decreases as a function of the time between the standard and comparison tones. As that time increases, it may become larger than the time between trials, so that the tones are not neatly grouped in episodic memory into the trials to which they belong. To overcome this problem Cowan et al. manipulated the time between trials as well as the time between the standard and comparison tones within a trial. Examining trials with the ratio between these two times held constant, and performance decreased only slightly as the time between the standard and comparison tone increased, until it exceeded 6 s. Between 6 and 12 s, the drop was a bit more severe. However, Cowan et al. (2001) reexamined the evidence, taking into account distinctiveness caused by intervals before the penultimate trial, and found no strong evidence of decay (although the data were preliminary in this regard).

A remaining possibility is that, in these procedures, sensory memory information that is attended can be rehearsed (Keller et al., 1995). A study that argues against the effects of time on nonsensory short-term memory (Lewandowsky et al., 2004) takes into account verbal rehearsal, but not the possibility of an attention-based, possibly nonverbal type of rehearsal (cf. Barrouillet et al., 2004). It remains to be seen whether sensory information that is unattended at the time that it is presented, and thus cannot be rehearsed, is lost over time in a way that can be explained by temporal distinctiveness or in a way that cannot be so explained.

## 2.03.6 Comments on the Future of Research on Sensory Memory

Sensory memory is one of the oldest topics in experimental psychology. Currently, there is only a small to moderate amount of ongoing research on the topic, but that does not imply that the great problems in the field have been solved, or that the field has become trivial or uninteresting. Sensory memory is an intrinsically fascinating set of neural mechanisms that must be strongly associated with basic conscious experience. As brain researchers investigate how humans know what is real and what is only imaginary, their research no doubt will lead them back to the persistent mysteries within the topic of sensory memory.

# 2.04 Working Memory

**S. E. Gathercole**, University of York, York, UK

## 2.04.1 Introduction

A common feature of our everyday mental life is the need to hold information in mind for brief periods of time. We frequently have to remember a new telephone or vehicle registration number, to write down the spelling of an unusual name that has been dictated to us, or to follow spoken instructions to find our destination in an unfamiliar environment. At other times, we need to engage in mental activities that require both temporary storage and demanding cognitive processing. Mental arithmetic provides a good example of this: successfully multiplying two numbers such as 43 and 27 in our heads involves storing not only the numbers but the products of the intermediate calculations, accessing and applying the stored rules of multiplication and addition, and integrating the various pieces of information to arrive at the correct solution. Our conscious experience of the calculation attempt is of a kind of mental juggling, in which we try to keep all elements of the task – the numbers we are trying to remember as well as the calculations – going at the same time. Often, the juggling attempt will fail, either because the capacity of working memory is exceeded, or because we become distracted and our attention is diverted away from the task in hand.

Working memory – which is the term widely used by psychologists to refer to the set of cognitive processes involved in the temporary storage and manipulation of information – supports all of these activities and many more. A useful informal way of conceptualizing working memory is as a mental jotting pad that we can use to record useful material for brief periods of time, as the need arises in the course of our everyday cognitive activities. Although it a valuable and highly flexible resource, working memory has several limitations: its storage capacity is limited, and it is a fragile system whose contents are easily disrupted. Once lost from working memory, material cannot be recovered.

The basic features of working memory are described in this chapter. Leading theoretical accounts of the cognitive processes involved in working memory are described, and key findings and experimental phenomena are outlined. As it is now also known that working memory is important not only for the temporary retention of information, but also for the acquisition of more permanent knowledge, theories of how different aspects of working memory mediate learning are also considered in this chapter.

## 2.04.2 The Working Memory Model

One influential theoretical account of working memory has framed much of the research and thinking in this field for several decades. In 1974, Baddeley and Hitch advanced a model of working memory that has been substantially refined and extended over the intervening period. The influence of the working memory model extends far beyond the detailed structure of its cognitive processes, which are considered in the following sections. The radical claim made by Baddeley and Hitch was that working memory is a flexible multicomponent system that satisfies a wide range of everyday cognitive needs for temporary mental storage – in other words, it does important work for the user. The distinction between short-term memory and working memory is a key element in the philosophy of this approach. The term working memory refers to the whole set of cognitive processes that comprise the model, which as we will see includes higher-level attentional and executive processes as well as storage systems specialized for particular information domains. Activities that tap a broad range of the functions of working memory, including both storage and higher-level control functions, are often described as working memory tasks. The term short-term memory, on the other hand, is largely reserved for memory tasks that principally require the temporary storage of information only. In this respect, short-term memory tasks tap only a subset of working memory processes. Detailed examples of each of these classes of memory task are provided in later sections.

A further key element of the Baddeley and Hitch (1974) approach is its use of dual-task methodology to investigate the modular structure of the working memory system. These researchers have developed a set of laboratory techniques for occupying particular components of the working memory system, which can then be used to investigate the extent to which particular activities engage one or another component. By the logic of dual-task methodology, any two activities that are unimpaired when conducted in combination do not tap common limited capacity systems. In contrast, performance decrements when two tasks are combined indicate that they share a reliance on the same component. This empirical approach has proved invaluable in fractionating working memory into its constituent parts, leading to the most recent version of the working memory model, advanced by Baddeley in 2000 (Baddeley, 2000) (**Figure 1**).

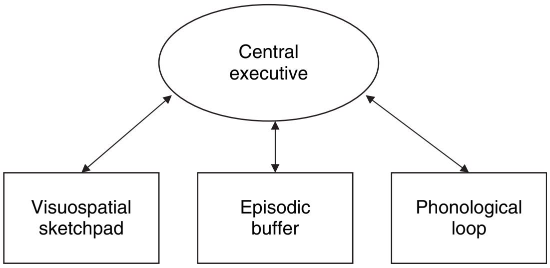

**Figure 1** The Baddeley (2000) working memory model.

This model consists of four components. Two of these components, the phonological loop and the visuospatial sketchpad, are slave systems that are specialized for the temporary storage of material in particular domains (verbal and visuospatial, respectively). The central executive is a higher-level regulatory system, and the episodic buffer integrates and binds representations from different parts of the system. The nature of each of these components and associated empirical evidence are described in the following sections. Note also that components of working memory are directly linked with longer-term memory systems in various informational domains. The nature of the interface between working memory and the acquisition of knowledge is considered in later sections of the chapter.

### 2.04.2.1 The Phonological Loop

Originally termed the articulatory loop by Baddeley and Hitch (1974), the phonological loop is a slave system dedicated to the temporary storage of material in terms of its constituent sounds, or phonemes. The two-component model of the phonological loop advanced by Baddeley in 1986 is shown in **Figure 2**. Representations in the phonological short-term store are subject to rapid time-based decay. Auditory speech information gains obligatory access to the phonological store.

Subvocal rehearsal reactivates serially the contents of the short-term store, in a process that corresponds closely to overt articulation (speaking), but which does

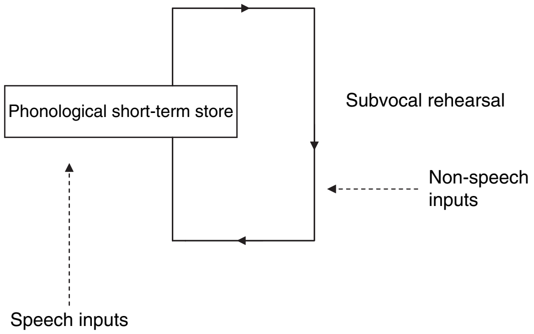

**Figure 2** The phonological loop model, based on Baddeley (1986).

not necessarily involve the movement of the speech apparatus or the generation of speech sounds. Representations in the phonological store that are rehearsed before they have time to decay can be maintained in the phonological loop indefinitely, provided that rehearsal continues. Rehearsal consists of the high-level activation of speech-motor planning processes (Bishop and Robson, 1989; Caplan et al., 1992) and is a time-limited process in which lengthier items take longer to activate than short items. Material that is not presented in the form of spoken language but which is nonetheless associated with verbal labels, such as printed words or pictures of familiar objects, can enter the phonological store via rehearsal, which generates the corresponding phonological representations from stored lexical knowledge.

#### *2.04.2.1.1 Empirical phenomena*

This fractionated structure to the phonological loop is consistent with a wide range of experimental phenomena from the serial recall paradigm, in which lists of items are presented serially for immediate recall in the original input sequence. Evidence that verbal material is held in a phonological code is provided by the fact that irrespective of whether the memory lists are presented in auditory form or in the form of print, recall is poorer for sequences in which the items share a high degree of phonological similarity (e.g., C, G, B, V, T) than for those which have little overlap in phonological structure (e.g., X, H, K, W, Q). This effect of phonological similarity, first reported by Conrad (1964) and replicated many times subsequently, indicates that serial recall is mediated by phonological representations. Degradation of these representations, possibly due to decay, will thus cause confusion between representations of items with highly similar phonological structures.

The obligatory access of auditory speech information to the phonological loop is demonstrated by the irrelevant speech effect. Serial recall of visually presented verbal items is impaired if spoken items are presented during list presentation, even though participants are told to ignore these stimuli. Moreover, the recall advantage to phonologically distinct over phonologically similar sequences is eliminated under such conditions of irrelevant speech (Colle and Welsh, 1976; Suprenant et al., 1999). This finding indicates that irrelevant speech operates on the same process that gives rise to the phonological similarity effect, so that the unwanted stimuli generate representations in the phonological store that disrupt those of the list items to be recalled.

Evidence for the existence of a distinct subvocal rehearsal process that operates on the contents of the phonological store is provided by other empirical phenomena. An important finding first reported by Baddeley et al. (1975) is that serial recall accuracy is impaired when memory lists contain lengthy items (e.g., aluminum, hippopotamus, tuberculosis) than otherwise matched short items (e.g., zinc, stoat, mumps). Detailed analyses have established that a linear function related recall accuracy to the rate at which participants can articulate the memory sequence: items that are be spoken more rapidly are recalled more accurately, to a commensurate degree. This phenomenon, known as the word length effect, is present for visually and auditorily presented verbal material and is suggested to reflect the serial rehearsal process, which requires more time to re-activate lengthy than short items. As a consequence, representations in the phonological store of lengthy items are more likely to have decayed between successive rehearsals, leading to decay and loss of information.

Support for this interpretation is provided by findings that the word length effect disappears if participants engage in articulatory suppression by saying something irrelevant such as "hiya, hiya, hiya" during presentation of the memory list, for both visually and auditorily presented lists (Baddeley et al., 1975, 1984). These results can be simply explained. Having to engage in irrelevant articulation during a memory task prevents effective rehearsal of the memory items themselves – it simply is not possible to say one thing and to rehearse subvocally something else. As rehearsal is prevented in this condition, there can be no further impairment of recall with lengthy as opposed to short memory items, as this effect is also tied to the rehearsal process.

It should be noted that because visually presented material requires rehearsal to access the phonological store, preventing rehearsal via articulatory suppression should also eliminate the phonological similarity effect with visual presentation, as the material will not reach the store for the similarity-based interference to occur. This prediction has been supported by findings from many studies (Murray, 1968; Peterson and Johnson, 1971).

The claim that the word length effect arises only from subvocal rehearsal has not gone uncontested. Lengthier items are slower not only to rehearse but also to recall, and there is convincing evidence that the increased delay in recalling longer items is one cause of lower performance, probably due to the increased opportunity for time-based decay of the phonological representations. Cowan et al. (1992) employed mixed lists composed of both short and long words to investigate the effects of recall delay. They found a linear relation between the amount of time elapsing from the beginning of the recall attempt and the accuracy of recall, with recall declining as the delay increased (see also, Cowan et al., 1994). One possibility is that the word length effect is multiply determined, and that the slower rate of rehearsal for long than short items is just one of several mechanisms causing lower levels of recall accuracy for lists composed of lengthy stimuli.

Debate concerning the detailed processes underpinning experimental phenomena such as the effects of word length and irrelevant speech (e.g., Neath et al., 2003; Jones et al., 2006) continues, and will in time result in a fuller understanding of the precise mechanisms of serial recall. More generally, though, the broad distinction between the short-term store and rehearsal subcomponents of the phonological loop has received substantial support from several different empirical traditions. It is entirely consistent with evidence of developmental fractionation of the subcomponents of the phonological loop during the childhood years (see Gathercole and Hitch, 1993; Palmer, 2000, for reviews). The phonological store appears to be in place by the preschool period: by roughly 4 years of age, children show adult-like sensitivity to the phonological similarity of the lists items for auditorily presented material (Hitch and Halliday, 1983; Hulme and Tordoff, 1989). The subvocal rehearsal strategy, in contrast, emerges at a later time, typically after 7 years of age. Flavell et al. (1967) observed many years ago that very young children do not show the overt signs of rehearsal, such as lip movements and overt repetition, that characterize older children. Children below 7 years of age are also not disrupted by recalling memory sequences composed of lengthy rather than short items (Hitch and Halliday, 1983), although word length effects do emerge in children as young as 5 years of age if they are trained in the use of rehearsal strategies (Johnson et al., 1987). Also, there is also no consistent association between the articulatory rate and memory span in 5-year-old children, although strong links are found in adults (Gathercole et al., 1994a). Together, these findings indicate that although the phonological store is present at a very early point in children, the use of subvocal rehearsal as a means of maintaining the rapidly decaying representations in the store emerges only during the middle childhood years.

The phonological store and rehearsal process also appear to be served by distinct neuroanatomical regions of the left hemisphere of the brain. Evidence from patients with acquired brain damage resulting in impairments of verbal short-term memory indicates that short-term phonological storage is associated with the inferior parietal lobule of the left hemisphere, whereas rehearsal is mediated by Broca's area, in the left premotor frontal region (see Vallar and Papagno, 2003; Muller and Knight, 2006, for reviews). Findings from neuroimaging studies using methods such as positron emission tomography and functional magnetic resonance imaging to identify the areas of the brain activated by verbal short-term memory tasks in typical adult participants have further reinforced the neuroanatomical distinction between the phonological store and rehearsal (see Henson, 2005, for review).

#### 2.04.2.1.2 A computational model of the phonological loop

Despite its simplicity, the Baddeley (1986) model of the phonological loop is capable of explaining much of the evidence outlined in the preceding section and several other experimental phenomena. It does, however, have one notable shortcoming as a model of serial recall. Although this paradigm requires the accurate retention of both the items in the memory list and their precise sequence, the model focuses exclusively on the representation of item information and therefore fails to account for how the serial order of list items is retained in the phonological loop. As a consequence, it cannot accommodate many detailed aspects of serial recall behaviour. One important characteristic of serial recall is the serial position function, the asymmetric bow-shaped curve that arises from high levels of accuracy of recalling initial list items (the primacy effect), relatively poor recall of mid-list items, and a moderate increase in accuracy for items at the end of the sequence (the recency effect). Another key finding is that the most common category of errors in serial recall is order errors, in which items from the original position migrate to nearby but incorrect positions in the output sequence (Bjork and Healy, 1974; Henson et al., 1996). The Baddeley (1986) model of the phonological loop provides no explanation of either of these features of verbal short-term memory.

Burgess and Hitch (1992) addressed this problem by developing and implementing a connectionist network model that incorporated a mechanism for retaining the serial order of items in addition to temporary phonological representations and an analog of rehearsal that corresponds to the phonological loop. The structure of the model is shown in **Figure 3**. It consists of four separate layers of nodes that represent input phonemes, words, output phonemes, and a context signal. Serial order is encoded by associating the activated item representation with a slowly evolving context signal containing a subset of active nodes that change progressively during presentation of the list, and can be conceptualized as a moving window representing time such that successive context states are more similar to one another than temporally distant states. Presentation of an item causes temporary activation of input phoneme nodes, word nodes, and output phoneme nodes via existing interconnections. When one item node succeeds in becoming the most active, a temporary association is formed between the winning item node

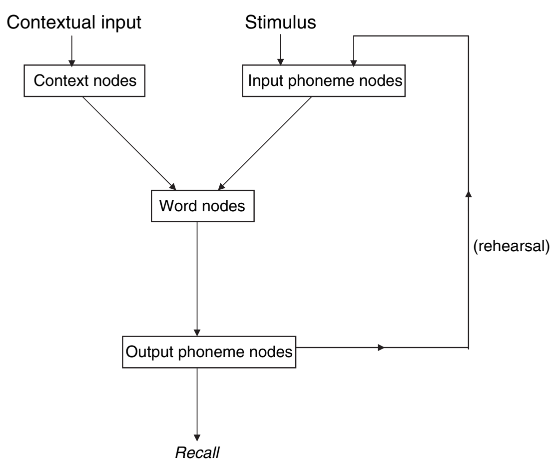

**Figure 3** Simplified architecture of the Burgess and Hitch (1992) network model of the phonological loop.

and currently active context nodes. The item node is then suppressed, allowing the same process to be repeated for the next item in the sequence. In this model, rehearsal consists of feedback from the output phonemes (activated following selection of the winning item node) to the input phonemes.

At recall, the original context signal is repeated and evolves over successive items in the same way as at input. For each signal, item nodes receive activation based on their initial pairing with context in the original sequence, and the winning item is selected and activates consistent output phonemes. Noise is added to this final selection process to induce errors. Where serial order errors do occur – that is, incorrect item nodes are selected – they tend to migrate to target-adjacent positions as a consequence of the high degree of overlap in the context nodes active in successive context states.

In addition to generating the classic experimental phenomena associated with the phonological loop such as the phonological similarity, word length, and articulatory suppression effects, this model simulates many of the features of serial order behavior that the phonological loop model on which it was based could not address. Consider first the serial position function. Primacy effects arise largely from the greater number of rehearsals received by early list items, and recall of both initial and final items is enhanced by the reduced degree of order uncertainty at these terminal list positions. A preponderance of order errors is also readily generated because context signals, like item representations, degrade with time. Thus on some occasions, the retrieved item representation will have been associated with an adjacent context signal, yielding recall of a list item at an incorrect output position. When items do migrate in simulations of the model, they show the bell-shaped migration function in which the distances traveled in the sequence are usually small rather than large, which has also been established in the behavioral data.

#### *2.04.2.1.3 The phonological loop and language*

Although the cognitive processes underpinning the phonological loop are well understood, one puzzle for many years was exactly why this system exists. It may have turned out to be useful for remembering telephone numbers, but why do we have the system in the first place? A number of possibilities were considered. One plausible hypothesis was that the phonological loop acts as a buffer for planned speech.

The presence of a phonological output buffer that stores the retrieved phonological specifications of intended lexical items and enables the smooth and rapid production of speech has long been recognized as a logical necessity by speech production theorists (e.g., Bock, 1982; Romani, 1992). There is, however, little evidence that the phonological store fulfills this function (see Gathercole and Baddeley, 1993 for review). It has consistently been found that adult neuropsychological patients with very severe deficits of verbal short-term memory leading to memory spans of only one or two items can nonetheless produce spontaneous speech normally: utterance length rates of hesitations and self-corrections are comparable to those of control adults (Shallice and Butterworth, 1977).

A second hypothesis was that the phonological loop provides an input buffer to incoming language that is consulted in the course of normal comprehension processes (Clark and Clark, 1977). Once again, findings from adult short-term memory patients provided the opportunity to test this hypothesis. The prediction was clear: if short-term memory plays a significant role in comprehension, the very low memory span of short-term memory patients should lead to substantial impairments in processing the meaning of language. Findings from many research groups and many different patients provided little support for this prediction. Despite severe deficits in phonological loop functioning, short-term memory patients typically had few difficulties in processing sentences for meaning, except under conditions in which lengthy, unusual, and ambiguous syntactic structures were used, or the sentences were essentially memory lists (see Vallar and Shallice, 1990; Caplan and Waters, 1990; Gathercole and Baddeley, 1993; for reviews). It therefore appears that although under most circumstances the language processor operates online without recourse to stored representations in the phonological loop, these representations may be consulted in an off-line mode to enable backtracking and possible re-analysis of spoken language under some conditions (McCarthy and Warrington, 1987).

There is, however, one area of language functioning in which the phonological loop appears to play a central role, and that is in learning the sound structure of new words. Evidence from many sources converges on this view. Studies of typically developing children have consistently found close and selective associations between measures of verbal short-term memory and knowledge of both native and foreign language vocabulary (e.g., Gathercole and Baddeley, 1989; Service, 1992; Cheung, 1996; Masoura and Gathercole, 1999). The accuracy of nonword repetition – in which a child hears a spoken nonword such as woogalamic and attempts to repeat it immediately – is particularly highly correlated with vocabulary knowledge, although so too are more conventional measures of verbal short-term memory such as digit span (Gathercole et al., 1994b). A similar link is found between verbal memory skills and the rate of learning nonwords in paired-associate learning paradigms, in which participants learn to associate unfamiliar phonological forms with either novel objects (Gathercole and Baddeley, 1990a, used toy monsters with names such as Pimas), unrelated words (such as fairy-kipser), or semantic attributes (e.g., bleximus is a noisy, dancing fish). Both of the latter examples are from a study reported by Gathercole et al. (1997), in which the phonological memory skills of the participating 5-year-old children were in contrast found to be independent of the ability to learn word–word pairs.

Further evidence that the phonological loop is involved in the long-term learning of phonological structures in particular has been provided by the study of individuals with developmental or acquired deficits in language learning. Specific language impairment (SLI) is a condition in which children fail to develop language at a normal rate despite normal intellectual function. Word learning represents a particular problem for affected children. It has consistently been found that children with SLI have substantial impairments of nonword repetition and of other measures of verbal short-term memory (e.g., Gathercole and Baddeley, 1990b; Bishop et al., 1996; Archibald and Gathercole, 2006). A corresponding neuropsychological patient, PV, had a severe deficit of the phonological loop, and was found to be completely unable to learn word–nonword pairings such as rose–svieti, but performed within the typical range on a word–word learning task (Baddeley et al., 1988). Experimental studies of paired-associate learning with normal adult participants have shown that word–nonword learning is disrupted by variables known to interfere with phonological loop functioning, such as phonological similarity and articulatory suppression (Papagno et al., 1991; Papagno and Vallar, 1992). In contrast, learning of word–word pairs is not influenced by these variables.

On this basis, it has been proposed that the primary function of the phonological loop is to support learning of the sound structures of new words in the course of vocabulary acquisition (Baddeley et al., 1998b). It is suggested that initial encounters with the phonological forms of novel words are represented in the phonological short-term store, and that these representations form the basis for the gradual process of abstracting a stable specification of the sound structure across repeated presentations (Brown and Hulme, 1996). Conditions that compromise the quality of the temporary phonological representation in the phonological loop will reduce the efficiency of the process of abstraction and result in slow rates of learning. In a recent review of this theory and associated evidence, Gathercole (2006) has suggested use of the phonological loop to learn new words is a primitive learning mechanism that dominates at the early stages of learning a language and remains available as a strategy throughout life. However, once a substantial lexicon is established in a language, word learners increasing rely on lexically mediated learning of new words, thereby building on the phonological structures that they have already acquired.

#### *2.04.2.1.4 Summary*

The phonological loop model advanced by Baddeley (1986), consisting of a short-term store and a subvocal rehearsal process, is the most influential current account of verbal short-term memory. Convergent evidence for the model is provided from a range of research traditions including experimental cognitive psychology, developmental psychology, neuropsychology, and neuroimaging. A similar diverse range of findings indicate that the phonological loop plays a key role in vocabulary acquisition (Baddeley et al., 1998; Gathercole, 2006).

The successful implementation of the model in the form of a connectionist network by Burgess and Hitch (1992) is an important development that has stimulated competing computational models of serial recall with distinct architectures. The network model has also been further developed to simulate learning of novel sequences by the phonological loop (Burgess and Hitch, 1999). The availability of detailed models of short-term memory and the reciprocal stimulation of empirical findings and computational simulations is a sign of advanced theoretical development that is in large part due to the guiding influence of the phonological loop concept on this field over many years.

### 2.04.2.2 The Visuospatial Sketchpad

#### *2.04.2.2.1 Theory and empirical phenomena*

The second slave system of the working memory model is the visuospatial sketchpad, specialized in the storage and manipulation of information that can be represented in terms of either visual or spatial characteristics. Short-term memory for visuospatial material is associated with increased activity in the right hemisphere regions of the inferior prefrontal cortex, anterior occipital cortex, and posterior parietal cortex, and acquired damage to these regions of the brain leads to selective deficits in remembering these domains of material (see Gathercole, 1999, for review).

Several tasks have been designed to tap the visuospatial sketchpad. These include recognizing the pattern of filled squares in a two-dimensional grid (Phillips and Christie, 1977; Wilson et al., 1987), remembering the order in which a set of blocks are tapped (often known as the Corsi blocks task), using a grid to generate a mental image corresponding to a set of spatial instructions (Brooks, 1967), and recalling the path drawn through a maze (Pickering et al., 2001).

Like its sister slave system the phonological loop, the sketchpad has now been fractionated into two distinct but interrelated components: A visual store or cache that preserves the visual features of perceived or internally generated objects and a spatial or sequential component that may serve a recycling function analogous to subvocal rehearsal (Logie, 1995). The strongest evidence for the separation of the sketchpad into these two components is provided by studies of neuropsychological patients with acquired brain lesions resulting in selective impairments of visual storage but preserved spatial short-term memory (Hanley et al., 1991) and converse deficits in spatial but not visual short-term memory (Della Sala et al., 1999; Della Sala and Logie, 2003).

Dual task studies have played an important role in illuminating the functional organization of the visuospatial sketchpad. One popular method for tapping the capacity for the generation and temporary storage of spatial material is the Brooks (1967) task, in which the participant is presented with a $4 \times 4$ empty grid in which one particular cell was designated as the starting square. The experimenter then gives a series of verbal instructions which participants are encouraged to remember by mentally filling in the grid, as shown in **Figure 4**. Following the

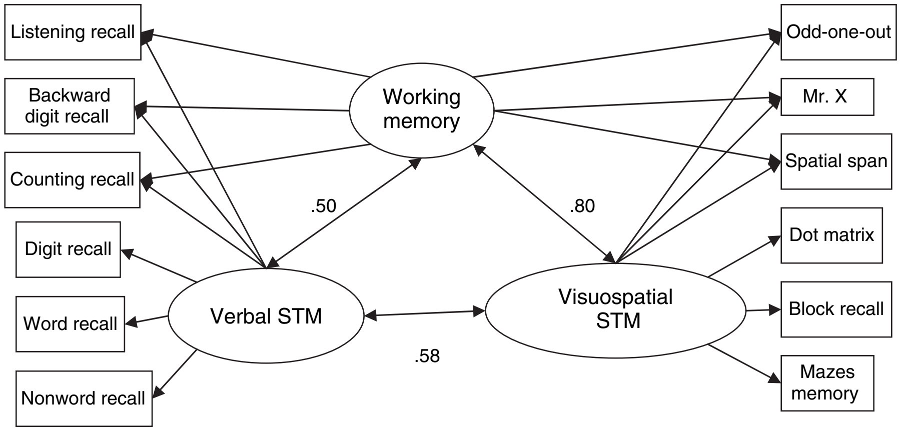

**Figure 4** Measurement model of working memory, based on data from children aged 4–11 years. STM, short-term memory. From Alloway TP, Gathercole SE, and Pickering SJ (2006) Verbal and visuo-spatial short-term and working memory in children: Are they separable? *Child Dev.* 77: 1698–1716; used with permission from Blackwell Publishing.

instructions, participants recall the sequence by filling in the grid with the numbers. This condition facilitates the use of spatial imagery and hence the visuospatial sketchpad. In a control condition which does not encourage the use of such spatial imagery, the spatial terms up, down, left, right were replaced by the nonspatial adjectives good, bad, slow, and fast to yield nonsensical sentences. Presumably, recall in this condition was supported by the phonological loop rather than the sketchpad.

Evidence that participants use mental imagery to mediate performance in the spatial but not the nonsense condition is provided by the superior levels of recall accuracy in the former condition (Brooks, 1967). In a systematic study of the effects of concurrent activities on memory performance in the two cases, Baddeley and Lieberman (1980) reported further evidence that distinct components of working memory are employed in the two conditions. Performing a concurrent task – tracking an overhead swinging pendulum – disrupted recall in the spatial but not the nonsense condition. Thus, spatial recall appears to be selectively impaired by the encoding of unrelated spatial content, consistent with the employment of a spatial code to mediate recall performance.

Subsequent investigations indicate that eye movements may play a key role in the maintenance of spatial images in the sketchpad. Postle et al. (2006) reported a series of experiments showing that voluntary eye movements impair memory for spatial locations but not for nonspatial features of visual objects, providing further support for a distinction between visual and spatial components of the sketchpad. Other studies have shown that the engagement of other movement systems such as hands (finger tapping), legs (foot tapping), and arms exerts similar disruptive influences on memory for spatial sequences such as Corsi block recall (e.g., Smyth and Scholey, 1988). It therefore appears that the maintenance of spatial representations in the sketchpad is supported by a central motor plan that is not specific to any particular effector system, by which is recruited the planning and execution of movements in the full range of motor systems.

There is some evidence that the visual storage component of the spatial sketchpad is selectively disrupted by the concurrent perception of irrelevant visual features. In a series of studies reported by Quinn and McDonnell (1996), memory for detailed visual characteristics was selectively impaired by visual noise that corresponded to a randomly flickering display of pixels similar to an untuned television screen that participants were required to view but asked to disregard. This finding is important, as it is directly analogous to the irrelevant speech effect in verbal serial recall (Colle and Welsh, 1976), which has been interpreted as reflecting obligatory access to the short-term store component of the phonological loop for auditory speech material.

One interpretational problem raised by many studies of visuospatial short-term memory is the extent to which these and other similar tasks reflect a genuinely distinct component of working memory, or alternatively draw on the more general resources of the central executive. The central executive, which is described in more detail in the following section, is a limited-capacity domain-general system capable of supporting a wide range of cognitive activities. Several different lines of evidence indicate that the central executive plays a major role in many visuospatial short-term memory tasks. Performance on visual storage tasks has been found to be strongly disrupted by concurrent activities that lack an overt visuospatial component but which are known to tax the central executive, such as mental arithmetic (Phillips and Christie, 1977; Wilson et al., 1987). Also, studies of individual differences have consistently shown that measures of visuospatial short-term memory are much more closely associated with performance on central executive tasks than are phonological loop measures, in both typically developing children (Gathercole et al., 2004a, 2006a; Alloway et al., 2006) and in a clinical study of adults with bipolar mood disorder (Thompson et al., 2006).

#### *2.04.2.2.2 Summary*

Although current understanding of the detailed cognitive processes involved in visuospatial short-term memory is less well advanced than that of the phonological loop, two basic facts have now been established. First, the sketchpad functions independently of the phonological loop – it is associated with activity in the right rather than the left hemisphere of the brain and is selectively disrupted by concurrent activities that do not influence the phonological loop. Second, the processes involved in manipulating and storing visual features and spatial patterns appear to be distinct from one another, again showing neuropsychological and experimental dissociations. It is rather less clear to what extent the visuospatial sketchpad represents a distinct component of working memory that is dissociable from the central executive.

### 2.04.2.3 The Central Executive

At the heart of the working memory model is the central executive, responsible for the control of the working memory system and its integration with other parts of the cognitive system. The central executive is limited in capacity, and is closely linked with the control of attention and also with the regulation of the flow of information within working memory, and the retrieval of material from more permanent long-term memory systems into working memory. Neuroimaging studies indicate that the frontal lobes of both hemispheres of the brain, and particularly of the prefrontal cortex, are activated by activities known to tax the central executive (See Collette and Van der Linden, 2002; Owen et al., 2005, for reviews).

#### *2.04.2.3.1 The supervisory attentional system*

In 1986, Baddeley suggested that central executive may correspond in part at least to the model of the supervisory attentional system (SAS) advanced by Shallice (1982) to explore the control of attention in action. The SAS has two principal components. The contention scheduling system consists of a set of schemas, which are organized structures of behavioral routines that can be activated by either internally or externally generated cues. When a schema reaches a particular level of activation, it is triggered and the appropriate action or set of actions is initiated. Thus, we have schemas that govern all our skilled behaviors: walking and talking, breathing and jumping, opening doors and using a telephone. Schemas can be hierarchically organized. Skilled car drivers, for example, will have a driving schema that is composed of linked subschemas such as steering and braking schemas. Many of our actions are governed by the automatic activation of these schemas in response to environmental cues. So, once we are behind the wheel of a moving car, the sight of a red brake light in the car in front will probably be sufficient to trigger the automatic activation of the braking subschema. Activation levels of all incompatible schemas (such as the accelerating schema, in this case) are inhibited when a schema is triggered.

The second component, the SAS, controls behavior via a very different process. The SAS can directly activate or inhibit schemas, thereby overriding their routine triggering by the contention scheduling system. The intervention of the SAS corresponds to volitional control and prevents us from being endless slaves to environmental cues – it allows us to choose to change the course of our actions at will. However, because the SAS is a limited capacity system, there are finite limits on the amount of attentional control we can apply to our actions.

Baddeley's (1986) suggestion was that the central executive corresponds to the limited-capacity SAS. He also proposed that two types of behavioral disturbance associated with damage to the frontal lobes arise from malfunctioning of the central executive, and coined the term dysexecutive syndrome to describe this disorder. These neuropsychological patients are typically characterized by one of two possible types of behavior. Perseveration is a form of behavioral rigidity in which the individual continually repeats the same action or response. An example would be greeting a newcomer by saying "Hello" and then continuing to make the same response many times to the same individual, increasingly inappropriately. Distractibility consists of unfocused behavior in which the individual fails to engage in meaningful responses but may, for example, continuously walk around a room manipulating objects. Baddeley suggested that such individuals have an impairment in central executive resources that reduces their capacity for volitional control of behavior via the SAS, which is instead dominated by the contention scheduling system. Perseveration results when a schema becomes highly activated and cannot be effectively inhibited by the SAS to allow the triggering of other appropriate behaviors, and distractibility results from the background triggering of behavior by environmental cues with no overriding focus by the SAS.

This conceptualization of the central executive has proved useful in guiding the development of laboratory tasks that engage the central executive. One such task is random generation (Baddeley, 1986). In a typical task, the participant is required to generate in a random manner exemplars from a familiar category, such as digits or letters, paced by a metronome. The importance of generating random sequences rather than stereotyped ones such as 1, 2, 3 or a, b, c is emphasized. In 1998, Baddeley et al. (1998a) conducted a series of experiments to investigate the hypothesis that the central executive is needed to intervene to override the activation of stereotyped response sequences in this task. There were several key findings consistent with this view. First, the degree of randomness of the sequences generated by the participants diminished (i.e., the responses became more stereotyped) when the generation rate was increased. This result indicates that the randomness of the responses was constrained by a limited capacity process. Second, the degree of randomness of the generated sequences was not impaired when the task was combined with other activities requiring stereotyped responses such as counting, but was substantially disrupted by nonstereotyped concurrent activities such as maintaining a digit load or generating exemplars of semantic categories. Applying the logic of dual-task methodology, it appears that both tasks tap a common limited-capacity mechanism, the central executive.

#### *2.04.2.3.2 Complex memory span*

The central executive also plays a key role in complex memory span tasks, which require both processing and storage. The first reported complex span task, reading span, was developed by Daneman and Carpenter in 1980. In this task, participants must read aloud each of a sequence of printed sentences, and at the end of the sequence they must recall the final word of each sentence in the same order as the sentences were presented. The number of sentences read on each trial is then increased until the point at which the participant can no longer reliably recall the sequence of final words. Findings from this task were impressive – complex memory span scores were highly correlated with the performance of the participating college students on their scholastic aptitude tests completed on entry to college. Importantly, the correlations with scholastic aptitude were considerably higher than those found with storage-only measures of verbal short-term memory.

A range of other complex span paradigms have been subsequently developed, all sharing the common feature of requiring both memory storage while participants are engaged in significant concurrent processing activity. A listening span version of the reading span test in which the sentences were heard rather than read by participants was employed by Daneman and Carpenter (1983), and was found to be correspondingly associated with academic abilities. Complex span tasks suitable for use by young children have also been developed. One popular task is counting span, in which the child has to count the number of elements in a series of visual displays, and at the end of the sequence to recall the totals of each array, in the order of presentation (Case et al., 1982). The odd-one-out task (Russell et al., 1996; Alloway et al., 2006) is a complex memory span task that requires visuospatial rather than verbal storage and processing (see also, Shah and Miyake, 1996). Participants view a series of displays each containing three unfamiliar objects, two identical and one different. The task is to point to the location of the odd one out, and then at the end of the sequence to recall the sequence of spatial locations of the different items. In other complex span tasks, the material to be stored is distinct from the contents of the processing activity. An example of one such task is operation span (Turner and Engle, 1989), in which participants attempt to recall digits whose presentation is interpolated with a sequence of simple additions that must be completed.

Despite the large degree of variation in both the processing and storage demands of the different complex memory span tasks, a highly consistent pattern of findings has emerged. Performance on such tasks is strongly related to higher-level cognitive activities such as reasoning and reading comprehension (e.g., Kyllonen and Christal, 1990; Engle et al., 1992), and also to key areas of academic achievement during childhood such as reading and mathematics (e.g., Swanson et al., 1996; Hitch et al., 2001; Jarvis and Gathercole, 2003; Gathercole et al., 2004b, 2006a; Geary et al., 2004; Swanson and Beebe-Frankenberger, 2004). In the majority of these studies, associations with learning were much higher for complex memory span measures than measures such as digit span of verbal short-term memory. Corresponding closer links with measures of intellectual functioning in adulthood such as reading comprehension, scholastic aptitude, and fluid intelligence have also been consistently found in adult populations (for reviews, see Daneman and Merikle, 1996; Engle et al., 1999b).

In order to understand why complex span measures of working memory performance are so strongly associated with learning abilities and other measures of high-level cognition, it is necessary first to consider what cognitive processes these measures tap. It has been suggested that the processing portions of these tasks are supported by the domain-general resources of the central executive, whereas the storage requirements are met by the respective domain-specific slave system (Baddeley and Logie, 1999). By this view, both the central executive and the phonological loop contribute to performance on verbal complex span tasks such as reading span, listening span, and counting span, whereas performance on visuospatial complex span tasks is mediated by the central executive and the visuospatial sketchpad.

There is now substantial evidence to support this proposal. A common processing efficiency factor has been found to underlie both verbal and visuospatial complex memory tasks (Bayliss et al., 2003). Two recent studies have investigated the latent factor structure underlying individuals' performance on both simple (storage-only) and complex span measures in both the verbal and visuospatial domains, in children (Alloway et al., 2006) and in adults (Kane et al., 2004). In both cases, the best-fitting model is a structure consisting of distinct verbal and visuospatial short-term storage components (corresponding to the phonological loop and visuospatial sketchpad, respectively), plus a domain-general factor corresponding to the central executive. A summary of the factor structure of the model from Alloway et al. (2006) is shown in **Figure 4**. It can be seen that the complex span tasks load both on the domain-general factor and the respective domain-specific storage system. These data provide an impressive degree of support for the basic structure of the working memory model.

So why is it the case that slow rates of academic learning therefore characterize children who perform poorly on complex memory measures of working memory (e.g., Pickering and Gathercole, 2004; Gathercole et al., 2006a)? We have suggested that the reason is that working memory acts as a bottleneck for learning (Gathercole, 2004; Gathercole et al., 2006b). The acquisition of knowledge and skill in complex domains such as reading and mathematics requires the gradual accumulation of knowledge over multiple learning episodes, many of which will take place in the structured learning environment of the classroom. Learning is thus an incremental process that builds upon the knowledge structures and understanding that have already been acquired: any factor that disturbs this acquisition process will have deleterious consequences for the rate of learning, as the necessary foundations for progress will not be in place. It is proposed that working memory capacity is one of the factors that constrains learning success in potential learning episodes. Many classroom activities require the child to keep information in mind while engaging in another cognitive activity that might be very demanding for that individual. Mental arithmetic is an example of such a demanding working memory activity for adults. In children, whose working memory capacity is considerably smaller and who do not have the same bedrock of stored knowledge and expertise to support cognitive processing, working memory challenges of a comparable magnitude are present in much simpler activities, such as writing sentences, adding up totals of objects displayed on cards, or detecting rhyming words in a poem read by the teacher. Children with poor working memory capacities will face severe difficulties in meeting the demands of these situations and, as a result of their working memory overload, will fail in part or all of the learning activity. Such situations represent missed learning opportunities and if they occur frequently, will result in a slow rate of learning.

### 2.04.2.4 The Episodic Buffer

The episodic buffer is the most recent addition to the working memory model, and was first outlined in a seminal paper by Baddeley in 2000 (Baddeley, 2000).

In this article, Baddeley argued the need for a separate buffer capable of representing and integrating inputs from all subcomponents of working memory and from long-term memory systems in a multidimensional code.

One justification for the episodic buffer is that it solves the binding problem, which refers to the fact that although the separate elements of multimodal experiences such as seeing an object moving and hearing a sound are experienced via separate channels leading to representations in modality-specific codes, our perception is of the event as a coherent unitary whole. At some point, the representations must therefore converge and be chunked together and experienced consciously as a single object or event; Baddeley's suggestion was that the episodic buffer may fulfill this function.

Other evidence also points to a close interface between the subcomponents of working memory and other parts of the cognitive system. It has long been known that meaningful sentences are much better remembered than jumbled sequences of words, with memory spans as high as 16 words compared with the six or seven limit for unrelated words (Baddeley et al., 1987). This indicates that representations in the phonological loop are integrated at some point with conceptual representations arising from the language processing system. Importantly, patients with acquired impairments of verbal short-term memory show reduced memory span for sentences as well as for word lists, but still show the relative advantage of meaningful over the meaningless material. Patient PV, for example, had a sentence span of five and a word span of one (Vallar and Baddeley, 1984). As PV's long-term memory was entirely normal, the reduction in her sentence span must arise from the point of interaction between verbal short-term memory (or the phonological loop). Baddeley (2000) proposed that the episodic buffer may provide the appropriate medium for linking the phonological loop representations with those from long-term memory, and that the central executive may control the allocation of information from different sources into the buffer.

The characteristics of the episodic buffer have been explored in a subsequent experimental programme by Baddeley and collaborators. One line of investigation has looked into whether the episodic buffer plays a role in the binding of different visual features of objects into chunks by comparing memory for arrays of colors or shapes with memory for bound combinations of these features (Allen et al., 2006). In a series of experiments, recognition memory for visually presented objects was tested by presenting an array of objects followed by a probe; the participants' task was to judge whether the probe was present in the original display or not. Across conditions, recognition memory was tested either for shape by presenting a display of different unfilled shapes, for color with a display of squares of different colors, or for both color and shape by presenting objects composed of unique shape/color combinations. In line with previous findings from this paradigm (Wheeler and Treisman, 2002), recognition performance was found to be as accurate in the feature combination as the single feature conditions. Thus, feature binding appears to be a relatively efficient process.

Allen et al. (2006) investigated whether this binding process depends on central executive resources, as might be predicted from the working memory model shown in **Figure 1**, in which information is fed into the episodic buffer from the central executive. To test this possibility, participants also performed demanding concurrent tasks that would be expected to require executive resources – counting backwards and retaining a near-span digit load – while viewing the object arrays. The results were clear: although recognition memory was generally less accurate under dual task conditions, memory for bound features was not selectively disrupted. The only condition that did lead to a greater impairment of recognition for feature combinations than single features was one that involved sequential rather than simultaneous presentation of objects.

On the basis of these findings, Allen et al. concluded that binding the features of simple visual features takes place in the visuospatial sketchpad and does not require executive support. However, it was suggested that storage of such automatically bound information is fragile and may fall apart when further feature combinations need to be encoded and stored in visuospatial memory.

The possible role of the attentional resources of the central executive in integrating linguistic information with representations in the phonological loop in the episodic buffer was investigated by Jefferies et al. (2004). The main focus of this study was the substantial advantage found in the immediate recall of prose compared with unrelated words, which Baddeley (2000) had suggested may be mediated by the integration of linguistic and phonological information in the episodic buffer. Jefferies et al.

conducted a series of experiments in which the relative difficulty of different kinds of lists was equated for individual participants. Thus, an example of an unrelated word list that corresponds to 50% above span for an average participant with a word span of six was the nine items essay, marmalade, is, lots, clowns, wine, spaces, often, a. In the sentence condition of a corresponding level of difficulty, an average participant with a sentence span of 13 would receive the following sequence of unrelated sentences for immediate recall: Railway stations are noisy places. Guns can cause serious injuries. Water is boiled in kettles. Pink roses are pretty flowers. In a further story condition, the sentences were thematically related, as in the following example: A teenage girl loved buying clothes. She went shopping with her mom. They traveled into town by bus.

The possible engagement of attentional processes associated with the central executive was investigated by comparing the impact of a continuous reaction time (CRT) task completed during the presentation of the memory sequence on performance in the different conditions. Following Craik et al. (1996), the CRT task involved pressing one of four keys corresponding to the spatial location of a visual target that appeared on a computer screen; as soon as the key was pressed, the next stimulus was presented. This task is known to place significant demands on controlled attentional processing. If the central executive does play a crucial role in loading phonological and linguistic information into the episodic buffer where it can be integrated into a multidimensional code underpinning sentence span, a selective decrement in the recall of sentences relative to unrelated words would be expected in the concurrent CRT conditions.

Jefferies et al. (2004) found that recall of unrelated words was more or less unaffected by the concurrent task, as was the recall of thematically organized material in the story condition. These findings indicate that the use of the phonological loop places few demands on attentional resources, and also that the activation of preexisting representations relating to the semantic and syntactic content of the stories occurs relatively automatically. In contrast, CRT did markedly impair performance in the condition involving the recall of unrelated sentences. It therefore appears that substantial attentional support from the central executive is required for the retention of unrelated chunks of linguistic information, possibly within the episodic buffer.

Although the study of the episodic buffer is still in its infancy, the concept is being refined in light of new evidence and is proving useful in guiding research on memory for relatively complex forms of material. The simple idea that the central executive is required to feed information through to the episodic buffer for the purposes of feature binding has not received strong support from the research completed so far: there is little evidence for central executive involvement in either the binding of simple visual features (Allen et al., 2006) or in the recall of coherent prose, although attentional support does appear to be crucial for the temporary retention of chunks of unrelated linguistic information (Jefferies et al., 2004). Ongoing and future research designed to delineate the precise conditions under which the central executive and episodic buffer interact seems certain to provide further fruitful insights into the role played by working memory in the storage and manipulation of complex and structured information.

### 2.04.2.5 Other Models of Working Memory

The multicomponent model of working memory initially advanced by Baddeley and Hitch (1974) is the most enduring and influential theoretical framework in the field. Its success rests with the breadth of scope of the model – incorporating verbal and visuospatial short-term memory, as well as attentional processes – and also with the capacity of the model to evolve in light of incoming evidence. Although the original tripartite structure of the 1974 model has been largely preserved, each component has been elaborated and differentiated over the intervening years, largely but not exclusively by using the dual task methodology to identify distinct subcomponents of the system. The model has also proved successful in accommodating evidence from a wide range of empirical traditions including cognitive development, neuropsychology, and neuroscience in addition to experimental psychology. It is, however, by no means the only model of working memory, and there are currently several other conceptualizations that are proving to be highly effective in guiding research and thinking in the area. Some of the significant alternative theoretical accounts of working are outlined in the following.

#### *2.04.2.5.1 Attentional based models*

One influential theoretical account of working memory of this type is Cowan's (1995, 2001) embedded process model, summarized in **Figure 5**. According to this model, long-term memory can be partitioned

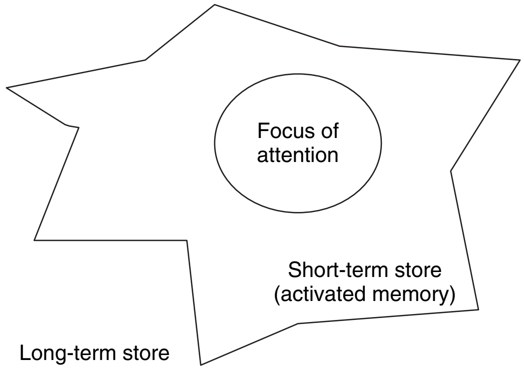

**Figure 5** Cowan's (1995) embedded process model of working memory.

in three ways: the larger portion that has relatively low activation at any particular point in time, a subset that is currently activated as a consequence of ongoing cognitive activities and perceptual experience, and a smaller subset of the activated portion that is the focus of attention and conscious awareness. The focus of attention is controlled primarily by the voluntary processes of the executive system that are limited in capacity in chunks. Recent work indicates that typically between three and five chunks of information can be maintained in the focus of attention (Cowan, 2001; see also Chen and Cowan, 2005; Cowan et al., 2005). In contrast, long-term memory activation is time-limited and decays rapidly without further stimulation.

Cowan et al. (2005) have put forward an interpretation of complex memory span performance and its links with scholastic aptitude measures that is markedly divergent from the explanation based on the working memory model considered in the section titled 'The central executive.' By this account, the crucial feature of complex span tasks is that the processing activity prevents the usual deployment of control strategies such as rehearsal and grouping, and thus exposes more directly the scope of the focus of attention, as indexed by the number of chunks that can be maintained simultaneously. Learning ability will be constrained by having a relatively poor scope of attention, laid bare by complex memory span tasks.

An attentional-based account of working memory function has been also advanced by Engle and associates (e.g., Engle et al., 1999b). In some respects, Engle's model shares a similar architecture with the Baddeley and Hitch (1974) framework, combining domain-specific storage of verbal and visuospatial material with controlled attention. The detailed functioning of the components is, however, quite different. Short-term memory consists of traces that have exceeded an activation threshold and represent pointers to specific regions of long-term memory. They therefore do not represent temporary representations in a specialized temporary store, as in the phonological loop. Controlled attention is a domain-general resource that can achieve activation through controlled retrieval, maintain activation, and block interference through the inhibition of distractors.

Unsworth and Engle (2006) have recently put forward a new explanation of why complex memory span tasks correlate more highly with measures of higher-order cognitive function than simple memory span, based upon the distinction between primary and secondary memory. According to this account, memory items that have been recently encountered are held in primary memory, and may also be transferred into the more durable secondary memory system (Waugh and Norman, 1965). The processing activity in complex span tasks displaces items from primary memory, so that recall performance is supported principally by residual activation in secondary memory. Unsworth and Engle suggest that it is the ability to retrieve items from secondary memory that is crucial to more cognitive activities such as reasoning. Note that this interpretation is somewhat similar to that advanced by Cowan et al. (2005); in both cases, the claim is that learning is served most directly by the quality of activation of long-term memory, and not by the capacity of the controlled attention process that generates conscious experience.

#### *2.04.2.5.2 The resource-sharing model*

A contrasting theoretical perspective on working memory was provided by Daneman and Carpenter (1980, 1983; Just and Carpenter, 1992). These researchers conceived working memory as an undifferentiated resource that could be flexibly deployed either to support temporary storage or processing activity. By this account, individuals with relatively low span scores on complex memory span tasks were relatively unskilled at the processing element of the activity (reading, in the case of reading span), thereby reducing the amount of resource available for storage of the memory items. This idea that working memory is a single flexible system fueled by a limited capacity resource that can be flexibly allocated to support processing and storage was applied by Case et al. (1982) to explain developmental increases in working memory performance across the childhood years.

They proposed that the total working memory resource remains constant as the child matures, but that the efficiency of processing increases, releasing additional resource to support temporary storage. Consistent with this view, Case et al. found in a study of 6- to 12-year-old children that counting spans were highly predictable from individual counting speeds. Furthermore, counting spans were reduced to the level typical of 6-year-old children when adults' counting efficiency was reduced by requiring the use of nonsense words rather than digits to count sequences. It was concluded that the decreased memory spans resulted from the greater processing demands imposed by the unfamiliar counting task, leading to a processing/storage trade-off that diminished storage capacity.

#### 2.04.2.5.3 Time-based theories

The resource-sharing model of working memory has been challenged substantially in recent years. Towse and Hitch (1995) proposed that participants do not process and store material at the same time in complex span tasks as assumed by the resource-sharing approach, but instead strategically switch between the processing and storage elements of the task. Evidence consistent with this task-switching model has been provided in a series of studies that have either varied counting complexity while holding retention interval constant (Towse and Hitch, 1995) or manipulated retention requirements in counting, operation, and reading span tasks, while holding constant the overall processing difficulty (Towse et al., 1998). In each case, the period over which information was stored was a better predictor of complex memory span than the difficulty of the processing activity. This has led to the claim that complex memory span is constrained by a time-based loss of activation of memory items (Hitch et al., 2001).

The consensus view at present is that no single factor constrains complex memory span (Miyake and Shah, 1999; Bayliss et al., 2003; Ransdell and Hecht, 2003). A more complex model recently advanced by Barrouillet and colleagues (Barrouillet and Camos, 2001; Barrouillet et al., 2004) combines concepts of both temporal decay and processing demands in a single metric of cognitive cost that is strongly related to performance on complex span tasks. In this model, the cognitive cost of a processing task is measured as the proportion of time that it requires limited-capacity attentional resources, for example, to support memory retrievals. When attention is diverted from item storage to processing in this way, memory representations cannot be refreshed and therefore decay with time. The heaviest cognitive costs and therefore the lowest levels of complex span performance are therefore expected under conditions in which there is the greatest ratio of number of retrievals to time. Experimental findings reported by Barrouillet et al. (2004) are entirely consistent with this prediction. Using a complex memory span paradigm in which they separately manipulated the rate of presentation of the memory items and the number of intervening items to be processed, complex memory span was found to be a direct linear function of the cognitive cost of the processing activity, computed as a ratio of the number of processing items divided the period over which they were presented. Thus, processing intervals that had relatively high loads (in other words, a relatively large number of items per unit time) were associated with lower span scores than processing intervals with low cognitive loads (low numbers of items per unit time).

#### 2.04.2.5.4 Summary

In this section, a number of alternative theoretical accounts of working memory have been considered. It can be argued that some of these conceptualizations provide valuable specifications of the nature of central executive processes and are not necessarily incompatible with the Baddeley and Hitch (1974; Baddeley, 2000) model. Certainly, the emphasis on time-based loss of information by Towse and Hitch and the ideas of Barrouillet and colleagues concerning cognitive load could readily be accommodated in an elaborated model of the central executive and its interface with the phonological loop. The majority of these alternative approaches also emphasize the role of attention in working memory, a concept given prominence also by Baddeley (1986). However, other claims that working memory is an activated subset of long-term memory and does not exist as a temporary storage medium distinct from preexisting knowledge are less easy to reconcile.

## 2.04.3 Overview

The ability to hold information in mind for brief periods of time, termed working memory by cognitive psychologists, is an essential feature of our everyday mental life. The purpose of this chapter is to provide a contemporary overview of current theoretical understanding of the cognitive processes of working memory. According to the influential model advanced originally by Baddeley and Hitch (1974) and revised and elaborated over the subsequent years (Baddeley, 1986, 2000; Burgess and Hitch, 1992, 1999), working memory consists of an attentional controller, the central executive, supplemented by slave systems specialized in the storage of verbal and nonverbal information (the phonological loop and visuospatial sketchpad, respectively). An additional component is the episodic buffer, capable of integrating information from different parts of working memory and other parts of the cognitive system. Each component of the model is limited in capacity.

This relatively simple model of working memory has proved capable of accommodating a wide range of empirical findings. Its fractionated structure has been informed by findings from experimental studies using dual task methods, by developmental dissociations in studies of children, and by evidence of distinct underlying brain from the fields of neuropsychology and neuroimaging. In the area of the phonological loop in particular, understanding of the underlying cognitive processes is sufficiently well advanced to allow the development of a computational model capable of simulating many detailed aspects of verbal short-term memory behavior.

Two components of the working memory model – the central executive and phonological loop – appear to play key roles not only in the temporary retention of information, but also in supporting longer-term learning, particularly during the childhood years. The phonological loop is important for learning the sound patterns of new words in the course of acquisition of vocabulary in native and foreign languages, whereas the central executive mediates academic learning in areas including reading and mathematics. Detailed theoretical accounts of the possible causal roles of working memory in these elements of learning are considered.

There are also several alternative theoretical accounts of working memory that are currently proving useful in guiding further research and understanding in this field. Some of these theories conceive of working memory as the subset of representations in long-term memory that have been activated either automatically via our interactions with the environment or effortfully, by being the focus of a consciously controlled attentional resource. Whereas the role played by attention is acknowledged in almost all current models of working memory, the distinction between models that assume specialized temporary storage mechanisms and those that see working memory as a property of preexisting knowledge representations is a fundamental one, yet to be resolved by empirical evidence. A further common feature of many theories is that time-based forgetting is a crucial feature of working memory.

Research in the field of working memory continues, stimulated by the availability of detailed theoretical accounts that guide empirical investigations of both typical and atypical working memory functioning. There is also increasing recognition that our current understanding of working memory can be put to more practical use, particularly in the fields of education and remediation (e.g., Gathercole and Alloway, in press). In this respect, working memory represents a strong example of how laboratory investigations of basic cognitive processes have the potential to enhance less esoteric elements of our everyday cognitive experience.

# 2.05 Serial Learning

**A. F. Healy and W. J. Bonk**, University of Colorado, Boulder, CO, USA

In many activities in everyday life, we are required to learn the serial order of a set of elements. For example, whenever we acquire a new word, we must learn a novel order of sounds. As Lashley (1951) pointed out in his classic paper, the problem of learning serial order is that elementary movements occur in many different orders in different actions. How, then, can an individual who knows the elementary movements in an action learn to produce them in the correct sequence? For example, how can a pianist who knows the notes occurring in a given song learn to produce the notes in the correct order? That is the central problem involved in serial learning.

## 2.05.1 Concepts

To address this problem, we need to define several important concepts and make some crucial distinctions: Performing a serial task requires subjects to display knowledge of both the elements in the task and their arrangement. The task elements are items, and their arrangement is their order. In discussing serial learning, order is usually based on the temporal sequence in which the items occur, but in some cases order is based instead on the spatial locations of the items. Thus, letters are the items in words, and the letters must appear in a fixed order for a given word to be identified. The words 'tap' and 'pat' have the same items, but their different orders create different meanings. We can describe the order of the items either in terms of their ordinal positions without reference to their relational sequence (in 'tap,' 't' is first, 'a' is second, and 'p' is third) or in terms of their relational sequence without reference to their ordinal positions (in 'tap,' 't' precedes 'a' and 'p' follows 'a').

In cognitive psychology, learning typically refers to the process of acquiring information over time, whereas memory usually refers to the retention (or forgetting) of information. Thus, in the study of serial learning, we are most concerned with the acquisition of order information, but we also need to understand the underlying memory processes that provide the foundation for such learning over time. In practice, assessments of learning typically involve multiple study and test episodes, but assessments of memory usually involve a single study episode followed by a single test. Thus, memory research can be viewed as providing a snapshot of the first stage of the learning process.

## 2.05.2 Tasks

The original procedure used to investigate serial learning was established by Ebbinghaus (1885/1913).

In this repeated study–test procedure, a list of items is studied and then tested by requiring recall of the items in the order in which they were shown. This procedure is repeated until the subject reaches a criterion of recalling the list without error. Later researchers replaced this procedure with the method of anticipation, in which subjects are shown one item for a fixed amount of time and are then required to anticipate the next item in the sequence. Subsequently, the next item is shown, which provides feedback to subjects as to the correctness of their last response. This procedure continues throughout the presentation of a list, and list presentation is repeated until the subject reaches a criterion, perhaps one time through the list without error. The investigator tabulates how many presentations of the list are required to reach the criterion.

In recent investigations, the focus has shifted from the learning of order information to immediate memory for order information. Consequently, the most popular procedure is that of serial recall. In this case, subjects are given a series of items to study and are then required to recall the entire list in sequential order. Serial recall can be contrasted with free recall, in which subjects are free to report the items in any order they want and do not need to indicate the sequence information in any way. In serial recall tasks, subjects learn multiple different lists rather than the same list repeatedly. Often the investigator includes a delay between the presentations of successive items (interitem interval) or between the presentation of the last item on the list and the recall test (retention interval). Sometimes extraneous distracting items are interpolated during either the interitem interval or the retention interval to prevent subjects from rehearsing (practicing) the items during those intervals.

In the recall procedures, to respond correctly, subjects must remember the items. Another method was developed to isolate memory for order even further by eliminating the need for the subjects to remember the items. Specifically, the items are given to the subjects either in advance or during the trial, and the subjects simply have to reconstruct the order in which the items occurred. For example, for the list ABCDEF the subjects might be told that the items were BFACED, and they would have to rearrange the items into the correct sequence by placing A into the first slot, B into the second slot, and so on. In reconstructing the order, the subjects thus place each item into its appropriate position, perhaps in a horizontal array of slots, but the slots do not necessarily have to be filled in order from left to right. If a left-to-right response is required, the task is serial reconstruction of order, whereas if no constraints on response order are specified, the task is free reconstruction of order, using the same distinction described earlier for serial and free recall.

A new repeated study–test procedure has been developed to investigate both memory for and learning of serial lists, with successive snapshots of the learning process taken until a criterion is reached (Bonk, 2006). This procedure can be viewed as a combination of three common tasks already described: serial learning, serial recall, and serial reconstruction of order. Under this procedure, subjects view a display showing a set of items including both targets and distractors. The targets are then highlighted one at a time to indicate the required sequence. Subjects observe this presentation and then reconstruct the sequence by choosing one item at a time. The items can vary in type, but in the initial study were clip art pictures. The sequences can vary in length, and in the initial study they were from 6 to 15 items long. To respond correctly, subjects must remember both the identity of the target items and the order in which they occurred. A given sequence of target items is shown and recalled multiple times until the subject reaches the criterion of two perfectly recalled sequences in a row.

## 2.05.3 Results

The most widely cited experimental result in the study of serial order is the serial position function, first described by Nipher (1878; see also Stigler, 1978) for serial recall. To obtain this function, every position in the list is scored separately, and the total number of correct responses at a given position is computed either across repetitions of the list (in a learning paradigm such as the method of anticipation) or across different lists (in a memory paradigm such as serial recall). The function typically takes on a bow shape (like a bow in archery), wherein items at the start and end of the list are remembered better than intermediate items. The advantage for the initial items is the primacy effect, and the advantage for the final items is the recency effect. In serial learning, the primacy advantage is typically much larger and includes more items than the recency advantage, which sometimes includes only a single item. Asymmetrical bow-shaped functions for the initial test of a given list in the new repeated study–test procedure developed by Bonk (2006) are shown in **Figure 1** for each of 10 list lengths. Asymmetrical

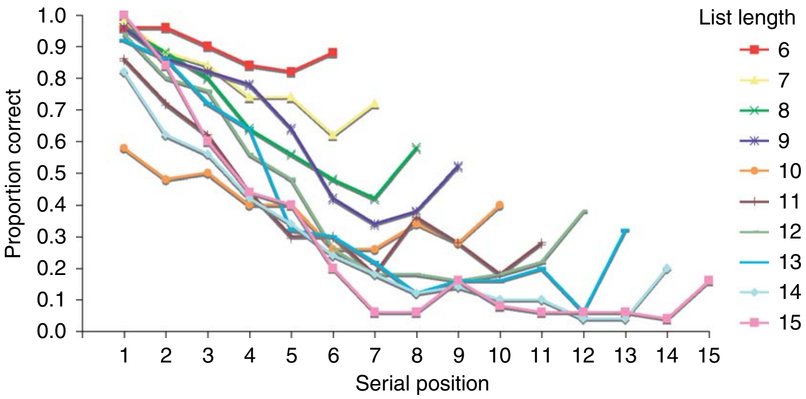

**Figure 1** Mean proportion of correct responses as a function of list length and serial position for initial tests in serial learning experiment by Bonk (2006).

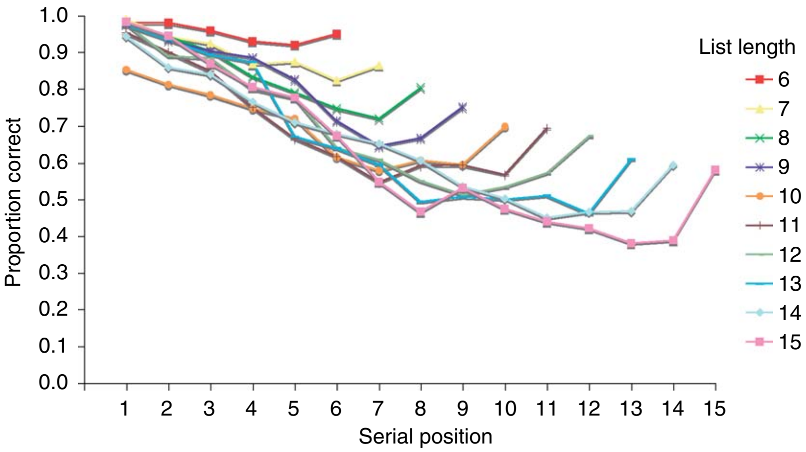

**Figure 2** Mean proportion of correct responses as a function of list length and serial position for all attempts through the first perfect recall of a given list by a given subject in serial learning experiment by Bonk (2006).

bow-shaped functions are shown in **Figure 2** for all tests of a given list through the first perfect recall, again for the same 10 list lengths. **Figure 1**, thus, shows curves reflecting serial recall, whereas **Figure 2** shows curves reflecting serial learning. The curves are different, but both show an asymmetrical bow shape. Although the level of performance in serial recall or serial learning may depend on many factors, such as the rate at which the items are presented or the familiarity of the items, the serial position curve typically takes on the same shape when it is normalized. Normalization requires computing the proportion of all correct responses that occur at each serial position of a given list by a given subject. For example, if a subject on a six-item list took three attempts to reach the criterion and during those attempts made a total of 15 correct responses, with 3 of them on the first serial position, the normalized proportion correct for that position would be $3/15 = 0.20$. The fact that the shape of the normalized serial position function is constant across serial learning conditions was first demonstrated by McCrary and Hunter (1953). The normalized functions for the serial learning results of Bonk (2006) are shown in **Figure 3**, again for all 10 list lengths.

Other widely studied results involve the errors made by subjects in tasks requiring serial order. A frequent type of error is one in which the correct item is given but is not placed into its correct position. In a serial recall task, this is a transposition error. Typically, transposition errors occur in pairs because the positions of two adjacent items are confused. For example, if subjects are given the list ABCDEF and they recall ACBDEF, they have transposed a pair of

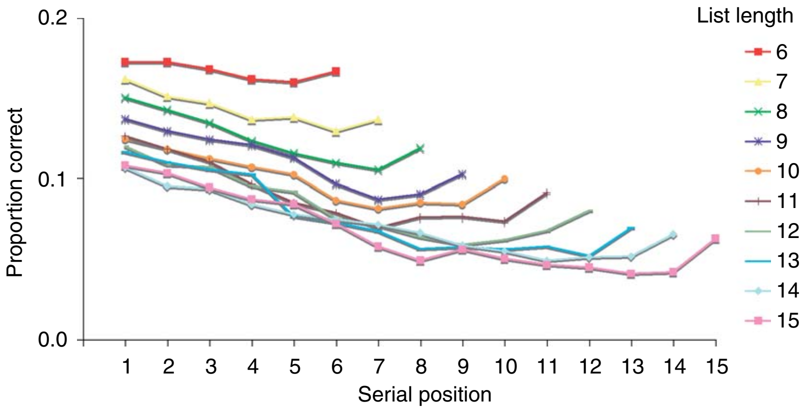

**Figure 3** Mean normalized proportion of correct responses as a function of list length and serial position for all attempts through the first perfect recall of a given list by a given subject in serial learning experiment by Bonk (2006).

letters, B and C. Such a paired transposition would result in errors at two of the six list positions, positions 2 and 3. A nontransposition error is any other type of error in this task, such as when an item that did not occur in the list is substituted for a correct letter. For example, if subjects respond with YBCDEZ to the sample list, they have made nontransposition errors at two of the six list positions, positions 1 and 6.

Even with shorter lists, a bow-shaped serial position function is found for serial recall. In a procedure known as the distractor paradigm, items are briefly presented, followed by a retention interval filled with an interpolated task, often consisting of items of a different type, all of which must be read aloud by the subjects. For example, a list of four letters might be presented followed by a variable number of digits, with subjects reading aloud both the letters and digits before they recall the letters in the order shown. This procedure allows the investigators to examine the amount of information remaining in memory after various delays when rehearsal of the information is prevented. Using this procedure and differentiating between transposition and nontransposition errors, Bjork and Healy (1974) found that symmetrical bow-shaped serial position functions were found for total errors at each of three different retention intervals (3, 8, or 18 interpolated digits). These functions, when decomposed into transposition and nontransposition errors, showed a bow shape only for the transposition errors; the functions for nontransposition errors were much flatter, as shown in **Figure 4**.

Transposition errors can be further described in terms of a positional uncertainty gradient, which is a function of the distance between the input positions of the correct item and the item that substitutes for it in the subject's recall response. When the distance is short, the probability of an error is typically larger than when the distance is long. Such error gradients are shown in **Figure 5** for two different conditions in which order information was isolated by telling the subjects in advance which items would occur and using the same set of items on every trial of the experiment (Healy, 1975). The list items occurred one at a time in different spatial locations arranged in a row, with the spatial and temporal positions independently manipulated. In the temporal condition, the items occurred in fixed spatial locations, so only the temporal sequence of the items needed to be learned and remembered. In the spatial condition, the items occurred in a fixed temporal sequence, so only the spatial locations of the items needed to be learned and remembered. The items in this experiment were four consonant letters in each condition. As in the experiment by Bjork and Healy (1974), there were three different retention intervals, with 3, 8, or 18 interpolated digits. These functions show three striking differences in the retention of temporal and spatial order information. First, the decline in accuracy across retention intervals is sharp in the temporal condition but modest in the spatial condition. Second, the serial position function (evident by examining correct responses) is bow-shaped in the temporal condition but not in the spatial condition. Third, the error gradients are steeper in the temporal condition than in the spatial condition.

One specific type of nontransposition error that often occurs is a confusion error, in which a given item is replaced with another item that is confusable

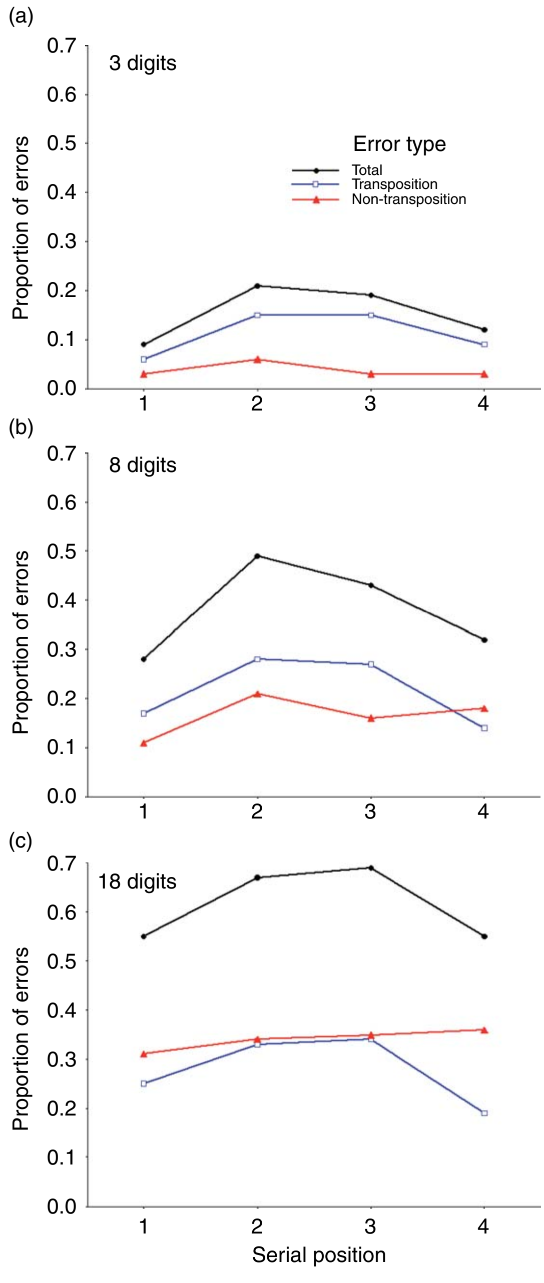

**Figure 4** Mean proportion of errors as a function of retention interval (i.e., for 3, 8, and 18 interpolated digits), and serial position for all errors (total) and separately for transposition and nontransposition errors in serial recall experiment by Bjork and Healy (1974).

with it. In our example, a confusion error would occur in the second position if subjects respond with AGCDEF. The confusion error is presumably a result of similarity between the original item and the one replacing it, such as the similarity in sound between the letters B and G in the example. Such an error could be classified as a phonological confusion error. Other types of confusion errors are also possible. For example, if the items were words, the confusions could be based on similarity of meaning rather than sound, in which case they would be semantic confusion errors (e.g., replacing 'cot' with 'bed').

Often a nontransposition error is not based on item similarity but, rather, on positional similarity. Specifically, subjects show a tendency to replace an item in a given list with an item from the same position in an earlier list (e.g., Conrad, 1960; Estes, 1991). For example, if subjects see the list ABCDEF followed by the list GHIJKL and they recall the second list as GHIJEL, they have replaced the item in the fifth position of the second list with the item in the same position of the previous list. This type of error is a serial order intrusion.

Both the serial position functions and the different types of errors give us clues that help us understand the cognitive processes underlying memory for and learning of serial order information.

## 2.05.4 Theories

### 2.05.4.1 Classic Theories

The classic theories are largely theories of serial learning because the most popular experimental paradigm used at the time they were developed was the method of anticipation, and this paradigm provided the data that were to be explained by the models.

#### *2.05.4.1.1 Associative chaining*

An early description of serial learning was based on an associative chaining model wherein one item in a sequence was linked to (associated with) the next item in a chain (see, e.g., Crowder, 1968). This model was a natural outgrowth of the serial learning task involving the method of anticipation in which each item in the list is explicitly given as a cue for the next item. In our example of the list ABCDEF, the letter A would be linked to the letter B, B to C, and so on. However, even for that task, the simple associative chaining model may not be appropriate, as is evident intuitively from the observation that missing one item in a serial list does not lead to failure to report all subsequent list items. For example, a chaining model may predict that, in memorizing a complete poem, if any word is forgotten then it would be impossible to recall subsequent words in the poem. This particular problem is overcome if there are associative links of

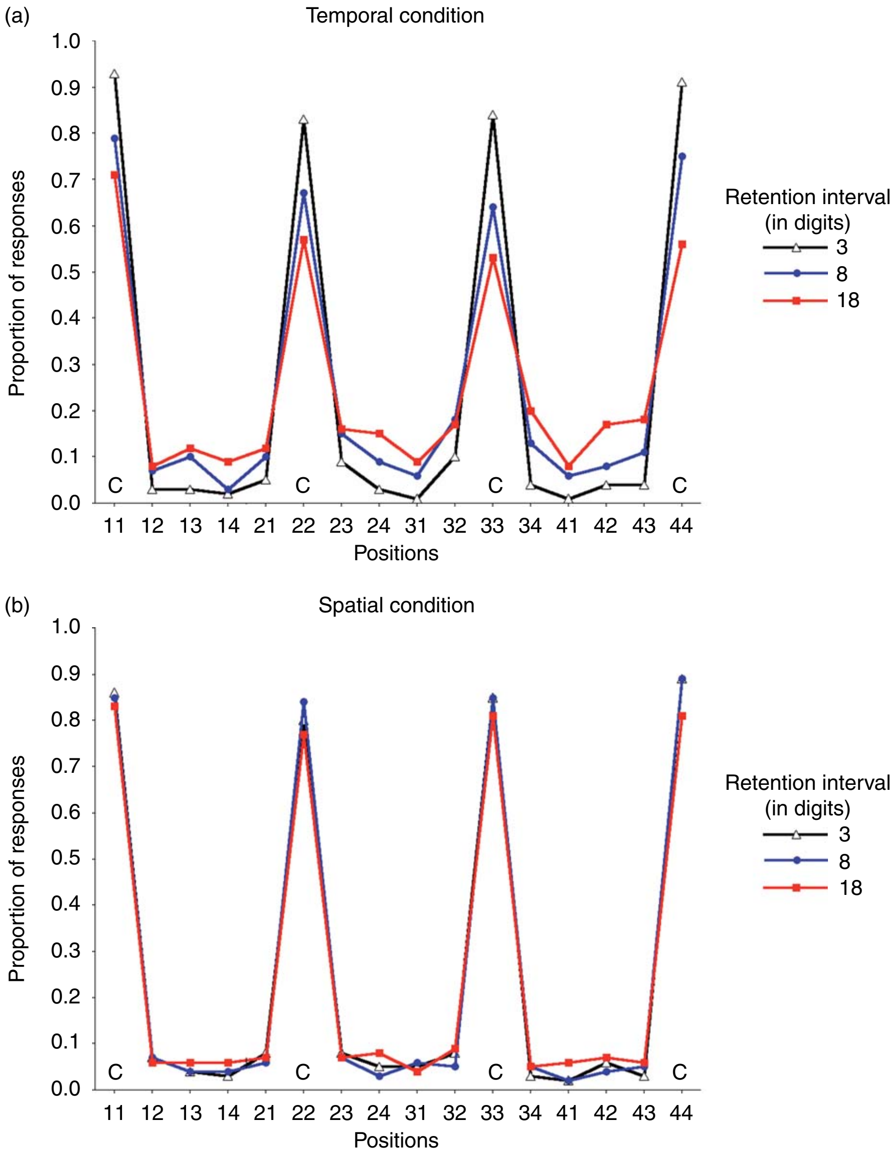

**Figure 5** Mean positional uncertainty gradients for temporal and spatial conditions of experiment by Healy (1975). The point plotted for position ij represents the proportion of instances in which the response occurring at position i was the item appearing in input position j of the trial. The label C indicates correct responses.

varying strength among all items in the list, not just neighboring items, with the associations for adjacent items stronger than the more remote associations linking items that are not adjacent in the list. Thus, if a word in a poem is forgotten, subsequent words could still be recalled on the basis of remote associations from earlier words in the poem that could serve as cues. However, even such compound chaining could not overcome other types of evidence against this class of models. For example, in one experiment using the method of anticipation, subjects learned a serial list of adjectives to a criterion of one perfect trial. Then they were given a task to learn a set of paired associates, with experimental pairs formed from adjacent adjectives in the previous list and control pairs formed from unrelated adjectives. Subjects learned the experimental pairs no faster than they learned the control pairs in the paired associate task (Young, 1962), which seems inconsistent with the assumption that in the serial learning task subjects formed strong associations between adjacent items (but see Crowder, 1968, for counterevidence supporting the existence of such associations).

#### 2.05.4.1.2 Positional coding

Another early description of serial learning is also based on associations between stimuli and responses; it involves a simple positional coding model. In this case, the associations are not from one item to the next but, rather, between a given item and its ordinal position (see, e.g., Young et al., 1967). In our example, the letter A would be associated with ordinal position 1, B would be associated with ordinal position 2, and so on. One version of this theory is a box model (Conrad, 1965), according to which each successive item in a list is entered into a box, with the boxes preordered in memory. Item information in the boxes gets degraded with the passage of time, and at recall subjects output items for each box in turn using whatever information is still available. Transposition errors occur in this model not because of a reordering of the boxes but, rather, because information about an item in a given box is degraded so that the remaining partial information may be consistent with another list item, leading to report of that other item rather than the correct one for that position. This simple model was also refuted by experiments testing it. For example, in a study like the earlier one testing the chaining model, subjects learned, using the method of anticipation, an ordered list of adjectives to a criterion of one perfect trial. Then they were given a task to learn a set of paired associates, in this case with the ordinal position numbers as stimuli and the serial list adjectives as responses. Subjects did not perform as well on the paired associate task, at least on the intermediate items, as they should have if they had in effect learned those associations previously during the serial learning task (Young et al., 1967).

#### 2.05.4.1.3 Positional distinctiveness

A simple but powerful model was proposed by Murdock (1960) to account for the serial position function in serial learning solely in terms of the distinctiveness of the positions. By this model, a given position's distinctiveness is determined merely by comparing its ordinal position value to the values of all of the other list positions. For example, in a five-item list, the difference between the ordinal position value for the first position and the value for the other positions is the sum of $|1-2|$, $|1-3|$, $|1-4|$, and $|1-5|$, which is $1+2+3+4=10$. In contrast, a similar calculation for the third position yields $|3-1|$, $|3-2|$, $|3-4|$, and $|3-5|$, which is $2+1+1+2=6$. Thus, as is also clear intuitively, the first position is more different from the other positions than is the third position. The actual calculation of distinctiveness is a bit more complex because log values are used instead of the ordinal numbers themselves. The use of log values allows the model to account for the finding that primacy effects are typically stronger than recency effects. According to this model, the serial position function should be the same shape for all lists of a given length, even if the lists vary in terms of their presentation time or the familiarity of the items that comprise them. Indeed, as mentioned earlier, normalized serial position functions have the same shape across all experimental conditions (McCrary and Hunter, 1953).

### 2.05.4.2 Contemporary Theories

Unlike the classic theories, contemporary theories are largely theories of immediate serial memory because the most popular experimental methodology became the immediate serial recall paradigm, and this paradigm provided much of the data that were to be explained by the theories. Thus, the emphasis has shifted from the learning of serial order information to immediate memory for serial order information. The new data by Bonk (2006), which examine serial recall on successive learning trials, provides an empirical integration of serial memory and serial learning results, but little theoretical integration has yet been proposed.

#### 2.05.4.2.1 Perturbation model

An elegant model was proposed by Estes (1972) to account for serial recall performance in the distractor paradigm. Like the classic models, the perturbation model is based on simple associations. However, the associations in this case are between an individual list item and a control element, which represents the given context or environment in which the list was learned. At the core of the model is the concept of a reverberating loop that links the control element to a given list item, with a recurrent reactivation of the list item each time the control element is accessed. Because all the items in a list are associated to the same control element, the difference in reactivation times reflects their input order. The timing of the reactivations, thus, provides the basis for knowledge of the order of the items in a list. This knowledge is assumed to be perfectly stored in memory immediately after the list is presented. Loss of such information, resulting in failure to recall the items in the correct order, may then occur for one of two reasons. First, the subject may lose access to the control element, perhaps because the experimental context has shifted as a function of time or because of some interpolated, interfering activity. Second, there may be perturbations, or disturbances, in the timing of the recurrent reactivations, presumably resulting from random neural activity. If the timing perturbations are large enough, two adjacent list items may be interchanged so that the later item is reactivated before the earlier item, thus leading to transposition errors in recall. The perturbation process can account for the symmetrical bow-shaped serial position functions found in immediate serial recall of short lists because the likelihood of interchanges resulting from timing perturbations is greater for intermediate list items (which have neighboring items on both sides) than for end items (which have a neighboring item on only one side). This same mechanism easily accounts for the positional uncertainty gradients observed for temporal (but not spatial) order recall, wherein the likelihood of a transposition error decreases as the distance in time increases between the input positions of the correct item and the one replacing it.

After its original formulation, the perturbation model was refined to account for the fact that order information can be viewed as hierarchical (Lee and Estes, 1981). If lists are divided into subsets, perhaps by adding pauses between groups of items, then subjects need to know on which list a given item occurred and in which subset of the list it occurred, as well as its relative position in the subset. According to the refined version of the perturbation model, each item is coded for its placement in this three-tier hierarchy. The hierarchy of codes is repeatedly reactivated, and the perturbation process applies independently at each level, so at each reactivation there is a probability that the relative position of adjacent lists, subsets, or items will be disturbed. This hierarchical perturbation process produces serial order intrusion errors, when an item in a given list or list subset is replaced by an item from the same position in an earlier list or list subset.

#### *2.05.4.2.2 Start-end model*

The start-end model (Henson, 1998) was proposed to account for the serial position functions, the positional uncertainty gradients, and the distributions of different types of errors in the serial recall task. At the heart of this model is the observation that the start and end of a list are most salient and therefore serve as anchors, or markers, to code for each item's position in the list (see Feigenbaum and Simon, 1962, for an earlier use of the notion of list end items serving as anchors). Each item gets a two-value code based on the strength of both the start and end markers at that point in the list. The start marker is assumed to be strongest at the beginning of the list and to get progressively weaker for subsequent list items. In contrast, the end marker is assumed to be weakest at the beginning of the list and to get progressively stronger for subsequent list items. Although the end is not evident at the start of the list, subjects anticipate the end (at least when they know the list length), and that expectation allows for the use of the end marker. The model reproduces the general finding that primacy effects are larger than recency effects by giving greater strength to the start marker than to the end marker.

This model makes use of a distinction between types and tokens as a way of representing items. A given item, such as a word, may occur in multiple lists or on multiple occasions in a given list. Each time the word occurs, the item is the same type, but the different instances of the word constitute different tokens. In the start-end model it is assumed that each item token codes both identity and positional information. The identity information specifies the content of that item (e.g., which word has occurred). The positional information is derived from the strength of the start and end markers for that item token. According to the model, the item tokens are unordered in memory; instead, they are ordered at the time of recall. Specifically, at recall the position of a given item is cued by its start and end marker strength values; the identity of the item that matches the cued strength values most closely is recovered and then recalled at that position. Another assumption made by the model is that once an item is recalled, its type is suppressed so that subjects will be less likely to recall a given item type more than once in a trial. This aspect of the model allows it to account for the Ranschburg effect (e.g., Jahnke, 1969), whereby subjects are likely to fail to recall second occurrences of a given item.

#### *2.05.4.2.3 Primacy model*

The primacy model (Page and Norris, 1998) is related to both the perturbation and start-end models but was formulated to account for a different set of results. The results in this case are those that formed the basis of Baddeley and Hitch's (1974) model of the phonological loop, which is a qualitative description of working memory that describes rehearsal processes but does not provide any specific mechanisms for serial recall. Thus, the primacy model can be viewed as a computational version of the phonological loop model (see also Burgess and Hitch, 1999, for an alternative quantitative version of this model). The primacy model does not specifically code position information, but such information is derived at the time of recall from the relative activation strengths of list items. These activation strengths vary as a function of the time when the list items occurred, forming a primacy gradient, with the strength greatest for the first item and declining for successive items in the list. These activation strengths can be thought of as reflecting the degree to which the context defining the start of the list is associated with each successive list item. By this view, the start-of-the-list context resembles both the control element of the perturbation model and the start marker of the start-end model. However, unlike the start-end model, there is no corresponding end marker in the primacy model.

To model the recall process, the primacy model implements the assumption that in a repeating cycle, the item with the greatest activation is selected for recall, and after it is recalled, it is suppressed. Subsequently, the item with the next highest activation is recalled and then suppressed, and so on. During the recall process, the activations for all list items decay exponentially with time. Errors result from the fact that there is noise in the process of selecting the item with the strongest activation (which can be viewed as noise in the perception of the activation strengths), even though there is no noise in the activation strengths themselves. Primacy effects fall out of the model naturally because of the primacy gradient, but recency effects occur because end items can only participate in a paired transposition error in one direction (i.e., with one neighbor), whereas intermediate items can participate in paired transposition errors in both directions (i.e., with neighbors on both sides). Paired transposition errors occur in this model whenever the perceived activation strength of a given list item is either less than the perceived activation strength of a subsequent list item or greater than the perceived activation strength of a preceding list item. Such paired transposition errors also rely on a property of the model called fill in, which is the assumption that when an item is missed in recall because of a transposition it is likely to be recalled in the next position. This model is, thus, consistent with the observation from Bjork and Healy (1974) that transposition errors show a bowed serial position function but nontransposition errors do not. Nontransposition errors typically increase as a function of serial position. To account for this finding, the primacy model assumes that once the item with the strongest perceived activation is selected, the activation is compared to a threshold value. If the activation is above threshold, the item will be recalled, whereas if it is below threshold, it will be omitted and the subject will resort instead to guessing an item, with this threshold comparison subject to noise. Thus, the primacy model can account for nontransposition errors as well as transposition errors.

#### 2.05.4.2.4 OSCAR

A novel approach to explaining serial recall was taken by Brown et al. (2000) in their oscillator-based computational model OSCAR. Oscillators are timing mechanisms that generate continuously changing rhythmic output. Oscillators occur at different frequencies, with high-frequency oscillators repeating more often than low-frequency oscillators. An analogy can be made to the hands in a clock face. The second hand completes its cycle more rapidly than the minute hand, which in turn completes its cycle more rapidly than the hour hand. OSCAR accounts for the learning of order by making use of oscillator timing mechanisms presumed to occur naturally in the mind. In OSCAR, during list presentation, associations are formed between a vector (an ordered series of numbers) representing a list item and a vector representing successive states of the learning context. The learning context is the current state of the dynamically changing internal set of timing oscillators. Thus, OSCAR, like other models, makes use of associations between items and a representation of the learning context. However, in OSCAR, unlike other models, the learning context changes continuously during list presentation. Just as Lee and Estes (1981) postulated a hierarchy of codes in the perturbation model, the oscillators in OSCAR vibrate at different rates, reflecting different levels of a three-tier hierarchy, including item position within a subset, subset position within a list, and list position within a session. Unlike the perturbation model, however, order errors arise in OSCAR solely during the retrieval stage. Specifically, at the time of retrieval, a sequence is recalled by reinstating the states of the set of oscillators that comprise the learning context. Each successive learning context vector is used as a probe recovering the list item vector that is associated with it. Retrieval errors occur based on the quality of the learning context vector and the extent to which that vector is specific to a particular item. Items occurring close together in time have similar learning context vector values; thus, noise in the retrieval process leads to positional uncertainty gradients like those found for the temporal condition in the study by Healy (1975). This model, unlike some of the others, can thereby explain observed differences between recall of temporal and recall of spatial order information.

#### 2.05.4.2.5 TODAM

Unlike the other contemporary theories reviewed here, which are restricted to memory for serial order, a model by Lewandowsky and Murdock (1989) is designed to account for serial learning as well as serial recall. This theory of distributed associative memory (TODAM) also differs from the other contemporary models in being based on associative chaining. Although, as mentioned earlier, problems had been found for the classic associative chaining model, these were largely overcome in TODAM. A third difference between TODAM and the other models reviewed here is that TODAM provides a more general account of memory, not being restricted to serial order (see Anderson et al., 1998, for another general model incorporating serial recall). A fourth difference is that the memory representations in TODAM are not localized but are, rather, distributed.

Specifically, in TODAM the representations of all list items are stored together in a common memory vector. The numbers making up the memory vector in TODAM represent values of individual features. Successive items are associated using a mathematical operation convolution that blends the constituent item vectors. The resulting convolution is also added to the common memory vector. If all information is contained in a single memory vector, how can the model recover the individual list items when needed? The retrieval mechanism used for this purpose is correlation, which is the inverse of convolution (i.e., it essentially undoes that operation). Thus, a memory probe representing a particular stimulus item can be correlated with the common memory vector to yield another vector that approximates the response item with which it had been associated. Once the approximation to the response item is generated via the correlation process, it must be deblurred (interpreted) before it can be recalled. If the deblurring process yields an overt recall response, the new vector resulting from that response can then be used as a stimulus probe to recover the next item in the list. The deblurring process might not result in an actual overt response. Nevertheless, the recall process can move forward to the next item in the list because the vector approximation can be used as a stimulus for a subsequent response. This implementation allows TODAM to overcome one of the key problems mentioned earlier plaguing the classic chaining model, namely, that missing one item in a serial list does not lead to failure to report all subsequent items. A subsequent version of TODAM (Murdock, 1995) also uses associations between higher-order chunks of items to avoid problems with simple associative chaining models.

To model serial learning occurring across repeated presentations of the same list, in a closed-loop variant of TODAM, the new information added to the memory vector for an item is reduced by the amount of information already present in the vector. This aspect of the model captures the idea that gradually less is learned about each item during successive repetitions of a list.

## 2.05.5 Theoretical Issues and Conclusions

A variety of theoretical mechanisms have been proposed to account for serial memory and learning, but there is little consensus as to which is the best. The various models differ along numerous important dimensions, such as the relation between item and order information and whether or not position or sequence information is explicitly coded. Some models do not discriminate between temporal and spatial order, whereas others apply only to temporal order. Crucially, most models do not attempt to provide a theoretical integration of serial memory and serial learning results. Thus, despite the theoretical insights and innovations in the five decades since Lashley (1951) first discussed the importance of this problem, we have not yet achieved a full and widely accepted understanding of the processes underlying serial order behavior, which provides the foundation for many activities in everyday life.

# 2.06 Repetition and Spacing Effects

**R. L. Greene**, Case Western Reserve University, Cleveland, OH, USA

Coyne (2006) dedicated himself to becoming as good a golfer as he could possibly be. He spent a year in this quest, hitting more than 100 000 golf balls and playing 5418 holes. He found that practice at this skill indeed led to improvement but was frustrated to find out that not all practice was equally effective. The beginning of his regimen led to the fastest improvement, an observation that led Coyne to compare his situation to that of a dieter finding that the first few pounds lost were the easiest. Coyne's observations are typical, as the importance, as well as the limitations, of repetition in the mastery of information or skill can be documented in countless domains (Ericsson, 2005).

That repetition is key to learning but that not all repetitions are equally effective are central observations underlying all serious thought on the topic. The central importance of repetition was recognized by many ancient and medieval thinkers. Hermann Ebbinghaus (1885/1964), who initiated the modern era of memory research, carried out a series of experiments that showed that retention improved as a function of the number of times that information had been studied. Ebbinghaus's theoretical approach assumed the centrality of repetition in the acquisition and strengthening of learning.

The fact that learning and memory are sensitive to repetition is not in question. However, the basis of repetition effects is still far from clear. Boundary conditions where repetition has no effect are particularly interesting in determining why repetition affects retention. A related topic of interest in the literature deals with the temporal distribution of repetitions. Generally, repetitions are more effective if they are spaced apart than if they are massed together (the spacing effect).

Anderson and Schooler (1991) have noted that both repetition and spacing effects are rational; that is, if one were designing an ideal memory system, one might construct it so that it would exhibit both of these phenomena. They pointed out that human memory evolved to manage a huge body of information containing millions of facts and experiences. Expecting perfect retrieval of all these facts is unlikely in the face of our limited physical abilities; it may also be unwelcome because we may quickly find ourselves overwhelmed by the massive amount of information we have stored. A rational memory system would be one where the retrievability of a memory is strongly related to the probability of that particular memory being needed. Repetition would surely be one clue indicating that a particular fact was important. If we had encountered or used a fact numerous times in the past, it would be more likely that we will need it again in the future than if we had only used that fact once. Similarly, when a particular fact or experience had been encountered or used at widely spaced intervals, it is probably more likely to be used again in the future than a fact used equally often but only in a massed cluster. Anderson and Schooler based their reasoning on theories of information retrieval, which underlie many of the computerized search systems found in libraries or on the Internet. Still, acknowledging that repetition effects and spacing effects are good phenomena for well-designed memory systems to show does not address the issue of the mechanisms that lead to these effects in human memory.

## 2.06.1 Continuity, Discontinuity, and Repetition

Coyne (2006) found that his golf practice (when not interrupted) led to a steady, albeit sometimes agonizingly slow, improvement in his performance. The seemingly continuous, but always slowing, effect of repeated practice is a ubiquitous finding in the field of learning and memory. The total amount learned increases as a function of repetition, but the rate of learning seems to change systematically across trials. The traditional learning curve depicted as a function of practice demonstrates negative acceleration, with the greatest learning occurring on the first trial. The amount learned on each subsequent trial seems to decline continuously. Eventually, the change in performance as a function of further practice is too small to be measurable. The phenomenon of *registration without learning* (Hintzman et al., 1992; Hintzman and Curran, 1995) is a demonstration of this, with participants showing no evidence of learning more information about the details of a stimulus, even while continuing to register its repeated presentations. Cleary et al. (2001) showed a similar pattern in learning about associations: When presented with word pairs that are repeated many times, participants may note the occurrence of individual items without showing improved associative memory. Because people seem to pay much less attention to later occurrences of repeated stimuli, first impressions become particularly important. Participants may not demonstrate evidence of having noticed small changes that are made to a stimulus after its first presentation (DiGirolamo and Hintzman, 1997). Miller et al. (2004) provided additional evidence regarding which features of a stimulus are most likely to be overlooked; specifically, accidental properties that are not inherent aspects of a stimulus are commonly ignored in later repetitions.

Authors such as Guthrie (1935) and Estes (1955) have long noted that this seemingly continuous improvement in performance does not necessarily mean that the learning process itself must be gradual or continuous. Many learning situations can be broken down into smaller components, and one cannot rule out the possibility that these components may be learned suddenly, possibly as a result of insight. If these components are learned at different times, the seemingly gradual nature of learning may instead reflect the accumulation of mastered components, each of which had been learned in a sudden all-or-none fashion. Distinguishing between a truly gradual learning process and the accumulation of numerous small insights is difficult, and it became common to assume that learning may be either gradual or sudden, depending on the situation and the nature of the participant. Harlow (1949) argued that learning to novel situations may be slow and continuous, but that sudden flashes of insight may occur when learning takes place in a familiar situation.

Rock (1957) was the first to move beyond the general concern that learning curves obscure sudden transitions in performance to an empirical methodology. He developed what became known as the drop-out procedure. He used a paired-associate methodology, in which participants had to learn a list of letter–number pairs. Study trials alternated with test trials, on which letters were presented and participants had to recall the corresponding numbers. After each test, Rock removed pairs that had not been answered correctly on that trial and replaced them with new pairs. Performance in this condition was compared to learning in a control condition, where participants were given the same unchanging list on multiple trials. The major finding was that there was no difference between the drop-out condition and the control condition; both groups mastered the list at the same rate. The fact that replacing old (but not yet mastered) pairs with new pairs did not impair performance led Rock to conclude that pairs were either completely learned or completely unlearned. Rock reasoned that if participants had been acquiring partial information about unrecalled pairs, performance should be impaired if such pairs were replaced by new ones. Because no impairment was found, he concluded that participants had not learned anything about a pair until the trial on which it could be recalled. That is, he argued for all-or-none learning: Rock believed that the fact that performance on a paired-associate list gradually improves across repeated study–test cycles obscures the fact that each pair is either entirely learned or unlearned, with the number of pairs moving from the unlearned to the learned state increasing across trials.

Rock (1957) acknowledged the fact that there was a potential flaw in his procedure. Some pairs are harder than other pairs. Presumably, the pairs that are not remembered on a particular trial would tend to be the most difficult pairs for that participant. In the drop-out condition, these particularly difficult pairs are being replaced on each trial by new pairs. Because the new pairs are randomly chosen to be added to the list, taken together they would be average in difficulty. Therefore, the drop-out group will end up with an easier list than the control group, which is stuck with the list that had been presented on the first trial. If this methodological flaw is serious, Rock would be mistaken in concluding that this methodology supports an all-or-none interpretation of learning. In later research, Steinfeld and Rock (1968) went to great lengths to argue that this artifact did not invalidate the drop-out procedure, but it is impossible to determine exactly how serious the problem is. Similar methodologies (e.g., that of Estes, 1960) run into analogous difficulties. In a review of this literature that was written just as research on this topic was winding down, Crowder (1976) noted this line of experimentation proved to be inconclusive but was valuable in shaking "the almost axiomatic belief of Ebbinghaus that repetition strengthens a unitary memory trace" (p. 273).

## 2.06.2 Basis of Repetition Effects

### 2.06.2.1 Theoretical Approaches

The philosopher Ward (1893) anticipated many of the later developments in theories of repetition effects. He distinguished between functional and atomistic accounts of repetition effects. Functional accounts would assume that repetition affects memory by altering a single location or representation. Every stimulus or experience has a particular trace in memory that is altered when it is encountered again. These alterations have the effect of making information about that stimulus easier to locate. Perhaps the most straightforward way of devising a functional account is to assume that memory traces differ along a single dimension, such as trace strength, so that this sort of approach is sometimes called strength theory. This approach is based on the assumption that repetition influences strength and that stronger traces are easier to remember than weaker traces. Ebbinghaus (1885/1964) seems to have implicitly adopted such a strength position, though his focus was on the strength of associations. Underwood (1969a) developed a somewhat more complex theory in which repetition-based strength was just one attribute that could vary among memory traces. On the other hand, atomistic theories maintain that two occurrences of an item lead to independent and distinct memory traces. Each of these traces would contain information about when it had been formed. Atomistic theories are more likely to be referred to now as multiple-trace theories. The German scientist Richard Semon, whose life and work in the early twentieth century has been described by Schacter (1982), was the first prominent multiple-trace theorist, although the model of memory proposed by the scientist Robert Hooke in 1682 can be interpreted in multiple-trace terms (Hintzman, 2003).

A fundamental difference between functional (strength) and atomistic (multiple-trace) accounts is in whether information about individual encounters with a repeated stimulus is maintained in memory. Functional accounts assume that repetition leads to the strengthening or alteration of a single location so that details about particular occurrences are lost. On the other hand, atomistic approaches claim that every occurrence leads to the formation of a separate memory trace, thereby maintaining the specificity of individual encounters. One class of experimental test of these approaches has focused on this fundamental difference by asking participants to make judgments about details of individual presentations of repeated events (see Hintzman, 2000, for a review of this approach). A pure strength theory would assume that participants would only be able to make a judgment about a stimulus by drawing an inference based on its strength; for example, a stronger stimulus can be assumed to have occurred more recently or more frequently. In contrast, multiple-trace accounts typically assume that each occurrence of a stimulus leads to the formation of a trace that records the context in which it was formed; therefore, participants would have access to detailed information about individual presentations of a repeated stimulus.

### 2.06.2.2 Judgments of Recency

To see how one might use memory judgments to discriminate between strength and multiple-trace approaches, a simplified account of a recency-judgment task (first developed for this purpose by

Morton, 1968) may be helpful. A participant may be given a list of digits and have to remember which of two test items had been presented later on the list. Imagine that a sequence like 7 5 2 9 1 6 5 8 4 3 is presented, and a participant is asked whether 4 or 5 had been presented later on the list. Note that 4 is the correct answer, but that the alternative 5 had been presented twice. According to strength theory, participants may tend to make the wrong choice because they may mistakenly attribute the heightened strength of the digit 5 to a recent presentation, as opposed to multiple presentations. In contrast, a multiple-trace account would claim that participants perform this task by retrieving occurrences of each digit and attempting to determine recency by examining details of each trace. Flexser and Bower (1974) carried out a systematic investigation of this task and concluded that multiple-trace approaches offered a better explanation of recency judgments. Hacker (1980) reached a similar conclusion by measuring response times in recency judgment.

### 2.06.2.3 Judgments of Frequency

There are several different ways in which one could test memory for frequency. One method would be a test of background frequency, which refers to the number of times that an event has occurred in one's lifetime. For example, Attneave (1953) studied the ability to make background-frequency judgments of letters of the English alphabet. These background-frequency judgments correlated .88 with the true frequency of occurrence in the English language, demonstrating that people are indeed sensitive to how often letters occur. Howes (1954) showed that people are sensitive to the background frequency of occurrence of words.

For the purpose of distinguishing between strength and multiple-trace accounts of repetition effects, tests of situational-frequency judgment are more useful. The prototypical way of studying situational-frequency memory is to present a list of words, which may be repeated varying numbers of times. At the time of test, list words are shown, and people have to indicate how often each was presented on the list. This sort of information is considered *situational* because participants do not have to remember how often items occurred throughout their whole lives but rather how often they occurred in a particular situation (i.e., on the laboratory list). People under typical testing circumstances are often very accurate, even when not expecting a test (Greene, 1984), leading some investigators to conclude that this sort of frequency information is encoded automatically (Hasher and Zacks, 1979, 1984). Although this claim of automatic encoding of frequency information is unlikely in the face of evidence that strategic factors may have a major impact on this task (Greene, 1984, 1986), all theoretical accounts of repetition effects must address why some information about frequency of occurrence is seemingly stored without intention. Strength and multiple-trace theories offer different explanations for how participants are able to estimate situational frequency. A strength theory would assume that participants access the memory trace corresponding to a test item and then assess the strength of that trace. The judgment of frequency is then based on the strength of that trace. For example, a very strong trace would be evidence that the corresponding item had occurred frequently on the list. On the other hand, a multiple-trace theory would assume that participants try to retrieve as many traces as possible of the test item. Those items that had occurred in the context of the list would then be counted, and a judgment of frequency would be based on that count (possibly after some adjustment to fit the expected ranges).

Results from the frequency-judgment literature tend to favor multiple-trace approaches. Although strength theory would have no problem in accounting for judgments of background frequency, it is not clear how this approach could explain people's ability to offer situational-frequency estimates that are independent of an item's overall background frequency. For example, strength theory would predict that background frequency should always contaminate situational frequency so that people should give higher situational judgments to items that occur more often in everyday life. In reality, situational judgments are largely independent of background frequency, and the slight effect obtained goes in the wrong direction: When situational frequency is held constant, participants give higher situational-frequency estimates to words of low background frequency than to words of high background frequency (Rao, 1983). Accuracy of frequency judgments is better for low-frequency words than for high-frequency words (Greene and Thapar, 1994).

Hintzman and Block (1971) carried out the classic demonstration of participants' ability to come up with specific situational frequencies. In this study, people were shown two lists of words, separated by a 5-minute interval. Each word occurred zero, two, or five times on each of the lists. These list frequencies were factorially crossed, so that the frequency of occurrence on one list would be completely uninformative as to the frequency of occurrence on the other list. After seeing the lists, participants were asked to estimate situational frequency of occurrence of each test word for each of the lists. The most important finding is that participants were very accurate on this task, so that their estimates of list frequency were chiefly determined by the true frequencies on the list being judged. Frequency of occurrence on the other list had only a small influence. The finding that people are able to make separate situational-frequency estimates for the same item in two lists is awkward for strength theory to explain: If these estimates were based solely on a unidimensional construct like strength, participants would not be able to make up these separate and largely independent estimates. On the other hand, multiple-trace theory would have no difficulty with this pattern, because these estimates would be based on a count of individual traces, each carrying information about the context in which it was created.

Greene (1990a, Experiment 5) carried out an even more extreme comparison of strength and multiple-trace approaches. Participants were given a list of words without being told what sort of test to expect. After the list had been presented, participants were shown a word accompanied by two other words. Participants had to choose which of the two accompanying words had been presented more frequently immediately before the single word. (For example, participants may have seen the word GOAT on the list three times. It may have occurred immediately after the word DIME two times and immediately after WALL once. DIME and WALL occurred elsewhere on the list, so that their total frequencies were equal. On the test, participants could be presented with GOAT, accompanied by DIME and WALL, and asked to pick the word that had preceded GOAT more often on the list. To be correct, they would have to pick DIME.) Participants had to answer this type of question for 36 words. Although this was a difficult test, all participants were able to perform above chance. Clearly, repetitions do more than merely strengthen a trace. Rather, every time a stimulus is presented, it leaves some sort of trace that records the context in which it had occurred.

### 2.06.2.4 Limitations on Multiple-Trace Accounts

Data from frequency-memory experiments provide strong evidence against the notion that repetition merely strengthens memories. It seems necessary to assume that repetition of stimuli leads to the storage of information that includes precise information about the time or context in which each presentation had occurred. However, this does not necessarily mean that repetition only leads to the formation of multiple traces. After all, it is possible that repetition has multiple effects. For example, it could lead both to multiple traces and to a strengthening of some representation in memory. There is some evidence that multiple-trace theories are not adequate for a complete account of the effects of repetition on memory.

#### *2.06.2.4.1 Effects of repetition on nonrepeated items*

A simple and pure multiple-trace account would claim that repeated presentations of an item should have the same effect on memory as presenting multiple once-presented items. For example, presenting 10 words three times each should lead to a functional list length of 30 items.

Let us consider a single once-presented item that may be presented in one of three conditions. In one condition, it is presented along with 10 once-presented words. In a second condition, it is presented along with 10 words, each presented three times, so that there would be a total of 31 presentations on the list. In a third condition, the item is presented along with 30 words presented once, so that there would again be a total of 31 presentations. We then administer a recognition test. We are interested only in recognition of the once-presented item. Recognition will certainly be influenced by the length of the list, but the critical issue would be if length should be defined in terms of total presentations (so that the second and third conditions are equivalent and should be more difficult than the first) or in terms of number of novel words presented (so that the first two conditions are equivalent, with the third being more difficult than the others). If one believes that repetitions act like presentations of new items by creating independent traces, then the second and third conditions should be equivalent. In reality, recognition is not influenced by total number of presentations but by the number of novel presentations so that the first and second conditions are both approximately equal and easier than the third (Ratcliff et al., 1990). The empirical picture is somewhat less clear-cut in free recall, but even here the effect of repeated presentations does not come close to matching the effect of added novel items (Tulving and Hastie, 1972; Ratcliff et al., 1990). Additional evidence that repetitions do not affect other items in the same way as a comparable number of distinct items was reported by Tussing and Greene (2001). This type of finding suggests that a simple application of the multiple-trace approach to repetition effects is inadequate.

#### 2.06.2.4.2 Superadditive effects of repetition on memory

Waugh (1963) observed that one can use simple laws of probability to derive expectations for memory of repeated items based on performance on once-presented items. Let us assume that two presentations of a repeated item lead to two completely independent memory traces. Recall or recognition of that item would be successful if the participant was able to retrieve one or both of these traces. If we define P as the probability of remembering a once-presented word, then the probability of remembering at least one occurrence of a repeated word should be $(2P - P^2)$ if the occurrences act like purely independent traces. This value can be considered an independence baseline, an indication of how high memory for repeated items should be if retention of separate occurrences was completely independent. Although not all studies find that recall of repeated stimuli significantly surpasses the independence baseline (e.g., Glanzer, 1969), there are numerous examples in the literature in which this has occurred (e.g., Johnston and Uhl, 1976; Goldman and Pellegrino, 1977; Overton and Adolphson, 1979). For reasons that are still unclear, the nature of the memory test seems critical, with performance on repeated items being more likely to exceed the independence baseline on recall tests than on recognition tests (Begg and Green, 1988).

At first glance, any reports of memory for repeated items exceeding the independence baseline might appear to be inconsistent with multiple-trace theories of repetition effects. After all, if multiple presentations of an item lead to the creation of separate traces, shouldn't retrieval of these traces operate just like retrieval of once-presented items? However, this argument is too simplistic. It overlooks the possibility that the memorability of an item might be affected by the fact that there were other occurrences of that item. For example, when a word is presented for a second time on a list, this repetition may remind the participant of the earlier occurrence, leading to further rehearsal and increased retrievability of the first presentation. (There is independent evidence that repeated presentations may lead to such a reminding process; see Hintzman and Block, 1973; Tzeng and Cotton, 1980; Winograd and Soloway, 1985). Thus, one cannot reject the multiple-trace approach simply because recall of repeated words may exceed the independence baseline. Rather, the multiple-trace approach suggests that the probability of recall should be predictable based on the probability of retrieval of the separate occurrences. To test the multiple-trace approach, some way must be found to allow for the experimenter to determine whether the participant is able to recall the first, second, or both occurrences of a repeated item.

Watkins and Kerkar (1985) devised such a study. The general procedure in their experiments was to ask participants to learn a list of once- and twice-presented words. Every presentation was tagged by an arbitrarily selected distinguishing attribute. Participants would be required to recall the words. Then they would be asked to remember the attributes. The goal was to determine whether memory for the items could be predicted on the basis of memory for the detailed attributes associated with particular presentations. Their first experiment can serve as an example of their approach. This experiment required recall of lists, each of which was composed of five words presented once and five words presented twice. The attribute manipulated here was the color of the presentations, with 10 different colors being used in printing the words. After the list was presented, participants were asked to recall the words. They recalled 0.18 of the once-presented words and 0.46 of the repeated words. (Note that recall of the repeated words greatly exceeded the independence baseline.) Then, Watkins and Kerkar attempted to determine whether recall of repeated items could be attributed to retrieval of particular occurrences. To determine how well particular occurrences could be retrieved, Watkins and Kerkar asked participants to remember the color that each word had been presented in, including noting two colors for repeated words. Participants were much less accurate in recalling the colors of repeated words than those of once-presented words. Thus, although people are able to recall repeated words better than would be expected based on recall of once-presented words, they actually remember the details of each occurrence of repeated words less well than they did for once-presented words. Watkins and Kerkar argued that there is a collective recollection of occurrences, which they called generic memory, that can benefit memory for repeated items separately from retrieval of the particular instances. Watkins and LeCompte (1991) presented further evidence that memory for repeated information can exceed recall of specific occurrences.

Hintzman (2004) had another demonstration that multiple-trace accounts cannot offer a complete account of repetition effects. He took what is commonly seen as the strongest evidence for these accounts, namely, participants' ability to estimate the frequency of occurrence of repeated items. He showed that these judgments of frequency were, in fact, more strongly related to presentation frequency than is performance on a recognition-memory test. Essentially, he dissociated memory for items from memory for how often they occur, although multiple-trace accounts attribute both to a common process (namely, the retrieval of separate occurrences). This finding is inconsistent with a pure strength-theory of repetition effects as well, because such a theory would also attribute the effects of repetition on recognition and frequency judgment to a single process, namely, the strengthening of a single trace for each stimulus. Fisher and Nelson (2006) carried out a conceptual replication of this finding by showing that the size of the repetition effect is numerically greater on frequency judgments than on recognition memory. These results suggest that any one-process account of repetition effects will be insufficient.

Overall, the literature suggests that repetition leads to the creation of separate memory traces, each of which contains information about the context in which it occurred. However, findings such as those of Watkins and Kerkar (1985) and Hintzman (2004) indicate that repetition has additional effects on memory beyond the creation of traces. These additional effects are at present still poorly understood. It is possible that a combination of strength and multiple-trace approaches will be necessary; formal models, such as that of Hintzman (1988), where repetitions create multiple traces that may be combined in various ways at the time of test, may eventually shed light on this. At present, however, we know that simple approaches are inadequate without yet being able to offer a successful complex explanation of repetition effects.

## 2.06.3 Spacing Effects in Memory

Ebbinghaus (1885/1964) noted that "with any considerable number of repetitions a suitable distribution of them over a space of time is decidedly more advantageous than the massing of them at a single time" (p. 89). This advantage of spaced practice over massed practice became one of the laws of memory formulated by Jost (1897). Spacing of repetitions became a widely used manipulation in studies of learning and memory (Bruce and Bahrick, 1992). Reviews of early research on this topic were carried out by Ruch (1928) and McGeoch and Irion (1952). However, given the wide variety of procedures used, many conflicting results were found, and researchers such as Underwood (1961) despaired of being able to demonstrate consistent and unambiguous benefits of repetition spacing. Melton (1967) rectified this by popularizing a straightforward way of demonstrating the beneficial effects of spacing. With this method, a list of words is presented one at a time to participants. Some of the words are presented two or more times, and the number of intervening items between occurrences of repeated items is carefully controlled. Some repeated words (massed words) are presented twice in a row, whereas other repeated words (spaced words) have one or more intervening words between occurrences. When participants are given a test on their memory for the words, a clear benefit for spaced repetitions over massed repetitions can be demonstrated. Recent reviews have established the advantage for spaced repetitions beyond serious question (Janiszewski et al., 2003; Cepeda et al., 2006). Although this conclusion had to be based on controlled laboratory experimentation, people evidently reach a similar conclusion based on their everyday experiences, as they may choose to devote spaced rehearsals to challenging material (Benjamin and Bird, 2006).

Several distinctions among commonly used terms may be useful. The advantage in memory for a repeated item over a once-presented item is a repetition effect. The advantage in memory for spaced items (repeated items that had their occurrences separated by intervening stimuli) over massed items (repeated items presented consecutively) is a spacing effect (sometimes called a distributed-practice effect). When one looks only at spaced items, any advantage in memory as the number of intervening stimuli is increased beyond one would be called a lag effect. Whether increases in spacing beyond one or two intervening items hold much benefit in remembering is less clear, although evidence increasingly suggests that this is the case (Kahana and Howard, 2005; Cepeda et al., 2006).

Spacing effects have received a large amount of attention from both theorists and experimenters. One reason why they are seen as particularly important is their wide generality. They may be found in a large number of subject populations, including nonhuman animals (e.g., Davis, 1970; Sunsay et al., 2004), human infants (Cornell, 1980), children (Toppino, 1991, 1993), and the elderly (Balota et al., 1989; Benjamin and Craik, 2001). Also, spacing effects have been found in educational settings for typical course materials, suggesting that the distribution of practice may be a useful way to improve retention without requiring additional time (Dempster, 1988). Bahrick (2005) has argued for the importance of viewing spacing effects from an educational perspective, and it is certainly true that spacing can influence long-term retention of material typically learned in school (e.g., Reder and Anderson, 1982; Rea and Modigliani, 1985; Bahrick and Phelps, 1987; Dempster, 1987; Rawson and Kintsch, 2005; Balch, 2006; Kerfoot et al., 2007).

A wide variety of theoretical explanations have been offered for spacing effects over the years. Although spacing effects may be found in many domains and using many tests, theorists have focused on the literature on human memory for word lists. At least with respect to this memory literature, two classes of explanation have been particularly influential, one emphasizing the importance of encoding and the other emphasizing the importance of retrieval.

### 2.06.3.1 Deficient-Processing Accounts

Some theorists (e.g., Hintzman, 1976; Zechmeister and Shaughnessy, 1980; Cuddy and Jacoby, 1982) have claimed that repetition spacing influences the processing of the second occurrence of repeated items. Typically, the claim is that massing repetitions leads to deficient processing of the second occurrence, relative to spaced repetitions. Hintzman et al. (1973) showed that repetition spacing seemed to influence memory for the details of the second occurrence, but not of the first occurrence, for repeated items.

This deficient processing of the second occurrence of repeated items may in part be due to involuntary processes akin to habituation; that is, we may not be able to keep ourselves from paying less attention to a stimulus that we had just encountered than one whose previous occurrences were more distant in time. However, it may well be that voluntary, strategic processes play a major role here. Zechmeister and Shaughnessy (1980) argued that, as participants are encoding a list of items, they are constantly deciding how to distribute their rehearsals between the current stimulus and the previous ones. The amount of rehearsal that a participant devotes to an item may be influenced by whether he or she feels that it is already well learned. There would be no point in devoting further rehearsal to an item that has already been mastered. Zechmeister and Shaughnessy found that participants overestimate the degree to which they will remember massed stimuli. They argued that this can lead to participants choosing to devote fewer rehearsals to such stimuli than to spaced items. Bahrick and Hall (2005) proposed a variant of this approach specifically aimed at retention over very long intervals.

There are many sources of evidence that converge on the claim that participants do not adequately encode the second presentation of massed items. When participants are asked to rehearse words aloud, they give fewer overt rehearsals to the second presentations of massed items than to the second presentations of spaced items (Rundus, 1971; Ciccone and Brelsford, 1974). When participants are allowed to pace themselves through a list presented on slides, they devote less exposure time to massed items than to spaced items (Shaughnessy et al., 1972; Zimmerman, 1975). Dilation of the pupil in the eye (a measure that is related to cognitive effort) is greater when participants are seeing spaced repetitions than when they are seeing massed repetitions (Magliero, 1983).

One straightforward test of this voluntary encoding account is to see whether spacing effects are eliminated when participants are not expecting a test on their memory for the material. That is, if participants are not deliberately rehearsing any items for a later test, then they would have no reason to treat spaced and massed items differently. The evidence here is strikingly mixed. Spacing effects are sometimes eliminated when lists are learned incidentally, but the details of the study and testing procedure are critical (e.g., Jensen and Freund, 1981; Greene, 1989, 1990b; Challis, 1993; Greene and Stillwell, 1995; Russo et al., 1998).

A second test for voluntary encoding-deficit accounts would involve an examination of the importance of experimental design. Repetition spacing could either be manipulated within lists (where participants are given a list containing both massed and spaced repetitions) or between lists (where participants receive a pure list, consisting either only of massed repetitions or spaced repetitions). The vast majority of studies in this area has used the within-list design. The magnitude of spacing effects in this design may be exaggerated because participants may rehearse spaced items during the presentation of massed items. If spacing effects result from an encoding deficit for massed items, you may see a reduction (and possibly a complete elimination) of spacing effects on between-list designs. Unfortunately, the literature on this point is very inconsistent, yielding all sorts of conflicting findings, and it is possible that the details of the design, study instructions, and memory test may be critical (Underwood, 1969b, 1970; Waugh, 1970; Greene, 1990b; Hall, 1992; Toppino and Schneider, 1999; Delaney and Knowles, 2005; Kahana and Howard, 2005).

Attempts to reduce spacing effects entirely to a voluntary deficient-encoding process, while inspiring some supportive results, have failed to present a consistent empirical picture. This has convinced some theorists that at least one other process is needed to explain spacing effects completely (Greene, 1989, 1990b; Braun and Rubin, 1998; Russo et al., 1998). In addition, it has been difficult to see how deficient-processing accounts developed to explain how participants remember intentionally learned lists of words can be easily expanded to cover the range of situations, materials, and subjects that can demonstrate advantages for spaced repetitions.

### 2.06.3.2 Encoding-Variability Accounts

Encoding-variability accounts of spacing effects make the assumption that the distribution of repetitions affects the likelihood that at least one of the occurrences will be successfully retrieved. Typically, it would be assumed that greater spacings would increase the probability that each presentation of a repeated stimulus would be encoded in a very different way, thereby making it more likely that a participant would be able to retrieve at least one of the occurrences.

One analogy that I have found useful in explaining this approach would be to liken this to the probability of being able to find a particularly important piece of paper. If you want to be sure that you will always be able to find the paper when you need it, you may try to have multiple copies of it. However, it would make no sense to place all of those copies in the same place. Rather, you should scatter the copies around at many different places. Although this would make it more difficult to locate all of the copies, it is assumed that you only need to locate one copy. Similarly, if every repetition of an item leads to a separate memory trace and if one only needs to retrieve one of the traces to remember the item, it would clearly be better if the separate traces are somehow distributed throughout memory.

This notion that repetition spacing influences encoding variability, which facilitates the probability of remembering at least one occurrence of an item, has been expressed in several forms. Landauer (1975) adopted this concept literally. He proposed a model in which memory traces are stored at random locations in a memory system. Traces for the occurrences of spaced items would tend to be stored farther apart than traces for the locations of massed items. If one assumes that only part of the memory space is searched during retrieval, then there would be an advantage for the spaced items.

An alternative way of envisioning encoding variability is with respect to the information with which items may become associated. For example, Glenberg (1979) suggested that interitem associations are critical on many memory tasks, particularly free recall. When two occurrences of a repeated item are presented in massed fashion, the two traces tend to become associated with the same items. In contrast, when the two occurrences are spaced apart, the resultant traces are associated with different items. Glenberg argued that the probability of retrieving at least one occurrence of a repeated item increases with the number of different associations that had been formed. Raaijmakers (2003) showed how this approach can be incorporated into a broader mathematical model of memory.

Gartman and Johnson (1972) pointed out that words can be interpreted in slightly different ways. This is clearest in the case of homographs like IRON or TOAST, where the same pronunciation and spelling pattern would be associated with seemingly unrelated meanings. Even when a word is perceived as having only one meaning, there may be slightly different connotations that could come to mind; depending on the context, the word PIANO could be encoded primarily as a musical instrument or as a heavy object. Gartman and Johnson suggested that repetition spacing influences the probability that each occurrence of a repeated word would receive a somewhat different interpretation and that this variability in meaning would increase the probability that at least one occurrence could be retrieved. Indeed, Gartman and Johnson reported that recall of homographic words does not show a spacing effect, presumably because different meanings may be invoked even at short spacings.

The notion that some variant of encoding variability underlies the spacing effect has been popular among theorists even in the absence of direct evidence that encoding variability benefits memory at all. Some interpretations of this approach would claim that encoding variability should influence memory for once-presented items; that is, the probability of retrieving at least one of two unrelated, once-presented words should increase as a function of the spacing between them. However, this prediction has been falsified, as spacing seems to have no effect on recall of once-presented words (Ross and Landauer, 1978). Also, direct attempts at controlling the presentation context of repeated items have found that encoding variability typically leads to a decrease in memory performance (Bellezza and Young, 1989; Greene and Stillwell, 1995; Verkoeijen et al., 2004).

Even in the absence of direct empirical support, the concept of encoding variability as at least one component in a theory of spacing effects continues to be popular. One reason is that some variants of this approach can offer a straightforward explanation for an otherwise puzzling finding, namely, the fact that memory for massed items may be superior to memory for spaced items if the test is administered very briefly after presentation. Glenberg and Lehman (1980) presented a particularly compelling empirical picture and proposed a proportionality rule that states that "when the retention interval is short relative to the spacing of the repetitions, performance is negatively correlated with repetition spacing; when the retention interval is long relative to the spacing intervals, performance is positively correlated with spacings of the repetitions" (p. 528). Glenberg and Lehman demonstrated this proportionality rule in free recall, with similar findings being obtained in other memory tasks (Peterson et al., 1963; Glenberg, 1976; see Cepeda et al., 2006, for a quantitative review of this pattern). This advantage for massed items after short retention intervals suggests that it is better to have two occurrences presented in contexts very similar to the testing context rather than to have only one. Although this finding of a massed-item advantage after brief retention intervals is only indirect support for encoding-variability approaches, it has been difficult to develop alternative explanations for this finding.

### 2.06.3.3 Multiprocess Accounts

Theorists have increasingly abandoned the attempt to reduce spacing effects to a single factor and have instead turned to multiprocess explanations, where spacing influences several aspects of memory (e.g., Glenberg, 1979; Greene, 1989, 1990b; Braun and Rubin, 1998; Russo et al., 1998). For example, Greene (1989, 1990b) has argued that deficient processing of the second occurrence of massed items largely explains spacing effects on tests where cues are provided to participants; such cued-memory tests would include recognition or frequency judgment. On the other hand, free recall is an uncued test because no retrieval cues are explicitly given to participants; some variants of the encoding-variability approach offer a better explanation of spacing effects on this test. This sort of explanation reflects the fact that one can find manipulations that have different effects on the spacing effect found in free recall or cued tests (e.g., Glenberg and Smith, 1981; Greene, 1989; Kahana and Greene, 1993). Still, the details of multiprocess approaches have yet to be worked out satisfactorily, as none has been able to offer a comprehensive account of the literature.

The popularity of multiprocess accounts largely reflects the fact that single-process explanations to date have necessarily left large portions of the literature unexplained. One limitation even for multiprocess accounts is that they have largely been applied only to results from memory experiments using adult human participants. In principle a factor like encoding variability can be applied to nonhuman animals (and indeed the concept owes much to the stimulus-sampling theory developed by Estes, 1955, to explain findings in the animal-learning literature). However, there has been little effort paid to seeing whether one can take theories of the spacing effect developed in the field of human memory and apply them in a fruitful way to other domains, such as animal conditioning or human skill acquisition. Until theorists in this area feel compelled to account for a wider range of empirical data, it will be impossible to claim that we have an adequate explanation of spacing effects.

## 2.06.4 When Repetition Does Not Improve Learning

Because repetition so clearly is an important factor in learning, it is understandable that we have focused on cases where there is a positive relationship. However, sometimes repetition is ineffective in promoting learning. The classic demonstration of this is the poor memory Americans have for the characteristics of the penny. Although Americans have seen this coin countless numbers of times, Nickerson and Adams (1979) showed that they can have quite poor recollection for its details. They may not be able to recall what words are on the penny or where the date is located. After all, people presumably use the color (brown) of the penny to distinguish it from other coins, so they do not need to attend to its other features. If people are given 15 s to study an unfamiliar coin (the mercury dime, which was in use from 1916 to 1945), they remember its details better than they remember those of the penny (Marmie and Healy, 2004). This illustrates the point that repetition in the absence of attention is strikingly ineffective in promoting learning.

The ineffectiveness of repetition in the absence of attention is also illustrated by the fate of items memorized through maintenance, or rote, rehearsal (e.g., Glenberg et al., 1977; Rundus, 1977). In these experiments, participants have to repeat items aloud over and over. When they are given an unexpected memory test on the rehearsed words, there is at best a very weak relationship between the number of overt rehearsals devoted to an item and later memory (Greene, 1987). Simply repeating an item over and over has little benefit for memory in the absence of attention or more elaborative processing of the material.

Repetition may impair learning if memory is tested for only one occurrence. If an item has been presented in several contexts, it may become difficult to retrieve the occurrence that is being tested. An early demonstration of this (although initially interpreted in a somewhat different way) was the negative part-whole transfer effect reported by Tulving (1966). In this procedure, a control group and an experimental group first learn a list of 18 words and then learn a list of 36 words. In the control group, the two lists are unrelated. In the experimental group, the earlier list of 18 words was then included in the list of 36 words. If repetition inevitably leads to improved memory, then the experimental group should have an advantage over the control group. However, Tulving found an effect in the opposite direction, with the control group outperforming the experimental group. A critical issue here is that there is increased opportunity for confusion between the lists when they overlap. Because participants in the experimental group do not necessarily realize that the 18-word list is entirely contained in the 36-word list, they may have difficulty when they try to restrict their recall to the second list (Sternberg and Bower, 1974). In a similar vein, preexposing some items on a list may impair recognition memory for them, at least in part because participants have difficulty knowing whether the familiarity of the items is due to the preexposure or to presentation on the list (Greene, 1999). Repetition may impair memory when the critical task requires participants to disregard some occurrences of a repeated stimulus.

A striking case where repetition may lessen memory is in serial (ordered) recall of short lists. When participants have to recall short lists of digits or letters, memory is impaired if one item is repeated on the list. This phenomenon, known as the Ranschburg effect, was introduced into the modern psychological literature by Crowder and Melton (1965). Crowder (1968) carried out a systematic manipulation of all possible locations of repeated items. He found that, when the two occurrences of a repeated item occupy immediately adjacent serial positions, recall of the series is enhanced. However, when the two occurrences are spaced apart, recall is impaired, with the greatest decrement occurring when there are two intervening items. The impairment is very localized, with only recall of the second occurrence being negatively affected. The Ranschburg effect is also rather delicate, leading Murdock (1974) to label it the "Ranschburg (non) Effect" (p. 297). Later research has shed light on the boundary conditions of this phenomenon, as changes in the nature of either the instructions given or the nature of the test can eliminate the effect (Greene, 1991). This effect seems to occur because recall of the first occurrence of the repeated item may inhibit output of the second occurrence (Greene, 2001).

## 2.06.5 Conclusion

Much of the literature on repetition and spacing effects has been carried out in the empirically minded spirit of functionalist psychology, so it is perhaps appropriate that strong conclusions can be drawn about empirical patterns but only tentative ones about theoretical implications. First, it is clear that the development of learning as a function of repetition is established beyond question in the research literature. Second, performance improves as a smooth, negatively accelerated function of frequency of study, though this does not necessarily imply that all aspects of learning take place gradually and continuously. Third, as a result of repeated practice, we form memories that contain the details of each occurrence and that we can access individually. Fourth, the effects of repetition cannot be reduced merely to retention of these separate episodes, as we seem to form generic memories that capture what these individual presentations have in common. Fifth, the effects of repeated study are enhanced if the study episodes are spaced apart in time. Sixth, these spacing effects are most likely due to a combination of factors, such as deficient processing of massed repetitions and superior retrieval for spaced repetitions. Seventh, repetitions may not always enhance memory, particularly when little attention is paid to a stimulus or when accurate remembering requires access to one particular occurrence of an event.

Although the theoretical implications of repetition and spacing effects remain to be worked out, their practical importance is beyond question (Dempster, 1988; Bahrick, 2005). Admittedly, much of the literature on these topics has followed standard laboratory methods employing word lists and college-student participants, thereby exhibiting the strenuous task reductionism typical of memory research (Crowder, 1985). Still, a meta-analysis carried out by Cepeda et al. (2006) suggested that repetition and spacing effects may influence learning for a wide variety of materials and over long retention intervals. As a wider range of procedures and perspectives are directed at these issues, we may hope to achieve greater theoretical progress in understanding these central manipulations for learning and memory.

# 2.07 Coding Processes

**R. R. Hunt**, University of Texas at San Antonio, San Antonio, TX, USA

The questions of what people know and how they come to know it have been a topic of scholarly inquiry forever. At the level of individual knowledge, all that any of us know is represented in memory, and memory representations are just that, representations. Whatever the event may have been, the processes of perception and comprehension yielded a psychological experience, and it is that experience of the event that becomes the memory. In this sense, the memory is a code that represents the original event, but that code is all the knowledge we as individuals have of the event. With these premises, the importance of studying coding processes in memory is obvious. Answers to the questions of what the nature of the code is and how the code is formed are answers to the venerable questions concerning the nature of knowledge.

Widespread interest in issues of coding only appeared with the cognitive renaissance of the 1950s and 1960s. The concept of coding is rarely found in psychology texts prior to 1950, but by 1972, coding was said to be truly central to modern theories of memory (Bower, 1972). In this chapter, we examine the origins of the concept, which reveal the theoretical function served by coding and the reason for its centrality in modern theory. An overview of the methods used to study coding is provided, as well as some description of factors known to affect the coding process. Finally, two broad metaphors used to describe the memory code will be discussed, along with several specific ideas that represent each of the metaphors. The reader is warned of a major caveat about the discussion, namely, that the effects of variables associated with the memory test will not be described, nor will the theoretical coaction of coding and retrieval be part of the discussion. One must keep in mind that many of the effects described in this chapter are relative to the conditions of retrieval (*See* Chapter 2.16).

## 2.07.1 The Coding Process

The process of coding is an integral component of many natural and artificial phenomena. Generally, coding can be defined as the transformation of messages, signals, or states from one representational form to another. With this definition, the presence of coding in activities from espionage to metabolism becomes fairly obvious. One might reasonably wonder, however, why phenomena require the apparently superfluous process of changing forms of representation. That is, if the representations denote the same thing, why insert a process to change the form of the representation? Leaving aside esoteric forms of coding for purposes of deception and secrecy, the principal need for coding processes seems to be that the end user cannot work with the original form of the representation, and coding is necessary to transform the original representation into a useable form. Relevant examples here range from the various transformations of energy after it contacts sensory receptors and before it is "used" in the brain to the necessity of transforming a visual experience to linguistic code to inform someone of the experience.

### 2.07.1.1 Coding from the Computer Model

The meteoric rise in the use of coding as a psychological concept is largely because of the developments in information science and computer technology between 1948 and 1960. Shannon (1948) published a mathematical theory of an abstract communication system, an important component of which was the bits of information transmitted by the system. The theory was written in a general mathematical form such that information could take any conceivable form and be transmitted over any kind of channel. Some psychologists soon realized that the idea could be applied to human information transmission (e.g., Miller, 1956).

Dovetailing with the abstract notion of information transmission was the more concrete model of the computer as an information processor. By 1958, Newell et al. advocated that the mind be described as an information processing system modeled on the workings of computing machinery. Early in the history of computer science, the computer was conceptualized as a general-purpose symbol manipulator, and the insight that the mind could be construed as a symbol-manipulating system (e.g., Newell and Simon, 1972) provided the foundation for the use of a computer model in theoretical psychology. With this foundation in place, the analogy of specific computer functions such as buffers, stores, and retrieval to human information processing, especially memory, was recognized quickly. Among these specific functions was the process of coding.

For the computer, the fundamental process of coding is the transformation of the external input into the representation defined by the machine language. The analogy here to energy transformation in human sensation and perception is patent. For example, the effective energy contacting the visual receptors is electromagnetic energy, but the human brain cannot use this form of energy. The first coding in vision is the transformation from electromagnetic energy to chemical energy at the level of the rods and cones. In turn, the chemical energy is transformed to electrical energy for transmission through the optic nerve for use in the cortex. Less concrete but equally compelling analogies were drawn to cognitive descriptions of learning and memory. By the 1950s, verbal learning researchers knew that some nonsense syllables were more nonsensical than others. Syllables such as FDR, KLM, and CBS obviously were treated differently than JQN, XFV, PGW. The assumption that the nominal stimulus was the functional stimulus had given way to the admission of a proximal stimulus. With that concession, behavioral theory now needed a psychological process of coding to account for the transformation from nominal to proximal stimulus.

### 2.07.1.2 The Function of a Code in Psychological Theory

Codes serve as representations for some other object or event. Codes carry information, perhaps not in the precise form specified by Shannon's (1948) theory, but information in the sense of symbolically representing something else. For our purposes, codes are the psychological manifestation of prior experience. The experience can be in the immediate past, in which case we call the code a perception. As the past grows more distant, we refer to the code as a memory. All psychologists agree that behavior and thought are influenced by prior experience, and because the code is the representation of that experience, understanding codes and the processes that produce them looms large for cognitive theorists.

Codes serve another function for psychological theory that is rarely discussed. That is, codes dispel the mystery of action at a distance. To say that current thought and behavior are caused by prior experience begs the question of how something in the past can cause something to happen in the present. The stock answer to this question is that experience changes the individual, but the customized answer includes the form of this change. Different theories propose different kinds of codes, but in all cases, the stored code solves the problem posed by causal action at a temporal distance. The original event does not cause current thought and behavior but, rather, the coded version of that event, which is accessible at the time of the behavior or thought. Not everyone agrees that this use of the code to bridge the temporal gap is a good thing. Watkins (2002), for example, noted that memory has been reified by assuming that a residual of the original experience is maintained over time and that this characterization is unrealistic. Nonetheless, the search for the contents of the memory code has been quite active.

## 2.07.2 Breaking the Code

On the assumption that the memory code is the proximate cause of the past's influence on current thought and behavior, the question of what is encoded from a given experience has become a popular research agenda in learning and memory. As with many other concepts in science, the memory code cannot be observed directly. Consequently, a variety of methodologies have been developed to infer the nature of the representation of a particular experience. Each method comes with assumptions that allow the inference to follow, and thus it is important to explicitly acknowledge these assumptions. The following discussion is intended to update an earlier review by Tulving and Bower (1974).

### 2.07.2.1 Transfer Paradigms

The transfer paradigm is a venerable method for studying the effect of prior experience and inferring the nature of the code for that experience. The use of transfer rests on the assumption that the effect of prior experience is proportional to the similarity of the prior experience and the current task. Perhaps the first use of the transfer paradigm to measure encoding and storage was Ebbinghaus's (1964) savings method. The savings score is a ratio of the number of trials required for original criterion learning to the number of trials to reach the criterion on a subsequent attempt. This ratio is assumed to index the stored memory from initial learning in that memory, for the original experience obviates the need for new learning on the second experience. Thus, the goal of the savings method is to determine the amount of the original experience that is available at a later time.

In contrast, contemporary use of the transfer paradigm has focused on the qualitative characteristics of encoding, as attested to by the wide acceptance of the principle of transfer-appropriate processing (Morris et al., 1977). The reasoning is straightforward. If performance on the criterion test varies as a function of the similarity between the test and the prior experience, one infers that the code includes values from that dimension of similarity. As an example, consider an experiment by Jacoby (1983). Subjects studied words for memory either by reading the words or by generating the words from a fragment. Half of the subjects were given a test of recognition memory, and half were given a test of perceptual identification. Perceptual identification requires that words be read under conditions of severe visual degradation. Prior experience with the words facilitates perceptual identification accuracy, but as Jacoby (1983) showed, only if that experience is reading. Generation of the study words produced no positive transfer to perceptual identification, although generation yielded much higher recognition memory than reading. Jacoby's demonstration of differential transfer from reading and generating at study illustrates the use of transfer paradigm to infer the content of the code.

Negative transfer also can be used to infer the contents of the code. An early example is the release from proactive inhibition (PI) paradigm (Wickens et al., 1963; Wickens, 1970). The basic paradigm involved presentation of short lists of words for immediate recall. The lists were similar on some dimension; for example, all words could be exemplars of the same category. As can be seen in **Figure 1**, performance declined quickly over the first two to three study-test trials. The decline was identified as PI, the cause of which is competition among the codes. The basis of the competition is assumed to be similarity of the codes. Thus, the presence of proactive interference provides a basis for inferring that the code contains information corresponding to the dimension of similarity. The inference is validated by eliminating the similarity on the final list in the series and observing better performance than on the previous trial, the so-called release from PI, which is depicted in **Figure 1** in the shift condition.

Straightforward inferences about the code from the release from PI paradigm are complicated by data reported by Gardiner et al. (1972). They presented different instances from the same category over three study-test trials and observed PI buildup over the trials, as would be expected. On the fourth trial, subjects continued to see instances from the same category but under different conditions. The standard control condition received no special instructions and continued to show PI on the last trial. In another condition, subjects were informed prior to studying the list that the instances were all exemplars of a subcategory (e.g., water birds). Memory improved with these instructions, as would be expected if the dimension of encoding shifts from that of the first three trials. The critical condition is the third condition, in which the special instructions concerning the material were given after study and prior to recall. These subjects also evidenced release from PI, results consistent with an alternative view of the cause of PI buildup and release. That is, PI reflects the increasing ineffectiveness of a cue as more items are subsumed by that cue, all in accord with the principle of cue overload (Watkins and Watkins, 1975). Release from PI then is caused by the availability of an appropriate new cue. Note that in this interpretation, negative transfer in the release from PI paradigm is not informative about coding processes.

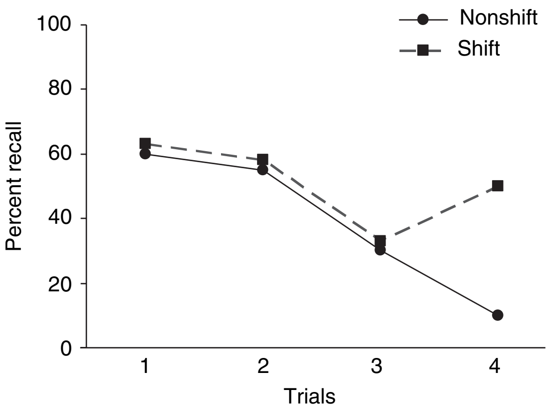

**Figure 1** Memory for material from the same category over the first three trials illustrates proactive interference. The shift condition sees material from a different category on the fourth trial, resulting in release from proactive interference. Adapted from Wickens DD, Born DG, and Allen CK (1963) Proactive inhibition and item similarity in short-term memory. *Journal of Verbal Learning and Verbal Behavior* 2: 440–445.

### 2.07.2.2 Retrieval Cuing

The relative effectiveness of retrieval cues frequently is used to make inferences about the nature of a code. The reasoning is the same as that underlying the use of the transfer paradigm, except that here the appeal is to the principle of encoding specificity (Thomson and Tulving, 1970; Tulving and Thomson, 1973). Encoding specificity states that as a necessary condition for successful memory, the cue must have been present at encoding. If a cue does lead to correct memory, one can assume, based on encoding specificity, that information shared by the cue and its target was encoded originally.

As an example, Nelson et al. (1974) used this logic to investigate semantic and phonetic coding of words. Word lists were studied for memory and then cued for recall by either rhymes or synonyms of the studied words. Half of the subjects who received rhyme cues had studied the words in the presence of the rhymes, and half had studied the words alone. Likewise, half of the subjects receiving synonym cues had studied the words in the presence of the synonyms, and half had studied the words alone. The results showed that recall to a rhyme cue was equally good for words studied in the presence of the rhyme and for words studied alone. Recall in the presence of the synonym cues was much better for the group that had seen the synonym cues at study than for the group that studied the items alone. From these results, Nelson et al. concluded that phonetic information about a word is encoded even when the word is not modified by a study context. Semantic information corresponding to the synonym is not encoded unless the study context biases that coding process. The results and interpretation make perfect sense, in that words have few alternative sound patterns, whereas the number of nuanced meanings of a word can be large.

The cuing methodology has been used extensively to study the interface between comprehension and memory. For example, Anderson et al. (1976) asked people to study sentences that contained a general noun (e.g., "The woman was outstanding in the theatre"). Later they were given a cued recall test and instructed to recall the last word of the studied sentences. The cue could be the general subject noun (e.g., 'woman') or a specific term that previous norming showed represented the comprehended instantiation of the general noun (e.g., 'actress'). Recall was better for the last word of the sentences when the cue was the particular instantiation rather than the general term that had appeared in the sentence. Using the logic of encoding specificity, Anderson et al. concluded that general terms are comprehended and encoded as particular instantiations rather than as abstract core meaning. This example nicely illustrates the relationship between questions about the memory code and the broad issue of the nature of knowledge. The conclusion from the Anderson et al. study suggests that the meaning of abstract nouns is represented by specific instances of those nouns rather than some abstract meaning that goes beyond the instances.

Using retrieval cues to infer the coded experience is limited to the logic of encoding specificity, namely, the presence of a cue at encoding is a necessary condition of cue effectiveness, not a sufficient condition. The implication of this limitation is that one cannot infer the nature of coding from the absence of a particular cue effect. For example, the declining performance over trials in a buildup of PI paradigm cannot be used to infer a corresponding decline in the encoding of the dimension of similarity across the trials, indeed, quite the opposite inference usually is made. In short, memory performance is affected by factors other than the presence of an appropriate cue. What can be done with some confidence is to infer that particular information was encoded when cue information facilitates memory. Nairne (2002) offers an interesting discussion of the limitations of cue effectiveness as a basis for inferences concerning the encoded trace.

### 2.07.2.3 Materials Effects

The existence of different kinds of codes also has been inferred from differential effects of material on memory. Perhaps the seminal modern instance of this approach involves comparing memory for a list of pictures versus memory for a list of words that are the names of the pictures. Other things being equal, the pictures will be better remembered than the words (e.g., Paivio, 1971). Paivio and others have interpreted these data as consistent with the idea that at least two classes of codes exist in memory, verbal and imaginal (Paivio, 1995). Pictures can be coded in both forms, whereas words are most likely to be coded in the verbal form, and the multiple forms of code for the pictures confer an advantage in memory performance. Alternatively, Nelson et al. (1976) suggested that the picture superiority effect is not a result of qualitative differences in the code but, rather, to a quantitative difference in the distinctiveness of the sensory code for pictures. Nelson et al. (1977), however, did argue for a difference in the necessity of semantic coding for words and pictures in that pictures require semantic coding prior to phonetic coding, whereas the semantic coding of words is not necessary for phonetic coding. Again, the nature of coding was inferred from the differences in performances for the classes of materials.

Variations in the memory code accompanying manipulations of materials have been used to explain other memory effects, including differences in memory as a function of clinical diagnoses. For example, clinically depressed patients tend to remember negatively valenced words better than positive words, whereas nondepressed people do not show this effect (e.g., Bradley and Mathews, 1983; McDowell, 1984). This effect is eliminated in tests that do not request intentional memory (e.g., Denny and Hunt, 1992; Watkins et al., 1992). Because prior research has shown that meaningfully elaborated codes are better remembered than less elaborated codes on intentional memory tests, these data have led to the conclusion that the encoded representation of negative experiences is more elaborate than the representation for positive experiences in depressed patients. The difference in memory for different types of materials as a function of clinical diagnosis is explained by inferring quantitative differences in the codes. Depressed patients have more elaborate codes representing negative events than do nondepressed people.

A potential problem associated with inferring the type of code from materials effects concerns the decision axis for postulating a class of codes. One would not postulate a qualitatively different class of codes for every dimension along which people can discriminate; otherwise, the kinds of codes would prove practically infinite. What was needed in 1974 (Tulving and Bower) is still not entirely obvious today, and that is a clear set of rules specifying when a differential effect of materials is evidence for different kinds of code. Moreover, care must be exercised to avoid the assumption that labeling material effects as different memory codes has explained anything. Discussing this issue, Tulving and Bower (1974) said, "it is of interest to note that it has not yet been made clear by anyone how the task of explaining memory phenomena is materially aided by the hypothesized existence of different memory stores" (p. 273).

### 2.07.2.4 Decision Time

Another method used to infer the nature of encoded material is the time taken to respond to queries about the prior experience. The assumption underlying this technique is that response time will be faster if the code contains the information requested by the query. The more inferences from the code required to answer the query, the longer the time will be. A good example of this approach comes from Posner's (1969) research. Subjects were shown two letters in succession, the first of which is the target letter, and the second is the probe. A decision is made as quickly as possible as to whether the probe matches the first target. Various matching rules can be used to instruct the subjects. Suppose the rule is that the two letters have the same name, and the target letter is a capitalized 'A.' The probe can either be a matching capitalized 'A' or one of two nonmatching probes, a lowercase 'a' or a different letter. When 'A' is followed by 'A,' the positive decision is made more quickly than when 'A' is followed by 'a.' The difference in decision latency decreases as the interval between the two letters increases. Assuming that the target letter is held in memory until the match is completed, Posner and his colleagues interpreted this pattern to indicate that the initial representation is visual, thus producing faster matches for visually identical patterns. As the encoding process continues, the visual code is supplemented by a phonetic code, leading to faster responding to the 'A-a' pair at longer interletter intervals.

Reaction time has been used extensively to infer imaginal coding in decision-making tasks (e.g., Brooks, 1967; Cooper and Shepard, 1973; Farah, 1985). As an example, Cave and Kosslyn (1989) showed stimuli consisting of two superimposed rectangles, one drawn in light lines and the other in dark lines. One of the rectangles was drawn vertically, and the other was superimposed diagonally over the first rectangle. The same two objects were used on each trial, although the relative length of the lines in the objects differed from trial to trial. The task was to decide whether the sides of the object drawn in light lines were equal to those of the object drawn in light lines on the previous trial. The principal manipulation was the subject's expectations of the size of the object to be judged and of which of the two rectangles would be drawn in light lines. The manipulation was performed by instructing the subjects that most of the time the same rectangle would be judged on the next trial and that the object would be of the same size as on the preceding trial. These instructions conformed to 75% of the trials. Thus, on 25% of the trials, the size, the object, or both were different from the preceding trial. The time to correctly decide about the targeted rectangle was affected by both expectations. Responses to unexpected objects as well as to unexpected sizes were slower. Considering just the expected object trials, response time increased linearly with the unexpected change in object size. These data indicate that the stimulus from the preceding trial affects performance on the current trial and that this effect systematically varies with the relative size of the stimuli. A reasonable interpretation is that the encoded representation from the previous trial affects performance on the current trial and that representation contains specific size information. That is, the representation is a visual image.

Although studies such as those of Posner and Cave and Kosslyn illustrate that reasonable inferences can be drawn about the nature of the code from decision latencies, one must be aware of the effect of speed–accuracy trade-offs when using latency data. Latencies in most tasks will vary as a function of the emphasis on speed or accuracy, and that trade-off can change the results of an experiment dramatically. Such changes could result in different conclusions about the nature of the code, when in fact the difference is essentially a strategy shift. Moreover, the use of decision latency tends to be limited to material on which accuracy of performance will be near perfect. Thus, the method is not appropriate for new learning or large amounts of to-be-remembered material.

### 2.07.2.5 False Memories

Memory is not always veridical to the past. People do remember things that did not occur, or at least did not occur as they are remembered. This fact has long been known and has been used as a tool to infer the qualitative nature of the original code. The assumption underlying this inference is that healthy memory is not capricious; rather, errors of commission in memory reflect the content of the coded representation of the probed experience. For example, early studies of false responding in recognition memory showed that synonyms and antonyms of studied words were seductive lures (Anisfeld and Knapp, 1968; Fillenbaum, 1969). The high false alarm rates for these distracters were taken to indicate that the coded representation of the study items was dominated by meaning. The same conclusion was drawn from studies that showed false recognition for sentences that expressed the same idea as studied sentences but were otherwise syntactically different from the studied sentences (e.g., Bransford and Franks, 1971). The coded representation of sentential content seemed to be the abstracted meaning of the sentence.

An important line of research that uses false memory to infer the nature of the code was initiated by studies of inferential processing in comprehension. The idea is that inferences are an integral aspect of normal comprehension and that the information implied in the inference would be part of the coded memory. For example, Johnson et al. (1973) reported a study in which subjects were asked to read several short descriptive stories consisting of two or three sentences. One story was: "John was fixing the birdhouse. He was pounding the nail when his father came out to watch him and help him do the work." The control condition saw the same story except 'pounding the nail' was replaced with 'looking for the nail.' In addition to the actual sentences presented in the story, the recognition test included inference sentences such as: "John was using the hammer to fix the birdhouse when his father came out to watch him and help him do the work." The test instructions were to recognize the sentences that were exactly the same as those presented at study. The group that received the study sentences that invited the tested inferences recognized approximately the same percentage of inference test items and studied sentences. Subjects given the control study sentences made few false alarms to the inference test items. These data are important indications that the coded representation of the prior experience includes the information from the inference, which apparently is indistinguishable from the presented material.

In a similar vein, Deese (1959) reported that people will intrude associatively related words in recall after studying a list of words that are all associated with unpresented words. For example, the study words might include 'sharp,' 'thread,' 'sew,' and 'pin,' but not the word 'needle.' On later recall tests, the probability of recall for the nonpresented associate often is equivalent to the recall of study items. Roediger and McDermott (1995) resuscitated this paradigm, and extensive research has been conducted using the paradigm to study false memories (see Roediger and McDermott, 2000a,b, for a review). A favored interpretation of the intrusions and false alarms that occur in this paradigm is that the critical item comes to mind during study and thus is encoded in the study episode. (*See* Chapter 2.14 for a thorough discussion of false memory.)

Past research has interpreted false memory to be the result of encoding either a general dimension or specific content such as an inference. This interpretation seems reasonable and, additionally, renders false memory less mysterious and capricious in that false memory very often is the product of the normal processes of comprehension of targeted material. One issue concerning inferences from false memory is whether the false memories result from encoding processes or occur at retrieval. For example, false memory of inferences from the Deese/Roediger/McDermott paradigm may be the result of the critical item coming to mind in the presence of targets in recall or recognition. That is, the inference occurs during the test rather than at study. Although this possibility cannot be ruled out entirely, two findings mitigate against an exclusive retrieval interpretation. One is that Roediger et al. (2001) report that false recall is negatively related to correct recall. If the false item were coming to mind as the result of recalling its associates, one would expect a positive relationship between these factors. The second finding is that warnings about false recall are more effective if issued prior to study rather than following study (McDermott and Roediger, 1998; Gallo et al., 2001; Neuschatz et al., 2003; but see McCabe and Smith, 2002, for contrary data).

### 2.07.2.6 Orienting Tasks

Orienting tasks, usually judgments that the subject makes concerning the to-be-remembered material, can have a powerful influence on recall and recognition (e.g., Hyde and Jenkins, 1969). With Craik and Lockhart's (1972) levels of processing came a wave of experiments manipulating orienting tasks, all of which assumed that these tasks exert their effect at least in part through specific encoding of a dimension of the material. The logic here is straightforward. If the memory trace is a by-product of perception and comprehension, and the focus of perception and comprehension can be controlled by the orienting instructions, then the qualitative content of the trace can be identified with the dimension specified by the orienting task. For example, Jacoby and Goolkasian (1973) gave subjects lists of word pairs, each of which was related either categorically or acoustically. The orienting task was to rate the degree of the relationship within the pairs. The subjects rating categorical relations recalled more of the items than the subjects who rated the acoustic relationship. The difference in memory is attributed to the nature of the trace (i.e., representations of categorical meaning lead to better memory than sound patterns).

Orienting tasks often are used in conjunction with other methods to infer the nature of the code. For example, Chan et al. (2005) combined the use of orienting tasks and the Deese false memory paradigm to examine the effect of associative versus phonological encoding on false memory. Study lists were either semantically or phonologically related words, and in both cases all the study words were related to a word that was not presented (e.g., 'bed,' 'rest,' 'awake,' or 'sweep,' 'steep,' and 'sleet' are all related to 'sleep,' which itself was not presented). The orienting instructions were to concentrate on the relationship among the words' meanings or among the sound patterns of the words. These instructions were orthogonal to the type of relationship among the words in the lists. The results, which are shown in **Figure 2**, showed an impressive crossover interaction between type of list and orienting task on false memory for the nonpresented items. Considerably more false memory occurred when the orienting task was congruent with the dimension of similarity in the study list. A reasonable interpretation of these data is that the orienting task controls the dimension of encoding and that the critical associate will only come to mind if the study items are coded on a dimension shared by the critical item. That is, if I see *sweep, steep, and sleet*, I will only think about *sleep* if I am attending to the sound of the words.

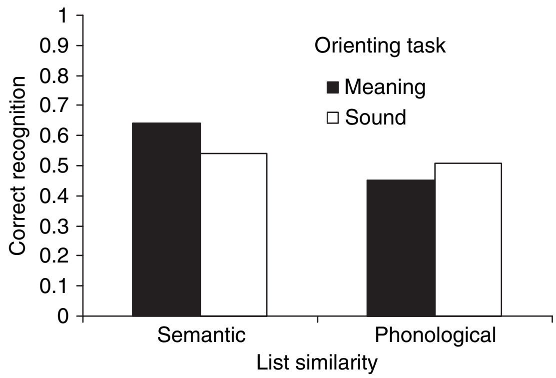

**Figure 2** False recognition of critical words as a function of the type of list similarity and orienting task. Adapted from Chan JC, McDermott KB, Watson JM, and Gallo DA. (2005) The importance of material-processing interactions in inducing false memory. *Mem. Cognit.* 33: 389–395.

Despite enormous amounts of research using the technique, we know that orienting tasks alone are not sufficient to identify the content of the code. Leaving aside the possibility that subjects may intentionally focus on dimensions other than that associated with the orienting task, incontrovertible evidence shows that orienting tasks do not control completely the dimension of encoding. For example, Nelson et al. (1979) found that the meaning of a word was encoded in a context that emphasized phonetic features. Hunt et al. (1979) report that visual features of words are encoded during semantic orienting tasks. The encoding of sensory attributes in the course of making a semantic judgment is quite reasonable given that the semantic processing requires sensory input, but this fact complicates the inference one can make about the code following an orienting task.

### 2.07.2.7 Neural Indices of the Code

A relatively new technique for identifying the code is the use of noninvasive, neural-dependent measures that record brain activity during encoding. The logic of identifying psychological functions from observations of neural dependent measures was formulated in the early 1800s by pioneers such as Gall and Spurzheim, but the development of powerful imaging techniques has made the idea more appealing than ever. A succinct statement of the neuroscientific approach to identifying the memory code begins with the assumption that experiencing an event results in activation of neural pathways that are dedicated to the processing of those types of events.

This activation leaves a trace in the form of altered neural functioning such as increased connectivity. This neural trace will be a critical participant in later memory of the event when activation occurs under appropriate conditions. Using this logic, the trace is identified as the site of the brain activity. To translate the neural code to a psychological code, one appeals to the assumed localization of the psychological functioning (e.g., visual/occipital, auditory/temporal, verbal/temporal-frontal, spatial/parietal, emotional/limbic).

An informative example of the logic underlying the neural identification codes is the study of imagery and memory. A dispute erupted in the 1970s over the nature of the code in memory for an imagined event. The dispute had two aspects. Is the code a modality-specific representation or some more abstract, post-perceptual code (e.g., Shepard, 1978)? And is the mental image a spatial representation or a propositional representation (e.g., Kosslyn, 1980)? Although these appear to be straightforward empirical issues, they proved resistant to adjudication by standard methods of experimental psychology (see, e.g., the following sequence of papers, Kosslyn et al., 1978; Pylyshyn, 1981; Intons-Peterson, 1983).

In the face of this stalemate, some argued that neural techniques are the panacea, "neural measures have the potential to be more decisive on these issues because they provide more direct evidence on the internal processing stages intervening between the stimulus and response in imagery experiments" (Farah, 1995, p. 964). In her reviews of research using various techniques to monitor regional brain activity during mental imagery, Farah (1995, 2006) showed that virtually every study implicates occipital activity in mental imagery, demonstrating that imagery and perception share cortical representations. Moreover, some of these shared cortical representations include spatially mapped areas of the occipital lobe. Thus, if one is willing to assume that the cortical representation is the psychological experience, the neural techniques have resolved successfully what appeared to be an intractable debate about the code underlying mental imagery.

Another interesting example of the use of brain measures to address a question of coding is described by Tulving (1989). The question was, Are there different kinds of codes for knowledge and memory? Tulving reported PET scans of brain activity when the subject was thinking of a recent Sunday afternoon picnic and when thinking of news accounts of French elections. In the best of the Ebbinghaus tradition, Tulving himself was the subject. The results of the scan showed activity in different brain regions when remembering the Sunday picnic than when reflecting on knowledge of the French elections, evidence interpreted to be consistent with the notion that memory and knowledge are represented by different kinds of codes.

Another important line of research using neural techniques was initiated by Wagner et al. (1998). The goal was to identify the locus of brain activity during encoding that is associated with remembered items but not forgotten items. fMRI scans were performed as the to-be-remembered words were presented, and then the scans were backsorted following a recognition memory test to determine what differentiated recognized items from nonrecognized items. Comparing high-confidence hits to misses, greater activity was seen in multiple prefrontal regions and left parahippocampal and fusiform gyri for the hits. Effectively, the conclusion is that relatively high activation in these areas established the code for successful memory. Paller and Wagner (2002, p. 93) have labeled this technique the "subsequent memory paradigm," which yields the contrast between neural activity for successfully remembered and forgotten items. Subsequent use of the paradigm has replicated the original Wagner et al. (1998) results and moved on to issues such as the correlates of coding underlying the subjective experiences of remembering versus knowing (see Paller and Wagner, 2002; Kahn et al., 2004, for reviews).

Research on coding processes that use neural-dependent measures is an exciting development that has produced new information about the brain correlates of learning and memory. However, as with all the other techniques described here, certain cautions are in order if one's goal is to specify as precisely as possible the memory code. Especially important is an issue raised by Henson (2005, 2006) and Poldrack (2006), which is analogous to deductive versus inductive inferences from behavioral data. In the case of behavioral studies of coding processes, a deductive inference would be one in which memory is predicted from a theoretical view of the nature of the code, whereas an inductive inference would be one in which the nature of the code is induced from the behavior. The latter, of course, is the much frowned upon *post hoc* explanation. In the case of the neural measures, the deductive inference is one in which brain activity is predicted from some theoretical idea. Tulving's (1989) study described earlier is an example of the deductive inference based on neural measures. The hypothesis was that two different kinds of memory codes exist, and the study measured brain activity in the situations that hypothetically activate one or the other of the codes. Notice that the precise regions of brain activity are not critical for the conclusion drawn from the data.

In contrast, the inductive inference, the postulation of a memory code from observation of brain activity, is based entirely on the region of the brain that is activated. Farah's (1995) conclusion that mental imagery is modality specific is based on the assumption that visual perception is mediated by the occipital cortex. Activation of that structure is used to infer visual experience. Not only is the specific brain region important when making these inductive inferences from brain to psychological function but the mapping of structure to function also must be one-to-one (Henson, 2005, 2006; Poldrack, 2006). If any reason existed to assume that the occipital cortex were involved in propositional coding as well as visual perception, one could not infer anything about a particular code from its activation. Thus, if the goal is to specify a particular encoding operation from neural data, one must be able to specify not only what brain area is associated with that operation but also that the brain area is only associated with that particular type of code.

#### 2.07.2.8 Summary of Methods

Memory scientists have been extraordinarily clever at developing techniques to study the nature of the representation in memory. The work is difficult because no direct observation of the memory code is possible, but rather, the code must be inferred from observations of behavior and/or brain activity. The use of indirect inferences to establish the nature of the representation is not at all unique to the question of coding, or even to psychology. It is the same hypotheticodeductive strategy that has led to the postulation of planets and subatomic particles. In contrast, the rules that govern an inference from observations to a specific hypothetical code must be made explicit in each case and examined for their validity.

The challenge confronting the attempt to precisely specify the code in any given circumstance was argued by Anderson (1978). Anderson's point was that inferences about the code are based on data, which in turn were collected under the auspices of theory-driven experiments. That is, a theory predicts some outcome given some setting condition. The problem arises when we realize that a theory postulating a particular code (e.g., a visual image) also assumes some set of processes. Any data explained by this theory also may be explained by an alternative theory that postulates an alternative form of representation (e.g., a propositional code) combined with alternative processes. Anderson concluded that for this reason, arguments about contents of the code cannot be adjudicated by behavioral research. Anderson's only suggested solution was the possibility that neural-dependent measures would become available, and as evidenced by Farah's opinion quoted earlier, some scientists believe that the solution has been achieved in the intervening years. That belief, however, rests on the assumption that the neural measure is a more direct observation of the code.

## 2.07.3 Factors Affecting the Coding Process

Acquisition and retention of information are determined in part by the circumstances surrounding the initial experience. It is these factors that are classified as the variables affecting encoding. Understanding the effects of these variables is complicated by the fact that criterion performance is affected not only by the coding process but also by the circumstances surrounding the test. Among the major advances in the study of learning and memory is the widespread appreciation for the relativity of the effect of both study conditions and test conditions, each of which constrains the other. Thus, the effect of encoding variables on later performance is relative to the nature of the test. Consequently, in contrast to earlier conceptualizations of learning and memory, we no longer make absolute statements about the general effect of acquisition variables. Nonetheless, the study of factors constituting the encoding environment continues to be a focal area of memory research. In this section, some of that research and its allied phenomena are described.

#### 2.07.3.1 Intent to Remember

Intuitively, intent to remember emerges as a dominant factor affecting later memory, but research on encoding processes has shown that intuition unequivocally to be wrong (e.g., Postman, 1964; Hyde and Jenkins, 1969; Craik and Lockhart, 1972; Challis et al., 1996). As we shall see, what does matter is the type of processing performed on the material, but trying to remember does not ensure that optimal processing will be engaged. **Figure 3** depicts the results reported by Hyde and Jenkins (1969). Subjects were asked to determine the words' pleasantness, check all of the 'e's in the word, or count the vowels in each word. For three groups of subjects, the orienting tasks were given as incidental memory instructions, and for another three groups the orienting tasks were accompanied by instructions to try to remember the words. As can be seen in **Figure 3**, adding intentional instructions improved performance in the nonsemantic orienting groups but had no effect on the performance following the pleasantness rating task. It is not the intent to remember but, rather, the nature of the processing that is important.

Indeed, an enduring contribution of levels of processing (Craik and Lockhart, 1972) is the acceptance of memory as a by-product of the processes of perception and comprehension of the original experience rather than as the intentional object of processing. After all, how many times during the course of the day does one try to remember, and yet healthy adults can remember most everything that happened yesterday. Furthermore, only occasionally do we know what, if anything, about current experience will be required from memory, rendering intent to remember any part of the experience a gamble against future demands. In light of these considerations, the lack of direct effects of intentional memory is understandable.

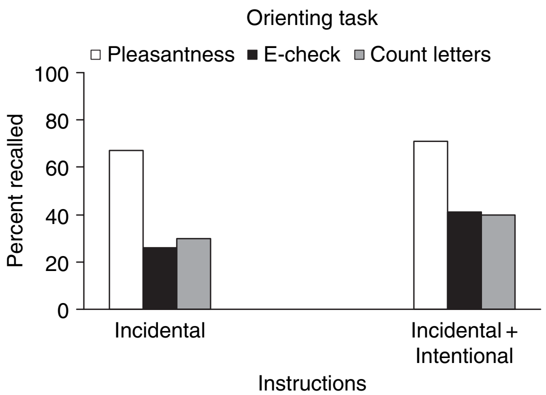

**Figure 3** Memory as a function of type of orienting task and intention to remember at study. Adapted from Hyde TS and Jenkins JJ (1969) Differential effects of incidental tasks on the organization of recall of a list of highly associated words. *J. Exp. Psychol.* 82: 472–481.

### 2.07.3.2 Attention

Coding processes to memory are influenced substantially by both quantitative and qualitative aspects of attention. Qualitative aspects of attentional processing are inferred from the effects of selective attention on memory, and those effects are encompassed by levels of processing. In addition to the effects of selective attention, evidence indicates powerful effects of the amount of attention devoted to encoding. Dividing attention between processing a to-be-remembered event and another activity at encoding comes at a cost to both.

Seminal projects by Baddelely et al. (1984) and Craik et al. (1996) both found that memory was affected negatively by dividing attention at the time of study and also that performance on the secondary task used to divide attention was negatively affected. This research clearly shows that coding processes require attentional capacity. More recent reports (e.g., Fernandes and Moscovitch, 2000; Naveh-Benjamin et al., 2005) have substantiated the earlier conclusion, rendering as apparent the fact that optimal memory for a prior experience requires allocation of conscious processing to that experience. This conclusion only applies to memory tests in which the individual intends to remember, an important example of the caution urged about conclusions concerning encoding without consideration of the retrieval context.

### 2.07.3.3 Types of Processing

Beginning with Hyde and Jenkins (1969), it became increasingly apparent that memory could be influenced powerfully by asking subjects to perform tasks that focused attention on various aspects or dimensions of the to-be-remembered material. Hyde and Jenkins concluded that the effect of these tasks can be attributed to the "nature of the stored trace" (1969, p. 480). As research intensified, the characteristic of the trace that determined performance took center stage. Hyde and Jenkins had contrasted tasks that required subjects to rate the pleasantness of words, to count the number of 'e's in the words, or to estimate the number of letters in the words. The pleasantness rating task invariably produced better recall, and in contrasting the three tasks, Hyde and Jenkins speculated that the difference lay in the fact that the pleasantness rating task required the words to be treated as meaningful units. This idea would be refined and elaborated by Craik and Lockhart (1972) in one of the most influential papers in the coding literature.

#### *2.07.3.3.1 Levels of processing*

Beginning with Estes's (1959) stimulus sampling theory, the notion that objects and events can be conceptualized as multidimensional has been routinely adopted in memory research. Encoding processes function to analyze experience along its various dimensions and select values on those dimensions to represent an experience in memory. The code can be described as the set of these values or features, or alternatively, at a more macro level, the code can be identified with a broad dimension (e.g., phonetic code). Research such as that of Hyde and Jenkins (1969) suggested that encoding semantic features yielded better memory for the event than encoding orthographic features, and Craik and Lockhart (1972) systematized findings such as these with their idea of levels of processing. The idea itself will be discussed later, but the empirical work surrounding the idea uncovered a powerful factor affecting the coding process.

The idea of levels of processing was simple, and the experimental paradigm that it fostered was easily implemented and produced huge effects, factors responsible for dozens of published papers demonstrating the basic effect in the wake of Craik and Lockhart's paper (Watkins, 2002). The effect originally reported by Hyde and Jenkins is that semantic encoding produces superior memory, but the research expanded the characterization to a broad dichotomy between semantic and nonsemantic encoding. The superiority of semantic encoding was demonstrated not only for memory for lists of words, but also for higher-order language constructions (e.g., Perfetti, 1979), and even faces (e.g., Bower and Karlin, 1974). **Figure 4** represents the results of Bower and Karlin's study, in which subjects studied faces by judging their honesty, likableness, or gender. Subsequent recognition memory for the faces was much more accurate following judgments of honesty and likableness. In the wake of the immense volume of literature provoked by levels of processing, one marvels that the basic effect of superior memory following semantic processing remains unexplained (Roediger and Gallo, 2002).

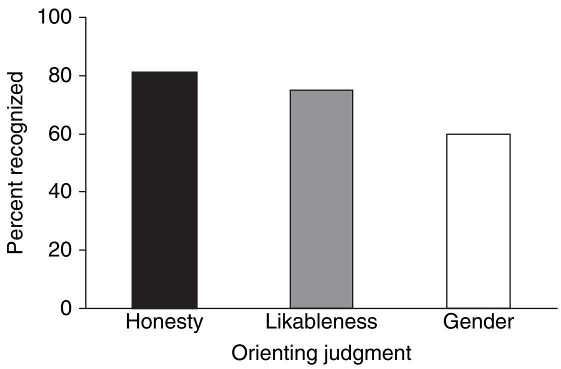

**Figure 4** Recognition of faces as a function of judging honesty, likeableness, or gender when studying the faces. Adapted from Bower GH and Karlin MB (1974) Depth of processing of pictures, faces, and recognition memory. *J. Exp. Psychol.* 103: 121–156.

#### *2.07.3.3.2 Self-generation*

Slamecka and Graf (1978) convincingly showed that memory for self-generated material is better than memory for externally provided material. This generation effect is operationally distinct from levels of processing in that the generation paradigm requires subjects to generate a word in the presence of highly constraining cues. For example, subjects may be told to generate antonyms of cue words that also fit the letter fragment (e.g., 'hot–c_ _d'). Other subjects either hear or see lists of the same word pairs and are asked to remember the second member of each pair. Other things being equal, the generated items are much better remembered than the externally provided items.

Similar to levels of processing, generation effects have no consensually agreed upon explanation, and little empirical work currently is devoted to this problem. Nonetheless, generation is a powerful encoding factor. Just how powerful is nicely illustrated in a study by Slamecka and Fevreiski (1983). They arranged a generation list that would yield tip-of-the-tongue states. Subjects were asked to generate words in response to dictionary definitions, and sometimes subjects could not generate the word but would report feeling that they knew that word. The control condition read the definitions followed by the word. **Figure 5** depicts the remarkable outcome, which was that the words that were not generated but were on the tip of the tongue were recalled better that the same word when it had been read.

The generation effect is limited to meaningful material; no generation advantage in memory occurs with meaningless material (Graf, 1980; McElroy and Slamecka, 1982), suggesting a possible connection between the psychological processes mediating generation and levels of processing effects. The generation effect also was eliminated in a study by Donaldson and Bass (1980), in which the subjects in the nongenerate condition were required to judge the quality of the relationship between the cue word and the target. The effect of this manipulation was to

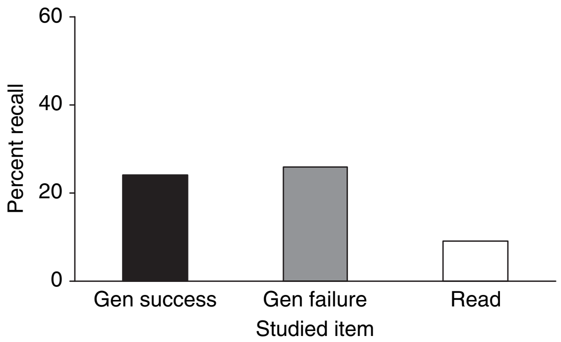

**Figure 5** Correct recall as a function of successfully generating, trying but failing to generate, or reading the word at study. Adapted from Slamecka NJ and Fevreiski J (1983) The generation effect when generation fails. *Journal of Verbal Learning and Verbal Behavior* 22: 153–163.

elevate performance in the nongenerate group to the level of the generate group, suggesting that the effect is a result of the attentional focus required by generation.

Begg and his colleagues have made a similar argument based on the premise that the generation effect was the result of impoverished processing of nongenerated items. Begg et al. (1991) demonstrated that generated and read items are equally well remembered if the quality of the processing of the items is equated. For example, if both the generation and read condition are asked to construct images of the words, no difference appears in memory as a function of generation. If both conditions are asked to pronounce the words, the generation condition now shows an advantage in memory. The interpretation of these data entails an important applied message about memory coding; namely, generation requires discriminative encoding processes that transfer to later memory demands, whereas perceptual processing of incoming information may or may not attract beneficial discriminative encoding.

#### 2.07.3.3.3 Organizational processing

Levels of processing and generation research largely have studied memory for unrelated words and have produced descriptions of item-specific coding processes. However, coding of relationships among items has long been known to be important to memory (e.g., Katona, 1940). The modern era of research on organizational coding was launched by Miller's (1956) proposal that discrete elements could be coded into higher-order chunks for storage in short-term memory. The function of such coding was to increase storage capacity by increasing the amount of information in the stored unit. Tulving (1962) later emphasized enhanced retrieval efficiency as the functionally significant impact of organization.

The most straightforward evidence for the importance of organizational processing is found in studies of memory for materials that contain known relationships. For example, word lists consisting of exemplars of known categories are better remembered than random lists, and categorized lists are better remembered when the category exemplars are presented contiguously than when they are presented in random order (Bousfield, 1953; Mathews, 1954). That an active coding process intervenes between list presentation and recall can be inferred from the fact that recall of randomly presented categorized lists tends to come out organized by category. Further evidence of active organization comes from Tulving's (1962) demonstration of subjective organization. Here multiple study-test trials occur for an unrelated list of words, which is presented in a different order on each study trial. Over the trials, a stable output ordering tends to develop – an ordering that is different from the various input orders and is usually idiosyncratic across subjects. The importance of organizational coding to memory has been argued from the almost perfect correlations Tulving found between his measure of organization and free recall.

The dependence of memory on organizational processing also is evident from the phenomena of whole-to-part and part-to-whole negative transfer. Tulving (1966) demonstrated that when subjects learn an initial list to criterion and then are given a second list to learn, half of which comprises the first list items, learning of the second list is impaired relative to a condition that learns an unrelated first list. Similar negative transfer was reported by Tulving and Osler (1967) when the second list consisted of half of the items from the first list. Tulving (1968) suggested that these data indicate the importance of organizational encoding to learning, in that the organization of the first list items interferes with learning (active organization) of the second list. This interpretation subsequently was supported by data showing that positive transfer could be arranged from list 1 to list 2 if list 1 organization is appropriate to list 2 learning (Bower and Lesgold, 1969; Ornstein, 1970).

#### 2.07.3.3.4 Distinctive processing

Laboratory studies promoting the importance of distinctiveness to retention have been reported for over 100 years (e.g., Calkins, 1894), research that parallels the intuition about the memorability of distinctive events. Despite, or perhaps because of, the intuitive appeal of distinctiveness as a factor at encoding, some confusion surrounds the meaning of the concept of distinctiveness (Hunt, 2006). The most common usage has distinctiveness as a property of events, as in the polka-dot Volkswagen in the funeral procession. In this view, distinctiveness is a property of events, and as such, distinctiveness cannot be explained by appeal to distinctiveness for obvious reasons of circularity. Rather, the standard approach has been to appeal to processes at encoding that entailed a subjective experience, usually of surprise or salience (Green, 1956), which in turn garnered attention in the form of additional processing of the distinctive event (Jenkins and Postman, 1948). In this view, distinctiveness has a quantitative effect on the encoding process.

Interestingly, the standard account of distinctiveness cannot explain the data from von Restorff's (1933) classic paper, which is peculiar because the standard account has been developed largely from data on the isolation effect. The isolation effect refers to enhanced memory for a target item that differs from the other items in the context, which themselves are similar on some dimension. The isolation effect refers to superior memory for the isolated item compared with memory for the same item, in the same serial position of a nonisolated control list. The items of the control list can be either all similar on some dimension or all different. The isolation list conforms to intuitions about what constitutes a distinctive event in that the target item violates the prevailing context. von Restorff was not the first person to use an isolation paradigm, but she was the first person to place the target item early in the list. Her reasoning was that at the early serial position, no context for the list has been established, and the isolate will not be perceived as salient. Nonetheless, the early isolate was better remembered than the corresponding control item. von Restorff's data pose a problem for the standard interpretation of distinctiveness as extraordinary processing attracted by the salience of isolate.

An alternative approach to distinctiveness began as an effort to integrate levels of processing and organization. Humphreys (1976) made the case that optimal encoding of an experience would include both the relationship among the elements comprising the experience as well as information about the elements themselves. Einstein and Hunt (1980) and Hunt and Einstein (1981) were able to demonstrate that the combined effects of organizational encoding and item-specific encoding led to better memory than either alone. Hunt and McDaniel (1993) suggested that the combination of relational and item-specific processing constitutes distinctive processing, using the argument that relational processing refers to processing of dimensions common to all items of an event, and item-specific processing refers to processing of properties of individual items not shared by other items in the event. The combination of relational and item-specific processing then precisely specifies a particular prior item, a description that captures the important discriminative function of distinctive processing. In this view, distinctive processing at encoding is defined as the processing of difference (item-specific properties) in the context of similarity (relational information). Nairne (2006) also has developed ideas about distinctiveness and memory that treat distinctiveness as a psychological phenomenon rather than as a property of events. Nairne's approach defines distinctiveness as the extent to which a particular cue complex specifies a particular event. As with the combination of item-specific and relational processing, Nairne's theory attributes the benefit of distinctive processing to the development of diagnostic information used in retrieval, rather than to quantitative differences in coding processes as specified by the standard treatment of distinctiveness. (For a more extensive discussion of distinctiveness, *See* Chapter 2.09.)

### 2.07.3.4 Prior Knowledge

Experience within a domain enhances memory for new events within the experienced domain. The more you know about something, the more likely it is that you will remember new information about something (Kimball and Holyoak, 2000). Moreover, this effect is presumed to be largely the result of encoding processes. One line of research leading to this conclusion is the study of experts' memory. Chase and Simon (1973) compared the memory of master chess players with that of novices for various arrangements of pieces on a chessboard. In some cases, the pieces occupied the positions of actual games in play, and in other cases the pieces were randomly arranged on the board. After briefly viewing the board, the subjects were asked to reproduce what they had seen. The experts remembered more than the novices when the boards were based on actual games, but when the pieces were randomly presented, memory was no longer affected by differences in prior knowledge. The superior memory of the experts was explained as the use of prior knowledge to organize the encoding of a new experience. The experts' advantage disappears outside the domain of expertise, such as with the random arrangement of chess pieces. The results described here for chess apply to other domains, such as bridge, music, medicine, and computer programming (see Ericsson and Lehman, 1996, for a review).

Without disputing the contribution of organizational encoding, evidence has been offered to show that prior knowledge also increases the likelihood of distinctive encoding. Van Overschelde et al. (2005) asked people to remember a list of names of college and professional football (American-style) teams. The list consisted of 10 teams' names. In one case, nine of the teams were professional, and one was a college team, whereas in the other case, all 10 teams were college teams. The lists thus comprised an isolation paradigm. Typically, the isolated item is better remembered than the corresponding item in the all-similar list, an effect attributed to distinctive processing of the target item in the isolation list. Van Overschelde et al. selected people for their experiment who were either knowledgeable about football or not. The result was that the experts recalled the critical item better when it appeared in the isolation list than in the control list, but no isolation effect occurred for the nonexperts. This result suggests that experts encode not only the similarity among items within their domain of expertise but also the differences among these items. That is, prior knowledge seems to influence not only organizational encoding but also distinctive processing.

## 2.07.4 Characterizations of the Code

A final science of memory will know the neural code for prior experience and have a set of mapping rules to relate that code to the psychological states of memory. Until we reach that final stage, psychological concepts of memory codes will guide our thinking about phenomena of learning and memory. The specific nature of stored information has been characterized in virtually countless ways (e.g., traces, engrams, nodes, images, processes, features, vectors of features, production rules, or logogens). A particular characterization of codes often is driven by the phenomenon under study. For example, research into the effects of learning and memory in problem solving and skill learning often uses a production rule as the code (e.g., Anderson, 1983). What is learned and stored in memory is characterized as an if–then statement in the form of condition–action sequences. This characterization is descriptive of skilled performance in the domain of problem solving in that successful problem solving entails producing a particular action in a particular circumstance. Proposals for particular codes also result from the processing requirements of a theory in which the code is embedded. For example, Neisser's (1967) pioneering theory of pattern recognition proposed that the first step of the recognition process was the analysis of the sensory pattern into units that are stored in long-term memory. These units essentially serve as the data on which processes operate, much as real numbers serve as the database for arithmetic operations. The units used by Neisser were features – a concept that continues to have broad appeal.

Among the myriad descriptions of the memory code, one can detect two general issues that distinguish classes of codes. One of these issues is whether the code should be characterized as structure or process. The structural metaphor perhaps is the more common and more intuitive conceptualization. Here the memory code is a residual, often called the trace, of the prior experience, which is stored in a memory system. The alternative metaphor is that of skill. Here the memory code is represented as a mental process. The skill metaphor is very different from the structural metaphor in that processes are not stored; just as skills are nowhere when you are performing them, memory is nowhere when you are not remembering. These different metaphors lead to interesting differences in memory research, including that on coding, and we examine briefly some of the principle representatives of the two metaphors.

The second general issue concerns the existence of abstract codes; that is, codes for prior experience that are not bound by a particular prior context. The existence of abstract codes has been championed by philosophers as the product of rational thought since at least the time of Plato, and no one seriously studying cognitive processes questioned the reality of abstract codes until quite recently. To some extent, the positions on the abstraction issue are correlated with the first general issue, with the structural metaphor being more compatible with the notion of abstract representations; however, the correlation is not perfect.

### 2.07.4.1 The Structural Metaphor

Structural analysis of the mind evolved from two important but very different models. The first is exemplified by Titchener's (1898) admirably clear statement of structuralism, in which of the goal of psychology was modeled on morphology in biology. According to Titchener, the job of the experimental psychologist was to perform "vivisection of the mind which shall yield structural results" (p. 450). The parts of the mind would be revealed by this analysis in much the same way that parts of the body are revealed by morphological analysis. It is precisely this kind of thinking that leads to research attempting to determine the constituents of the memory code that was described earlier.

The second model influencing modern structuralism is the computer. Application of the computer model to human cognition allowed a distinction between structural components and control processes that modeled the distinction between programming commands that are fixed and commands that are contingent on the content. Atkinson and Shiffrin's (1968) theory proposed that certain psychological processes are voluntary (control processes) and that certain structural components of information processing are fixed. The fixed components were memory systems, which are defined in part by the kind of code stored. Thus, coding processes are intimately bound to particular memory systems within a structural analysis. Different structural analyses yield different kinds of codes, as we see in the following discussion.

#### 2.07.4.1.1 Stage theory of information processing

Atkinson and Shiffrin's theory exemplifies the stage analysis of the mind that characterized the halcyon days of information processing. Learning was a matter of transporting information from sensory reception to storage in long-term memory. The trip occurred in three stages. Each stage was a memory storage system, and each system required a different code.

The first stage of processing was the sensory memory store, which theoretically held codes in the form of raw sensory information. Groundbreaking work by Sperling (1960) provided evidence for the existence of a very short-lived memory that contained no meaning, characteristics that fit perfectly with a sensory code. Sperling's work on the visual store was complemented by Darwin et al.'s (1972) report of data suggesting the existence of an auditory store that holds acoustic sensory codes.

The second stage of processing culminated in storage in short-term memory. An important part of the processing was the recoding of the sensory information to its corresponding phonetic form. Evidence for a phonetic code in short-term memory was derived from studies showing interference in memory for short lists of words as a function of phonetic similarity (e.g., Baddeley, 1966). The argument that the code for short-term memory is the sound pattern of the material fit neatly with the importance assigned to rehearsal. That is, rehearsal typically is assumed to be a verbal process, and verbal processes require speech codes.

The final stage of processing was the transfer of information from short-term to long-term memory. Rehearsal was assumed to be the important mechanism of transfer, by which the phonetic code was recoded into its corresponding semantic representation. Again, the evidence for a semantic code in long-term memory was derived from studies showing that semantic similarity interfered with performance on tests of long-term memory (e.g., Baddeley, 1966).

Thus, the stage theory assumed that information processing is characterized in part by coding processes that recoded the information from a previous stage to a form appropriate for storage in the higher stage. In the strongest statement of the theory, the form of the code was assumed to be a structural component, which means that the code has to be in the specified form if the information is stored in the particular system. That is, nothing but a phonetic trace can be stored in short-term memory. Consequently, it is not surprising that research showing that the code in short-term memory could be visual (e.g., Posner, 1969), or even semantic (e.g., Shulman, 1974), raised concern about the stage model. One reaction to the theoretically incongruent data was to revise the model of short-term memory in light of the new evidence on the nature of the code.

#### 2.07.4.1.2 Working memory

The concept of working memory emerged as a revised description of short-term memory (Baddeley and Hitch, 1974) in the wake of the stage model's failure. Working memory is different from the stage model in several dimensions, the most important of which for us is the question of coding. Rather than assume a single store containing a phonetic code, working memory's structure includes three separate storage structures to accommodate three different codes. The structure of working memory includes a phonological loop that stores a phonetic code, a visuo-spatial sketchpad that stores a visual code, and an episodic buffer that stores semantic codes (Baddeley, 2000).

Evidence for the independence of the storage systems and their structurally bound codes was inferred from studies of interference. For example, the existence of a phonetic code has been inferred from the interference produced by the phonetic similarity effect (Baddeley, 1966), but this effect can be eliminated under certain circumstances. If the word lists are presented visually and the subject is required to repeat the word 'the' as rapidly as possible during list presentation, phonetically similar lists are remembered just as well as control lists. If, however, presentation of the lists is auditory, the phonetic similarity effect does occur; that is, the phonetically similar list is more poorly remembered than the control list. These data and their interpretation are drawn from Baddeley et al. (1984), who argued that auditory input gains obligatory access to the phonological loop but that visual input requires recoding to a phonetic form. This recoding is performed by the articulatory control process, but that process also is responsible for the production of speech. Thus, rapidly repeating the word 'the' during visual presentation of the list prevents phonetic recoding and storage in the phonological loop. As a consequence, the visual presentation accompanied by interference does not yield a phonetic similarity effect because the words are never coded phonetically.

The existence of a visual-spatial code has been adduced from analogous experiments that involve visual presentation of material accompanied by visual secondary tasks (e.g., Baddeley et al., 1973). In addition, neuroimaging research has offered support for the independent existence of a short-term visuospatial system of the sort proposed by working memory (Smith and Jonides, 1999). The episodic buffer has received little research attention, and at this time no evidence is available concerning the hypothesized code for that system.

The theory of working memory continues to be developed and has provoked a good deal of research, much of it related to the nature of codes in short-term memory. The theory has nothing to say about codes stored in long-term memory, and for the structural view of long-term memory, we turn to the memory systems approach.

#### *2.07.4.1.3 Memory systems*

The paragon of modern structuralism in cognitive psychology is the idea generally known as the memory systems approach. Essentially the approach advocates the existence of multiple memory systems in both short- and long-term memory and sets a research agenda of discovering the systems and delineating subsystems. A variety of classification schemes have been proposed, and the one described here is that of Schacter and Tulving (1994; Schacter et al., 2000). Schacter and Tulving outlined a list of defining features for a system that includes the operating rules, the neuroanatomical location of the system, and the type of information stored in the system. The later characteristic is the one of interest to us.

In 1972, Tulving proposed a distinction between what he called semantic memory and episodic memory. Semantic memory stores context-free information that corresponds to knowledge. For example, semantic memory contains information such as 'St. Louis is in Missouri, tomatoes are fruit, Dick Cheney shoots at birds.' These representations are abstract in the sense that the information coded in semantic memory is not constrained by time or space. In contrast, episodic memory stores information bound by its spatial and/or temporal context. For example, episodic memory contains information such as 'I went to the pharmacy yesterday, my wife and I saw Spamalot last Friday, I was told yesterday that John does not like tequila.' Note that the information in episodic memory has a personal as well as a temporal and/or spatial reference. The information stored in episodic memory corresponds to what we normally take to be memory rather than knowledge.

Since Tulving's original proposal, additional memory systems with their associated codes have been discovered. One is the procedural system that contains representations of cognitive and motor skills. These codes are similar to the codes in semantic memory in that they are abstract but differ from semantic memory in the kind of content. The code for the procedural memory literally is the representation of how to do something, like tie your shoes. The procedural code is not readily recoded verbally (try describing how to tie a shoe without using your hands), which is very different from the code in semantic memory. Another recently proposed system is the perceptual representation system. This system contains codes representing the visual and the auditory form of words. For example, the visual form 'cat' is stored in the perceptual representation system as well as a separate code representing the sound of that visual pattern. As with the semantic and procedural codes, the codes in the perceptual representation system do not contain contextually defining information. Unlike those two systems, the perceptual representation is just that, viz., the modality-specific representation of a word or object. Finally, working memory also is included as one of the components of the system.

### 2.07.4.2 Summary of Structural Approaches

Memory codes are fundamental to the structural view of the mind in that a defining feature of any theoretical structure is the kind of code it contains. That is, the type code is one of the inherent characteristics of a system, just as skin is an inherent characteristic of mammals. The combination of system and characteristic code then is used as the principal explanation for performance. For example, consider the following situation: Subjects are asked remember a small amount of material but are prevented from rehearsing that material after its presentation and then tested within 30 s of the presentation. Memory for the material will be surprisingly poor (e.g., Peterson and Peterson, 1959). One explanation is that the test drew on short-term memory, which contains a limited duration trace, an aspect of the code contained in short-term memory. As with all metaphors used in science, the structural metaphor not only serves to explain performance but also molds the form of research. Under the structural umbrella, a prominent and respectable research activity is that of identifying and classifying the nature of codes. Thus, much of the research provoked by any of the previously mentioned structural views will be devoted to a description of the memory code. In this function, the structural notion of a memory code has been invaluable for cognitive neuroscience. As mentioned previously, most of the cognitive neuroscience of memory is devoted to identifying brain sites associated with memory phenomena – sites that then are taken to be the brain codes for the prior experience.

### 2.07.4.3 Process Metaphor

A very different characterization of memory in general and coding in particular arises if mental functioning is assumed to be analogous to a process or skill. The idea is that memory performance is determined by the mental processes operating at the time of an experience rather than by where the memory trace is stored. Craik and Lockhart's (1972) framework, levels of processing, was the seminal impetus for the processing metaphor, and in 1993 it was declared the most successful theory of learning and memory in the previous 25 years (Roediger, 1993). According to its authors, levels of processing "suggested that the memory trace could be thought of simply as the record of those analyses that had been carried out primarily for the purposes of perception and comprehension and that deeper, more semantic analyses yielded records that were more durable" (Lockhart and Craik, 1990, p. 88). Thus, levels of processing assume that the coding process focuses on either the meaning of an event or on nonsemantic properties, such as visual or phonetic features of the event. Attention to semantic features is considered deeper processing, and research has shown time and again that all other things being equal, semantic processing leads to better retention.

The gradual discovery of boundary conditions to semantic processing superiority has led to revisions to the original idea, wherein the central role of depth has been replaced by concepts such as elaborative processing (Craik and Tulving, 1975), distinctive processing (Jacoby and Craik, 1979), and sensory-semantic processing (Nelson, 1979), but the effect of Craik and Lockhart's thinking is manifested in the assumptions these revisions all share with the original view. Chief among these is that coding processes yield a memory trace consisting of qualitative features representing the event. Certain types of traces are more beneficial for retention than others; which type varies with the theorist, but in all cases memory is determined by the qualitative nature of the code. The qualitative nature of the trace is determined by the encoding processes, not by where the trace is stored, as is assumed by most structural theories.

In close temporal and spatial contiguity to Craik and Lockhart's work, a more radical version of the process metaphor began its development with Kolers' (1973) work.

In accord with levels of processing, memory systems played no role in the explanation of performance, but in addition, memory traces of the sort used by structural theories and by levels of processing were shed. The important role of memory traces as conceptual bridges between the past and present was assigned to the psychology processes brought to bear on the current event: The analytic operation of coding the experience becomes what is remembered. The implications of this shift for the concept of coding are far-reaching, as is evident in the following quotation from Kolers (1979):

> On the present view, every encounter with a stimulus elicits a different analysis from every other.... In other words, recognition is achieved by virtue of the correlation between the operations carried out on the two encounters with the stimulus event. The more similar the operations, the readier the recognition. But as nothing ever repeats itself exactly, recognition is based on the transfer of skills across occasions and partial correlation. *If the operations that are activated are themselves the record of the stimulus, then as the operations change, the representation of the stimulus also changes; there is no permanent trace of an object, nor even a fixed trace, but skill-developed and occasion-dependent representations.* (p. 383, italics added)

The position expressed here eventually would be known as proceduralism (Kolers and Roediger, 1984). The basic tenet of coding in proceduralism is that the code is the set of psychological processes engaged for perception and comprehension of an event. Levels of processing, in contrast, assumed that these processes produced a trace or code, which was stored in memory. Proceduralism adheres to a much stricter use of the skill metaphor, whereby there is no stored trace or code. After all, where is your typing skill when you are not typing or your adding skills when you are not adding? Rather than assuming a stored trace, the connection between the past and present in proceduralism is represented by the similarity of the psychological processes engaged by the present event to some operations engaged in the past. The more similarity between the two sets of processes, the greater will be the transfer. The metric of similarity includes the modality through which the events are experienced on the reasonable premise that the psychological processes of vision and audition, for example, are different. Thus, one can see that the code for a given event is quite particular and tightly bound by the processing context.

As counterintuitive as the idea is for our intuitions about memory, Kolers (e.g., 1974) offered programmatic evidence for the approach that was sufficiently persuasive to produce important progeny in cognitive psychology. Most notable of these in memory are Roediger's ideas about data-driven and conceptually driven processing and Jacoby's process dissociation theory, both of which take proceduralism's assumptions about coding as foundational.

#### 2.07.4.3.1 Data-driven and conceptually driven processing

The distinction between data-driven and conceptually driven processing emerged as an explanation for dissociations in performance on different types of memory tests. Roediger et al. (1989) argued that these dissociations reflect differences in the processing demands of differences between study/test conditions. The basic assumption is that a particular type of prior processing may be more effective for one type of test than for another. An important example for the development of the data-driven/conceptually driven distinction is the previously discussed research of Jacoby (1983). As a brief reminder, Jacoby asked people to study words under different conditions. In one condition, the words were read without any context. In another condition, the words were generated by the subjects in the context of semantic clues. On a later recognition test, the people who generated the items at study performed better than those who read them – the standard generation effect. However, if the test was to identify visually degraded words, previous reading of the word led to better identification than did previous generation.

Roediger et al. (1989) used Jacoby's (1983) work as the basis for distinguishing the coding of meaning (conceptually driven processing) and the coding of perceptual features (data-driven processing). The dichotomy between semantic and sensory-based codes is not new to our discussion, having been an important component of the stage model, the memory systems, and levels of processing. What is different is that Roediger et al. couched the distinction in processing language. The code for meaning is the psychological processes engaged to analyze the event, and the effect of this prior processing will be revealed only in future circumstances demanding similar analysis of the event. The code created by generating the word 'cat' will not facilitate future demands to read the word 'cat'. In that sense, one can appreciate Kolers' previous quotation to the effect that as the operations change, the representation of the event changes.

The distinction between data-driven and conceptually driven coding has been a powerful stimulant for research and has served an impressive role in classification and organization of memory tests (e.g., Blaxton, 1989; Rajaram and Roediger, 1993). Situations have arisen, however, that resist clean dichotomizing into data-driven and conceptually driven processing. A very simple example is the standard recognition memory test, in which one must process the test item perceptually before a decision concerning its status can be reached. On the face of it, this situation seems to require both data-driven and conceptually driven processing. The authors of the idea recognized this implication early on: "Tests may involve both types of processes. Indeed, a more useful assumption is to describe two continua, one for each type of processing, to acknowledge that these two modes of processing can be varied orthogonally" (Srinivas and Roediger, 1990, p. 390). The interesting point for our discussion of coding is the realization that characterizations of the trace for an event as exclusively perceptual or conceptual, the very assumption that caused trouble for the stage model, are too simplistic. Advocates of the data-driven/conceptually driven view avoid that mistake by assuming that the code will include both types of information in most all cases.

#### 2.07.4.3.2 Process dissociation theory

Another descendant of Kolerian proceduralism is the process dissociation framework (Jacoby, 1991). Like the memory systems and data-driven/conceptually driven ideas, Jacoby's theory was motivated largely by the challenge of understanding test dissociations. Unlike the other approaches, process dissociation explicitly disavows any effort to identify processes, codes, or systems on the basis of the type of task. Both the memory systems and the data-driven/conceptually driven schemes use the task confronting the subject to identify the type of code that will be required by that task. As research began to discover violations of the prescribed system- or process-task relationship, both the systems and the data-driven/conceptually driven approaches moved to a middle ground: the code for any given event is likely to be mixed. The same data suggested to Jacoby (1991) that these approaches cannot succeed in explaining memory phenomena. The reason is that the explanatory (predictive) power of either approach rests heavily on the ability to identify the theory-specified code representing an event. The primary means for doing so is to assume a code-task purity (i.e., a particular kind of task will recruit a particular kind of code). At best, the inability to identify task-pure codes robs these approaches of some of their precision.

Jacoby's alternative is to specify the nature of the processes as *a priori* rather than identify the operative processes on the basis of task performance. The details of the theory accomplishing this specification are beyond the purview of this chapter, but the assumption about the nature of the code is pure Kolerian proceduralism. Psychological processes are brought to bear on tasks with which we are confronted. These processes vary not only with task demands but also with both external and internal contexts, intent being an important component of the later. In this view, precisely the same process (a.k.a., code) is unlikely to be repeated, a position identical to that expressed in the italicized portion of the quotation from Kolers listed earlier. Consequently, every memory has a unique code in that no two situations engage identical psychological processes.

### 2.07.4.4 Summary of Process Metaphor

One can conceptualize cognitive activities including learning and memory as analogous to motor skills. Just as particular motor tasks require particular motor processes, so do particular cognitive tasks engage particular processes. In both cases, performance on a task is determined by prior processing as it is related to the task. That is, the effect of prior processing can be either positive or negative. For example, my racquetball game improves with racquetball practice, but my squash game deteriorates as I practice racquetball. The same is true of cognitive tasks. Although it may be that the structural metaphor can encompass all of the memory phenomena marshaled by the process camp, the differences in the metaphors are important influences on research. Three implications of the process metaphor are quite different from anything derived from structural thinking.

Perhaps the least intuitive of these implications is that the influence of the past is not carried by a permanently existing code stored in the system. If learning and memory are thought of as processes, then like typing, or for that matter digestion, memory is nowhere when you are not remembering. Within the process metaphor, the function of the memory code is assigned to transient psychological processes, and research focused on the overlap of processes from one task to another is essentially the process approach to studying the code. However, the vast amount of research sponsored by the structural metaphor aimed at describing memory systems would never occur under the auspices of a process metaphor.

A second and only slightly less counterintuitive implication of proceduralism is that abstract codes of the kind traditionally associated with knowledge do not exist. Take, for example, the following information: George Washington was the first president of the United States. An abstract code for this information would be stripped of any contextually specific aspects of prior experience with the information, such as when, where, or through what modality the experience occurred. If, however, we adopt a proceduralist's definition (i.e., the code representing an experience is the set of operations that yielded that experience), no representation would be free of context-specific content. The operations producing the experience include those sensory–perceptual processes associated with the modality of processing, and in most cases, it is reasonable to assume that other aspects of the context would influence the encoding operations. The implied lack of an abstract code poses a challenge for proceduralist's accounts of learning and use of concepts, where a concept traditionally is assumed to be distilled from, but not identical to, any particular prior experience. The difference between the abstractionist's and the proceduralist's positions is the venerable difference between rational and empirical knowledge, and it is exciting to see empirical work emerging on this important epistemological issue (e.g., Whittlesea et al., 1994; Heit and Barsalou, 1996; Hannah and Brooks, 2006).

A third implication of the process metaphor extends beyond the issue of coding and is of general importance to conceptualization of cognition. In two different senses, proceduralism is integrative, whereas structuralism leads to modularity. The first sense of integration is that proceduralism need not distinguish various cognitive processes (e.g., perception, memory, reasoning) except on operational grounds for clarity of communication. The aforementioned principles of proceduralism apply regardless of the operational classification of the process, rendering distinctions between such concepts as memory and reasoning unnecessary. The second dimension along which proceduralism is integrative is mind–body dualism. Crowder made this important point by noting that many theories explicitly distinguish between perception and cognition, which he suggests is dualism in a different guise because:

> perceptual skills are considered more legitimately bodily processes than the "mental" cognitive functions such as generation, reflection, and creativity. For example, Tulving and Schacter relegate priming to the activity of the perceptual representation system, as distinct from the episodic memory system. (Crowder, 1993, p. 143)

Taking skill as a metaphor for all cognitive processing, perceptual as well as conceptual, removes any boundary between body functions and mental functions.

## 2.07.5 Summary of Coding Processes

An enormous amount of research has been directed toward understanding coding processes and their resultant memory representations. The reason for the effort is that the memory code is viewed as the concept that carries the effect of prior experience into the present. In that capacity, the memory code will determine the similarity metric among prior events and between prior and current events. This similarity will determine the types of events that will interfere with each other as well as the effectiveness of certain kinds of cues in the retrieval of particular memories.

All the methods that have been used to infer the memory code are of necessity indirect, based on observations of behavior or brain activity, but the descriptions of the codes inferred from these methods point to three main ways in which the coding process operates. Codes can be a select portion of a complex event, in which case the representation is the portion of the event selected for attention. Codes can be a transformation in the form of the input such as the verbal coding of a picture or the organization of discrete units into a whole. Elaboration is a third form of coding, which yields a representation that contains more than was in the literal physical energy of the original experience. The code resulting from elaborative processing reflects the influence of prior knowledge on perception and comprehension of an event.

Placed in proper context, research on memory coding is an indication of the value of psychology in advancing our knowledge about fundamental questions of mental functioning. This chapter began with the assertion that the problem of knowledge, what can people know and how do they come to know it, is the impetus for coding research. The research has yielded a range of descriptions of particular types of codes that are the fodder for systematic theoretical classification. With that theoretical classification lays the promise of resolution to the perennial issues of the nature of knowledge, issues such as that between abstract, universal knowledge versus particular, contextually bound knowledge.

The resolution has not been achieved, but it is exciting to know that research in psychology has such ambitious aims.

# 2.08 Mental Imagery

**C. Cornoldi, R. De Beni, and I. C. Mammarella**, University of Padua, Padua, Italy

## 2.08.1 Introduction to Imagery and Definitions of Mental Imagery

In our everyday life, during interactions with people and with the environment, a crucial role is fulfilled by the ability to maintain and to recall images (i.e., mental representations including perceptual information). Most of the time, mental images are incidentally activated, such as, for example, when we think back to people's faces or certain episodes of our life. Other times, images are easily retrieved to answer particular questions; for example, people can recall and visualize in their mind how many windows there are in their house and the color of the curtains.

Mental images have always fascinated philosophers; in fact, Greek philosophers such as Plato and Aristotle discussed mental images, the latter considering imagery crucial in both cognition and thinking. Aristotle's theory could be considered the antecedent of the modern analogical imagery view, which maintains a close relationship between perception and imagery (e.g., Shepard and Metzler, 1971; Kosslyn, 1980, 1994). In fact, according to Aristotle, a mental image is an inner representation of real objects, like a copy of real-life scenes. Moreover, medieval thinkers like Augustine and Aquinas gave a central position to imagery in their interpretation of psychological processing from sensation to imagination and memory. Similarly, the British empiricists, for example, Berkeley, Hobbes, and Hume, considered mental images as traces of sensory information. As for more recent times, it is only from the 1970s that psychology reconsidered imagery as a central topic of study (i.e., ever since the advent of cognitive psychology). In fact, behaviorists had failed to consider imagery as a serious topic for experimental investigation because it was not directly observable and thus could not be investigated with a completely objective methodology. The cognitive sciences represented a new era for research on imagery processes. Interest toward mental events was once again a central topic in psychology, and different experimental paradigms were applied to the investigation of higher cognitive processes, such as imagery. Individual reports and subjective introspective experiences were considered objects of interest for experimental psychology, and imagery was included as a legitimate topic of investigation.

In the psychological literature, various definitions and theories regarding mental images were put forward, and most of them were influenced by the interdisciplinary interests surrounding this process. According to Holt (1964), a mental image refers to all the subjective awareness experiences within a sensory modality, which are not only perceptual. Intons-Peterson and McDaniel (1991) affirmed that mental images might be produced by the interaction between visual representation and a subject's knowledge, suggesting that they are knowledge-based products. Carroll (1993, p. 277) defined imagery as "the ability in forming internal mental representations of visual patterns and in using such representations in solving spatial problems" and proposed a relationship between spatial abilities, visual perception, and imagery. Similarly, Richardson (1999) postulated that mental images are complex mental products, inner representations where information on the actual perceptual appearance of objects can be described and transformed.

Mental imagery is a private and a subjective experience because we cannot observe whether other people have a mental image nor directly know its properties. This implies that its scientific investigation depends on verbal reports and on the phenomenal experience of participants (Richardson, 1980). However, psychological investigation has tried to operationalize or give construct validity to the concept of mental image. For example, according to Paivio (1971), a mental image is defined on the basis of three kinds of operations, that is, (a) by variations in stimulus properties (e.g., high vs. low imagery value), (b) by processing instructions (e.g., instructions to imagine vs. instruction to verbalize), and (c) by individual differences in imagery ability. According to Kosslyn (1980, 1994), a mental image is not simply a phenomenal experience, but a form of internal representation in which information about the visual appearance of a physical object can be manipulated: Visual mental images correspond to short-term memory displays, which are generated from more abstract representations in long-term memory (Kosslyn, 1980; Denis and Kosslyn, 1999). However, the methodological difficulties in the study of imagery have affected a recursive debate between imagery theorists (who support an analogical or pictorial position) and propositionalists (who maintain the existence of an amodal representation, e.g., Pylyshyn, 1973).

### 2.08.1.1 Debate on the Nature of Representations

The contrast between empirical and rational theories on the acquisition and on the representation of knowledge is recurrent in the history of thinking (e.g., Aristotle against Plato, British Empiricists against Descartes in philosophy and propositionalists against imagery theories in psychology). To summarize, the propositionalists affirm that mental images are epiphenomena, having a symbolic-like format, with no sensorial properties and an explicit explanation of the relations between elements (Pylyshyn, 1973, 1981). According to propositionalists, the representations that underlie the experience of mental imagery are similar to those used in language. The second position, upheld by imagery theorists like Kosslyn (1980, 1994), holds that mental imagery representations are able to depict, not describe, objects; they are analogical representations of objects in our mind and correspond to a quasi-perceptual experience, with a specific modality format.

The initial debate focused on behavioral results such as those obtained by Kosslyn et al. (1978). In the original study, participants were required to memorize a map of an island, where a series of landmarks was drawn, then to imagine the map and to pay attention to one place (e.g., the beach). When the experimenter gave the name of a second place (e.g., the tower) participants had to imagine moving from one place to the other and to press a button as soon as they had reached the second place in their mental image of the map. The results of the study revealed that the further away the second place was from the initial place (the beach), the longer it took for participants to give the response. The conclusion of the authors was that mental images have spatial properties.

The critiques made by Pylyshyn (2002) were as follows: It is not clear whether the results revealed a property of the cognitive architecture or a property of what people know or believe about imagery functioning. Pylyshyn (1981) repeated the experiment by showing participants a map with lights going on and off at the target locations; participants were required to imagine when a light was on and to press a button when they could see it at a second place. Results did not reveal correlations between the distance on the imagined map and reaction times. Similarly, Cornoldi et al. (1996a) found that the distance effect is in relationship to the theories people have about imagery functioning. However, differently from Pylyshyn (2002), they concluded that naïve theories do not simply affect responses but also affect imagery retrieval processes (for a complete debate on these paradigms, see Denis and Kosslyn, 1999).

The debate moved into a new phase when neuroimaging began to be used to study brain activation during mental imagery (see for reviews, Cabeza and Nyberg, 2000; Kosslyn et al., 2001). During mental imagery, some functional magnetic resonance imaging (fMRI) studies showed an activation of topographically mapped brain areas depicting shapes (see Thompson and Kosslyn, 2000). Furthermore, if these areas are damaged, visual imagery is impaired (Kosslyn et al., 1999). A crucial result to reach the conclusion that imagery involves quasi-perceptual experiences would be if the same visual areas were activated when an object is perceived and when it is imagined. Despite a great number of studies carried out to investigate the involvement of primary visual cortex in imagery, the issue is still open, because results are controversial. In a series of positron emission tomography (PET) experiments, Kosslyn and colleagues found an increased blood flow in Brodmann Area 17 (primary visual cortex) during imagery activity (Kosslyn et al., 1993, 1997); however, other studies with fMRI methods suggest that primary visual cortex is not activated during mental imagery (e.g., D'Esposito, 1997; for a review, see Cabeza and Nyberg, 2000).

In a recent research, Kosslyn and coworkers (Slotnick et al., 2005) tried to disambiguate the long-standing debate on the nature of mental imagery representations and found evidence supporting the depictive view of visual mental imagery. In fact, the authors' contrasting imagery and attention retinotopic maps showed that visual mental imagery can evoke topographically organized activity in striate and extra-striate cortex, in accordance with the stringent criterion required for supporting a depictive theory, as mentioned by Pylyshyn (2002).

Alongside the two opposite positions (propositionalists vs. imagery theorists), intermediate models have been proposed. For example, mental images have been considered as being generated from long-term memory information, thus representing an intermediate format between amodal abstract representations and perceptions. The information in long-term memory would be represented in a more abstract format, whereas conscious mental images would acquire a more sensorial format (Marschark and Cornoldi, 1990). In fact, it is possible that short-term visual memories maintain perceptual detail, but during the integration of information in long-term memory, they lose part of their sensorial properties (Cornoldi et al., 1998).

### 2.08.1.2 Perceptual and Conceptual Representations: Visual Traces and Generated Images

Cornoldi et al. (1998) proposed a distinction between a visual trace, sharing a large number of characteristics with perception, and a generated image, more dependent on conceptual processes but still distinguishable from an amodal representation. In fact, not only the psychological literature but also subjective experience supports a differentiation between a visual memory based on a recent perceptual experience and a generated mental image. In synthesis, a visual trace is directly received from perception while it happens. For example, when we perceive a shape, we try to maintain it in our mind. In contrast, a generated image is derived from long-term memory information as, for example, when we try to activate an image of our previous car. If the first requires a low degree of attentional control to be kept activated, the latter requires a higher degree of control; moreover, the analogy with perception would be almost complete for a visual trace and only partial for a generated image, and a visual trace would be characterized by sensorial and phenomenic properties and a generated image by perceptual–conceptual properties. It must be noted that a visual trace is also different from a perceptual experience and that, even after short time intervals, a visual experience can be affected by long-term memory reconstructive processes and thus approximate the features of a generated image. The well-known experience of the inability to remember well-known patterns (e.g., the shape and colors of a common banknote, see the example of a 20-euro piece in Figure 1) is common to mental images but also concerns recent visual traces.

**Figure 1** People are not able to accurately remember the visual appearance of objects, even if they are frequently exposed to them.

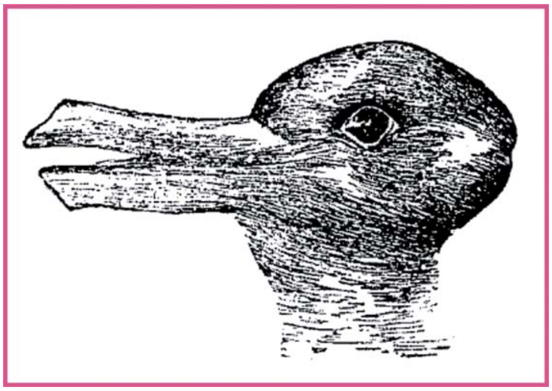

**Figure 2** The reversal of a mental image is particularly difficult but can be facilitated by the prevention of verbalization.

The distinction between a visual trace and a generated image can be also used to explain the phenomenon of verbal overshadowing, or the difficulties people meet in the reversal of mental images (Cornoldi et al., 1996b). According to Brandimonte and colleagues (Brandimonte et al., 1992a; Brandimonte and Gerbino, 1993), verbal recoding of visual stimuli occurs almost automatically when pictures are easily nameable; the verbal recoding uses long-term memory knowledge and influences the image of an ambiguous visual stimulus, determining the verbal overshadowing effect. However, if verbalization is prevented, the visual trace still maintains its perceptual properties. If you look at the picture presented in **Figure 2** and then close your eyes, you will explore the experience of a well-established image that cannot be easily reverted. If, for example, a person has in mind the image of a rabbit, that person will have difficulty visualizing a duck, and vice versa.

## 2.08.2 Different Kinds of Mental Images

Given the fact that mental images are extensively present in human life and respond to different functions, it is not surprising that they appear heterogeneous and may be differentiated. The literature on imagery has proposed a series of taxonomies among different kinds of imagery representations. Richardson (1969), for example, proposed a classification of mental images considering their different properties along the following dimensions: conscious control, phenomenological quality, intentional content, spatial location, and mode. For example, memory images were defined as conscious control phenomena with a quasi-perceptual quality, content related to experience without spatial location and with a potentially amodal format. It is noteworthy that at a higher cognitive level, a distinction can be made between mental images derived from memory and images derived from the imagination. The first refers to all images that we could evoke from memory, such as the image of the Eiffel Tower in Paris. Memory images could differ in vividness, clarity, details, colors, or multisensorial properties. Furthermore, they can be distinguished from fantasy images, created by combining elements stored in memory in new ways, as, for example, in the image of a flying horse. In fact, the creation of integrated images obtained by combining together single images represents a typical mental imagery situation, derived from the classical mnemonic tradition showing that interactive images facilitate the retrieval of an element if the other element is available. **Figure 3** presents an example of interactive image created with the support of fantasy. If the image of a rainbow and the image of a guitar must be integrated in a single interactive image, one could, for example, imagine a natural-looking guitar and a rainbow illuminating it.

The distinction between images from memory and those from the imagination is not rigid because images from memory are not exact reproductions of the equivalent perceptual experiences, whereas fantasy images are created on the basis of features derived from visual experiences. A related distinction refers to common and bizarre images. The first type represents objects, as we know them in the real world; in contrast, the latter are impossible and strange

**Figure 3** People trying to include in a single interactive image the images of a guitar and a rainbow could use fantasy to create an effective original representation.

representations of an object. Examples of bizarre images could be a dog smoking a cigar and a man chewing a bone, whereas the corresponding more common image would be a man smoking a cigar and a dog chewing a bone. This distinction has memory implications and has been the basis of mnemonic art. Cornoldi et al. (1988) found that bizarre representations improved memory recall if subjects could evoke the kind of image they wanted. Further studies (Einstein et al., 1989) reported that recall can be influenced by the distinctiveness of materials. They found that in a list of words where all the stimuli were imagined in the bizarre modality, recall was no better than when using common images. When the bizarre and common mental images were generated alternatively in the same list of words, however, the bizarre images produced a better memory performance, indicating that bizarreness *per se* does not produce superiority in memory but needs to be accompanied by another factor, such as distinctiveness.

Other classifications are more focused on the spatial properties of layouts. For example, Kosslyn (1987) distinguished between exact metric coordinates and memory for the relative relation between objects (i.e., coordinate vs. categorical representations; see also Lansdale, 1998). Studies regarding the specialized involvement of different brain structures show that the right hemisphere is important in processing metric spatial information, whereas the left hemisphere participates in processing relative spatial relations (Kosslyn et al., 1989). Other classifications of spatial images refer to the type of processing (sequential vs. simultaneous), to the reference center (egocentric vs. allocentric), and to personal space (peripersonal vs. extrapersonal).

### 2.08.2.1 General, Specific, Contextual, and Episodic-Autobiographical Images

Can mental images also represent general concepts? The existence of general and prototypical images is an ancient topic of debate. We know that the ability to create a universal or prototypical representation from the analysis of particular cases is a fundamental process in knowledge and conceptual development, but we do not know whether this representation can assume an imaginal format. Radical empiricists (Locke, Hume, Berkeley) denied the existence of general images by arguing that mental images are always based on the representations of specific objects that have been experienced, whereas a general term evokes an abstract idea. From this position two different interpretations developed: one affirming that general images representing the essential properties characterizing the general term (such as a prototypical representation) can be generated, and the other suggesting that general terms are either abstract or refer to an exemplar representation. The distinction between general, specific, contextual, and episodic-autobiographic mental images embraces the first option. The distinction has received support in recent years by cognitive (Cornoldi et al., 1989; De Beni and Pazzaglia, 1995; Helstrup et al., 1997) and neuro-anatomical data (Gardini et al., 2005). An example of a general image may consist of a skeletal representation of the main features of a bird including both coordinate and categorical spatial information. A specific image of a bird should be a particular exemplar of the category (e.g., a canary); moreover, a contextual image refers to an image in which the object or the exemplar is inserted within a context, for example, the canary in the cage. Finally, episodic-autobiographical images correspond with images of single life-episodes connected with an object and having a specific self-reference, for example, my canary escaping from its cage during a sunny day of May. Episodic-autobiographical images involve the retrieval of available episodic traces resulting from autobiographical events. The retrieval of autobiographical memories, even in the absence of specific instructions, seems strictly associated with the activation of mental images (Brewer, 1988).

Cornoldi et al. (1989) investigated the relationship between the generation of different kinds of mental images and memory recall performance. By comparing memory performance for general, specific, and autobiographical mental images, they found that the recall of general and specific mental images did not differ, but autobiographical mental images produced a better recall performance with respect to general and specific ones. De Beni and Pazzaglia (1995) distinguished between self-referred mental images within the personal autobiographical context, in which an individual imagines himself or herself together with the object without a precise episodic reference, and episodic-autobiographical images, representing a specific episode of the subject's life in relation to the object. Episodic-autobiographical mental images increased memory performance with respect to the contextual images but required longer generation times compared with other image categories. This finding could be explained by the fact that the generation of this kind of image requires the previous generation of a general image. It could also be explained by the fact that the search of a particular episode related to the object must take place, or it might be a result of the richness of details of this kind of image.

According to Cornoldi and coworkers (Cornoldi et al., 1989; De Beni and Pazzaglia, 1995) (see **Figure 4**), the mental image generation would start with the retrieval of a global shape information of the object (which can be used to generate a general image) and be subsequently enriched with details, for example, those of a particular exemplar belonging to the category of an object, or contextual information when an object is imagined in a particular context or with reference to characteristics of a familiar type of an object, thus creating the conditions for generating, respectively, a specific and a contextual image. In contrast, the generation of episodic-autobiographical mental images would undergo a different generation process directly involving the retrieval of the image from the episodic-autobiographical memory store.

In an fMRI study, Gardini et al. (2005) provided anatomical support for the results repeatedly observed in cognitive studies. The researchers, in fact, investigated the neural correlates of general and specific mental images from concrete nouns. Results showed different brain activities for both types of images; in particular, general images activated right frontal areas to a greater extent than specific images, whereas specific ones mainly activated the left-superior frontal region and the right thalamus, demonstrating that general images involve brain areas associated with the generation of global images differently from the specific images, requiring additional support from areas in charge of retrieving visual details.

## 2.08.3 Models of Mental Imagery and Memory

Most of the authors studying imagery agree with the idea that not only do the generation and the recall of mental images involve memory systems, but also their maintenance and transformation require temporary systems or subsystems of memory devoted to the treatment of visual and spatial information.

In the following paragraphs, we focus on three different approaches to the relationship between mental imagery and memory. We describe the models of Paivio and Kosslyn, and we discuss the potential role played by the visuospatial working memory system in maintaining and elaborating visual and spatial representations.

### 2.08.3.1 Paivio's Dual-Code Theory

To explain the effectiveness of imageability in predicting memory performance, Paivio (1971) proposed two different categories of processes that people can use when they encode information: images and verbal processes. He proposed studying mental images by observing the influence of imagery on memory performance, starting with a series of studies on nouns

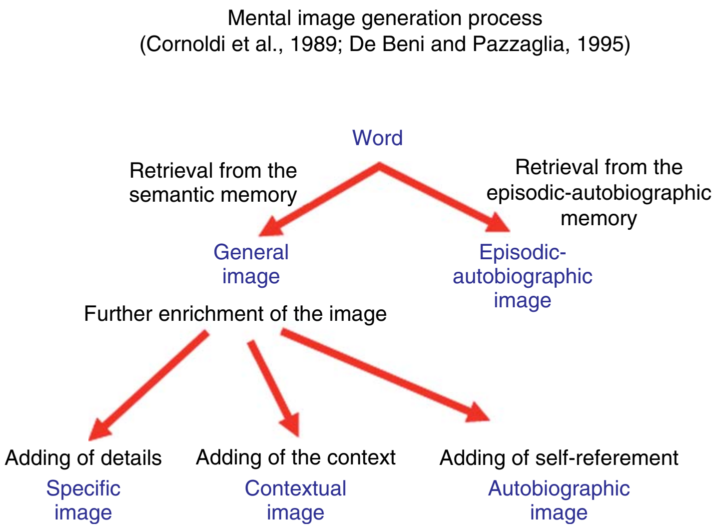

**Figure 4** The generation process of mental images (Cornoldi et al., 1989; De Beni and Pazzaglia, 1995).

and paired-associates recall. Paivio et al. (1968) examined the implications of different indexes of verbal stimuli such as meaningfulness (i.e., the number of verbal associations that a word would elicit in a given period of time), concreteness, the extent to which words refer to a tangible object, imagery value (which refers to the ease or difficulty with which words prime a mental picture), and familiarity for memory performance. Results obtained by Paivio et al. (1968) demonstrated that imagery value and concreteness were strongly related to recall, and meaningfulness and familiarity did not produce an effect on recall when the imagery value was controlled for. A particular result, concerning paired-associate recall, was that concrete-abstract pairs were recalled better than abstract-concrete pairs. The result was interpreted on the basis of the assumption that a prior image can represent an appropriate imaginal tag for subsequent information.

Paivio (1971) proposed a dual-coding theory of mental processing (see a schematic representation of the theory in **Figure 5**). The theory assumes that cognitive behavior is mediated by two independent systems specialized for encoding, transforming, storing, and retrieving information. The verbal system is responsible for the encoding and processing of verbal material and the nonverbal for encoding nonverbal input, such as images. The kind of encoding that a stimulus undergoes depends on three types of variables, that is, the nature of the material (high vs. low imagery value), the instructions given to the participants, and their imagery abilities. Paivio's model (1971, 1978) identifies three levels at which information might be processed. The first is the representational level, where the sensory trace activates the appropriate symbolic representation in long-term memory: The logogens are the basic units in long-term memory for verbal stimuli, whereas the imagens represent the basic units for imagery material. The second is the referential level, where symbolic representations in one system activate corresponding representations in the other system. These interconnections are assumed to be involved in naming objects or in creating the image of an object. In particular, referential connections between the two processes are activated when one kind of information (verbal or imagined) activates the other system. In this case there is double encoding. According to the theory, nouns with high imagery value are subjected to double encoding. "The increased availability of both codes increases the probability of item recall because the response can be retrieved from either code" (Paivio, 1971, p. 208). Finally, the associative level involves associative connections among both verbal representations and images.

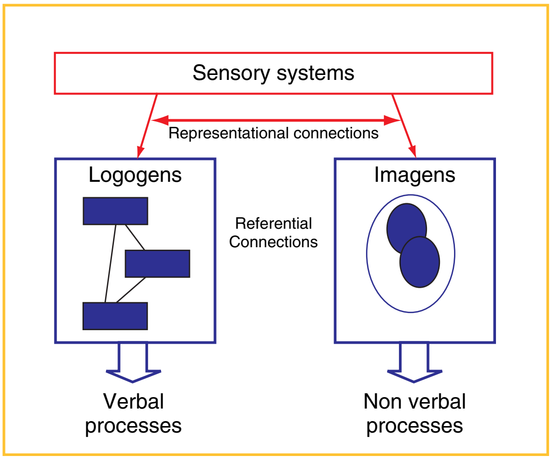

**Figure 5** A graphic representation of Paivio's (1971) Dual-Codes Theory.

### 2.08.3.2 Kosslyn's Visual Buffer

Kosslyn (1980, 1994) proposed a computational model of image generation and provided a description of the functional structures supporting this process. His model is valid for both imagery and high-level visual perception, considered to share structures, functions, and properties. Imagery is a multicomponential process, involving a series of different processes, like image generation, maintenance, inspection, and transformation. Mental generation involves the activation of an image using long-term memory information, inspection of the different parts of an image, and arrangement of the details of an image (Kosslyn et al., 1992, 1995). Mental images do not correspond to simple visual memories but are the result of a multicomponential process that assembles the different parts together and generates a new representation.

Kosslyn's model (1980) was created based on an analogy with computer graphics. Computer graphic files store information in a compressed and nonpictorial form; when they are displayed, they are translated into a mathematical map (bitmap), which specifies the color of each pixel (tiny dot) on the screen. Kosslyn suggested the involvement of two kinds of deep representations: image files containing information regarding the perceptual characteristics

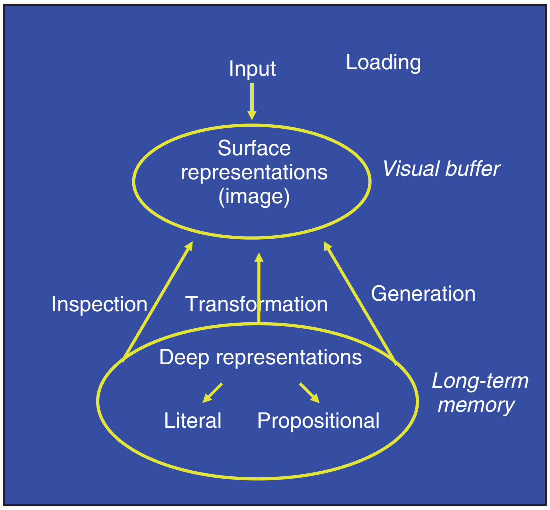

**Figure 6** Schematic representation of the interaction between long-term memory and visual buffer (Kosslyn, 1980).

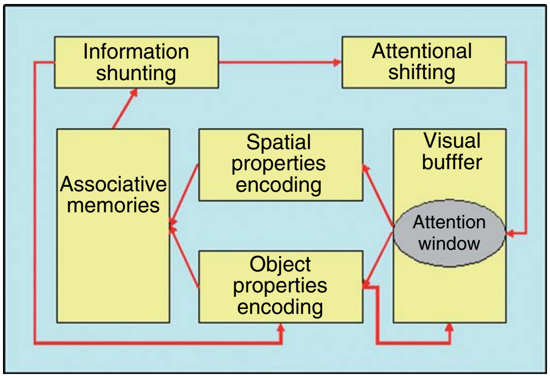

**Figure 7** Processes interacting with the visual buffer (Kosslyn, 1994).

of the skeletal image of objects, and propositional files containing abstract descriptions of objects and their parts expressed in a propositional format (see a schematic representation of the model in **Figure 6**).

Mental imagery activity can be distinguished in a series of processes. For example, the PUT process arranges parts into an image, the FIND guides the top-down search in associative memory, and the PICTURE is responsible for the activation of stored visual representations. However, a different set of processes is hypothesized to be involved in the inspection and transformation of images: REGENERATE refreshes and sharpens the existing images, LOOK FOR searches for a named part within the existing images, SCAN repositions the image by means of a linear transformation, ZOOM increases the resolution of the image, and so on. A critical component of Kosslyn's model is the Visual Buffer, which is considered to be a short-term memory system with spatial properties ($x$, $y$, $z$ coordinates, adjacent cells, etc.) located in the occipital lobe. In fact, the images are generated in the visual buffer either on the basis of information loaded by perception or on the basis of information stored in long-term visual memory (see **Figure 7**). In 1994, Kosslyn revised the model in his book *Image and Brain*, addressing the importance of seven basic components:

- The visual buffer, which holds spatially organized patterns of activation;
- The attention window, which focuses on the information in the visual buffer selected for further processing;
- The object properties encoding system, analyzing the physical properties of an object;
- The spatial properties encoding system, which analyses the spatial location of an object;
- The associative memory, containing information about the physical and conceptual properties of the objects;
- The information shunting, which uses stored information to collect further information about an object with top-down processes; and
- The attention shifting mechanism, which shifts the focus of attention from a specific location to a different one.

### 2.08.3.3 The Visuospatial Working Memory Approach

A partially different approach to imagery was adopted by other researchers, based on the idea that there is a memory system involved during the generation, maintenance, and manipulation of visual information and mental images. The visuospatial working memory (VSWM) approach (Baddeley, 1986; Logie, 1995) to imagery shares many characteristics with the visual buffer system postulated by Kosslyn (1994). However, experimental studies and research paradigms within this framework have followed different directions. The first studies with implications for the link between visual imagery and VSWM were carried out by Brooks in the late 1960s. In particular, in a 1968 study, participants were required to visualize a block capital letter and, following its contour, to answer 'yes' if the corner they mentally followed was on the bottom or the top of the figure and 'no' if it was inside the figure. Moreover, participants could

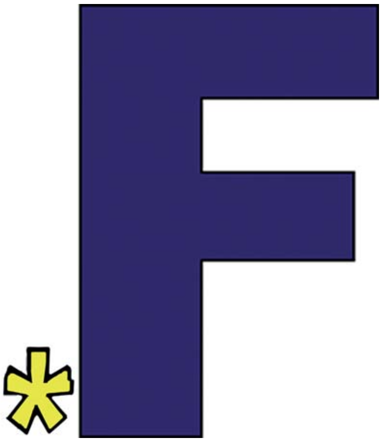

**Figure 8** An example of a mental imagery scanning task used by Brooks (1968): People are invited to mentally move along the contour of a capital letter and decide about the properties of its corners.

respond either vocally or by pointing to the letters Y and N on a sheet (see an example in **Figure 8**).

Starting from the bottom left-hand corner (indicated by the yellow asterisk) and going in the direction of the arrow, the correct responses would be: yes-yes-yes-no-no- and so on. Brooks (1968) observed that participants performed worse when responding by pointing to the letters on a sheet than when giving a verbal response, whereas the opposite happened when they had to scan a sentence rather than an image. Brooks concluded that the visualization of a block capital letter involves different cognitive resources than those used to point to printed words on a sheet. These results were consistent with the view that there is a specialized cognitive system able to process visual inputs and to generate and retain images.

The original working memory model proposed by Baddeley and Hitch (1974; Baddeley, 1986) is a nonunitary system comprising three separate components. The central executive has attentional functions and coordinates the activities of the two slave systems, the phonological loop, which maintains and processes verbal information, and the visuospatial sketchpad, in which visual and spatial information are maintained and processed by two different, but complementary, visual and spatial subcomponents (Della Sala et al., 1999). Salway and Logie (1995) attempted to examine the role of working memory and of VSWM, in particular in imagery tasks, by using several kinds of interferences on a single main imagery task. Specifically, they analyzed the effect of random generation (usually interfering with the central executive component), articulatory suppression (interfering with the phonological loop), and spatial tapping (damaging VSWM) on the performance of the Brooks matrix and a verbal task (1968). Participants were asked, in one condition, to imagine placing consecutive numbers in consecutive squares of a visualized matrix; in the second condition, they had to retain a sequence of consecutive words, for example, ‘good, bad, slow,’ and so on, placing them in a set of nonsense sentences that were to be retained without the use of any form of visual image. Results showed that articulatory suppression damaged the second (verbal) condition, that spatial tapping disrupted the first (spatial) condition, and that random generation interfered with both tasks in an important way. In 1995, Logie suggested a revised model of the VSWM involving a passive visual store (i.e., the visual cache) and an active rehearsal mechanism (i.e., the inner scribe). The visual cache provides a temporary store for visual information (color and shape), whereas the inner scribe handles information about movement sequences and provides a mechanism by which visual information can be rehearsed in working memory.

Within the classic multicomponent model of working memory, there is a debate as to whether mental imagery, having a specific visuospatial format, involves a working memory component, which maintains the specific properties of the information (i.e., the visuospatial sketchpad) or whether it also requires central processes, such as those involved in the central executive system. In the modified view of VSWM (e.g., Logie, 1995), in fact, the generation of an image appears to be the prerogative of the central executive, whereas the retention of its visual and spatial properties may be the responsibility of a temporary store, such as the VSWM system.

On this basis, we could also wonder whether there is a potential overlap between the concepts of VSWM and Kosslyn’s visual buffer. From Logie’s point of view, if the central executive is responsible for imagery generation and manipulation, it would also host the visual buffer controlling the operations involved in imagery maintenance. Kosslyn’s processes acting on the contents of the visual buffer such as GENERATE, ZOOM, SCAN, and so on, could be seen as procedures activated from long-term memory and also operated by the central executive. However, in this case, specific modal processes, in Kosslyn’s model clearly attributed to a specialized system, would be included in the amodal activity of a Central System. Moreover, the visual buffer would contain the visual properties of the image, the information about its location, and any semantic information associated with the image, but these operations would better match the operations of the visuospatial component of working memory.

Within this context, Bruyer and Scailquin (1998), using the dual-task paradigm, analyzed which working memory component is involved in the generation, maintenance, and transformation of mental images, demonstrating that both spatial tapping and random generation interfere with the generation of mental images, but only spatial tapping damages the maintenance of mental images, whereas random generation produces major interference on the transformation (i.e., rotation) of mental images. The difficulties in associating mental imagery with a specific working memory component could be overcome within a continuity model, which assumes that control can be involved at different degrees. In this framework, the VSWM processes may be distinguished according to the degree of controlled activity (see **Figure 9**); in particular, at a lower level, a simple recall of previously acquired information is required, whereas at the higher level, an elaboration of information to produce an output different from the originally presented stimulus is involved (Cornoldi and Vecchi, 2000, 2003). According to this view, a plausible specification of the imagery tasks along the continuum could involve maintenance, inspection, generation, selection, combination, and transformation, respectively ordered on the basis of the active control required (see Cornoldi and Vecchi, 2003).

Another crucial issue in VSWM concerns the nature of the components and of the type of representation maintained in memory. In fact, although there is converging evidence supporting the multicomponential nature of VSWM, there is no agreement on the number and identity of its components. A great number of neuroanatomical data, starting from the work of Ungerleider and Mishkin (1982), has supported the distinction between a spatial and a visual component, for example, by focusing on a where system or on a dorsal stream, processing spatial information, and on a what system or on a ventral stream, processing the features of perceived objects. Another fractionation in VSWM processing was suggested by Pickering et al. (2001), who distinguished between a static format of the generated representations (e.g., a matrix in which locations are presented simultaneously) and a dynamic format (e.g., a matrix in which locations are presented one at a time). A similar distinction was made also by Pazzaglia and Cornoldi (1999) between spatial-sequential and spatial-simultaneous processes: A spatial-sequential task requires recalling spatial positions presented in a sequential format, whereas in a spatial-simultaneous task, participants have to recall positions presented simultaneously. Pazzaglia and Cornoldi (1999) distinguished between these two spatial components and a visual one in which participants have to memorize objects with different shapes, colors, and textures.

## 2.08.4 Paradigms in the Study of Mental Imagery and Memory

Mental images are mental representations, which, just like thoughts, are not directly observable. As Richardson (1969) stated in the early days of the

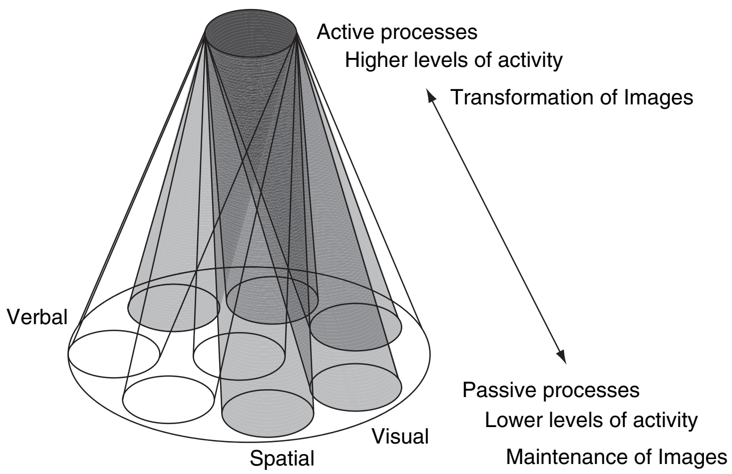

**Figure 9** The continuity model of working memory: Mental imagery involves different portions of working memory differentiated according to the type of content and the degree of control (Cornoldi and Vecchi, 2003).

renaissance of research in this area, the problem regarding mental image investigation is to find a valid method to measure imagery. In fact, from the early days of cognitive psychology, this problem has been at the center of psychological questions concerning imagery. In the present state of research, different methodologies have been developed and applied to the imagery domain, offering the possibility of further investigating this phenomenon.

### 2.08.4.1 Cognitive Paradigms of Mental Imagery Processes

Within cognitive psychology, imagery has been investigated mainly in two different ways. The first examines mental imagery as a dependent measurable variable. It studies qualitative and subjective aspects of imagery and the extent to which mental images are similar to the physical objects that are being imagined. The latter concerns the use of mental images as independent variables (manipulated by researchers) in which observable aspects are reflected in behaviors, and especially in the performance obtained by participants (Richardson, 1999). In this paragraph we focus on the direct study of imagery processes, whereas in subsequent paragraphs, we examine the implications of two main manipulations of variables related to imagery (i.e. materials and abilities).

Studies directly focused on mental imagery representations and processes have used a large range of different paradigms. A few of them have been based on the examination of the subjective imagery experience, as, for example, when people are invited to rate the vividness, or other properties, of their mental images. For example Cornoldi et al. (1992) studied which characteristics influence a vividness judgment; Baddeley and Andrade (2000) examined which manipulation depresses mental imagery, inferred by decreases in the experience of vividness.

A problem with the use of subjective experience ratings is that they are affected by the criterion people use to decide whether or not their image is of a high quality. Since Galton's (1883) first started using vividness ratings to find people with different imagery abilities, the problem has been to decide to what extent vividness ratings describe differences in representations and to what extent they describe differences in criteria. For this reason, the majority of studies focusing on the properties of mental images have also used more objective criteria, such as time, effects of the experimental manipulations, verbal descriptions of the results of imagery processes, drawings, and external ratings (for a review, see Pearson et al., 2001). For example, in the mental pathway task, people are invited to imagine a matrix with a series of cells (e.g., a simple 5 × 5 board), imagine following a pathway on the board in correspondence with the verbal instructions given (go left, down, etc.), and point, on request, to the position reached at the end of the instructions on a corresponding blank matrix. This task has been particularly successful in studying the strengths and deficits of mental imagery processing in totally congenitally blind individuals (e.g., Cornoldi et al., 1991).

The chronometric study of mental imagery has produced the main experimental paradigms in the field. The most popular paradigm is surely represented by the so-called mental rotation tasks, derived from the traditional psychometric literature on spatial abilities testing, requiring a decision of whether two figures are differently oriented examples of a single figure, or if one of them is actually different (typically its mirror image) from the other. In a series of very influential studies, Shepard and coauthors (e.g., Shepard and Metzler, 1971) reconsidered the method and manipulated the angular variation between the two pictures (see examples in **Figure 10**). They found that the time necessary for giving a response was a function of the rotation angle, showing how the decision was not based on a consideration of the properties of the object (feature $x$ is on the right of feature $y$, feature $z$ is above feature $y$, etc.), which would not have been affected by the rotation angle but was based on a process of mentally rotating one figure to see whether it perfectly matched the other one.

There are many other examples of chronometric studies of mental imagery. For example, in the preceding paragraphs, we provided examples of image generation tasks, such as images generated from a verbal label, and mental scanning tasks (e.g., scanning an island or a capital letter). In fact, in the popular taxonomy of mental imagery processes, generation, scanning (and inspection), and transformation represent three classic cases. A fourth case is

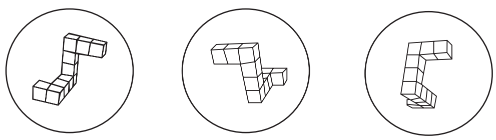

**Figure 10** Examples of pictures used for a mental rotation task: People must decide as quickly as possible if the two figures are identical or mirror images.

imagery maintenance, which can be studied either with the classic paradigms of visual memory or with reference to subjective experience (people are invited to press a button when they realize their image is vanishing).

In the field of imagery transformation, the quality of the image can be directly derived from the verbal response of the individual. For example, in a mental subtraction task, people must generate an image from the visual exposure of a drawing and then a subsequent image from the visual exposure of a part of it; their task is to subtract the second image from the first and report the verbal label of the resulting image (see **Figure 11**). Brandimonte et al. (1992b) found that the performance in this task is facilitated by the block of verbalization.

Other studies focused on different types of mental synthesis, where participants are required not only to maintain and combine different images but also to produce a different image unrelated with the single primitive images. This particular case, given the novelty and the potential originality of the final result, has also been considered an example of creative imagery. Finke and his colleagues (Finke et al., 1989) asked subjects to carry out a series of transformations on imagined figures mediated by verbally presented instructions. The transformations were designed so that the final pattern would resemble a familiar object, as in the following example of the task: Imagine a B, now rotate the B 90 degrees to the left, then add a triangle below the rotated B, and finally report what the resulting pattern looks like (see **Figure 12**).

A different and more recent example of an imagery transformation task was suggested by Vecchi and Richardson (2000), who devised the jigsaw puzzle test, considered by the authors as an active VSWM task, because participants must hold in mind the arrangement of the puzzle pieces and actively mentally manipulate their combination. In fact, the task requires that the puzzle be solved by moving the pieces only mentally, without actually touching or moving the pieces in question (see an example in **Figure 13**). Drawings represent common, inanimate objects derived by Snodgrass and Vanderwart (1980), with a high value of familiarity and of image agreement. Each puzzle is numbered, and participants give their responses by writing down the corresponding number of each piece on a response sheet.

The study of imagery processes can also be based on a fractionation of complex processes into more simple ones and on the individuation of measures tapping the most simple components, as illustrated by a series of studies by Postma and coauthors. In an analysis of memory for locations, Postma and De Haan (1996) separated the object location memory into three processes: the first process requires encoding metric information and the coordinates of a particular object located in the environment; the second process, called object-location binding, requires linking the object's identity to its position; and finally, the last process integrates the first two mechanisms and combines metric information with object identity and location (Kessels et al., 2002a,b).

**Figure 11** Examples of stimuli used for mental subtraction tasks: People, after exposure to the visual stimuli, must imagine the subtraction of the second part from the first and decide which is the resulting pattern (in this case a fish, a papillon, and a cloud).

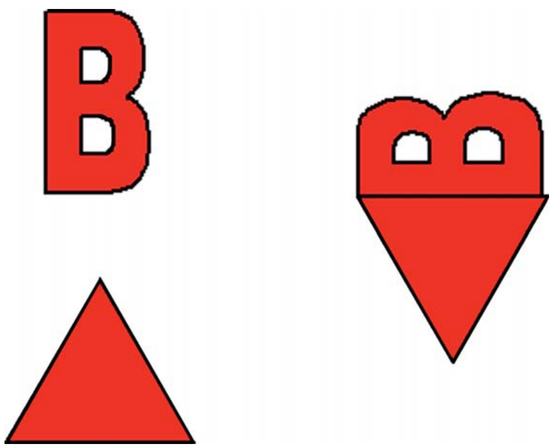

**Figure 12** Example of a creative synthesis task.

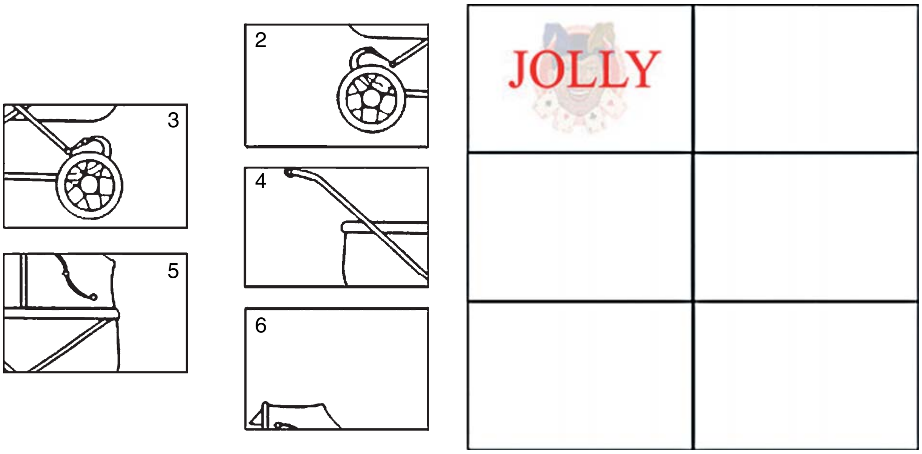

**Figure 13** Example of an item derived from the jigsaw puzzle test (adapted from Vecchi and Richardson, 2000).

### 2.08.4.2 Neural Implications

Neuropsychological paradigms have also been useful in the study of visuospatial imagery. They offer data that have increased, in many respects, our knowledge of mental imagery processes and representations. In particular, the study of single cases has revealed important dissociations and relationships. For example, Bisiach and Luzzatti (1978) reported evidence that a unilateral neglect disorder, which usually causes patients to ignore the left half of the visual field, can also result in deficits in mental imagery. They offered the example of Milan's famous Piazza del Duomo: A patient with an unilateral neglect in front of the cathedral will typically ignore the left part of the square, but – in the case of Bisiach and Luzzatti's patient – the same experience happened in the area of a mental imagery representation. In fact, invited to imagine being in front of the cathedral, the patient was not able to describe its left part. This difficulty was not related to a preceding perceptual difficulty, nor to the particular characteristics of the square, because – when invited to imagine the square giving his back to the cathedral – his imagery block involved the other side of the square (i.e., the side accurately described when facing the cathedral).

Deficits can also be purely confined to visual imagery (Beschin et al., 1997). Farah et al. (1988) reported the case of a patient who had perceptual abilities and object recognition preserved. He was also able to copy drawings correctly and to draw objects from memory, but he could not correctly answer sentences requiring imagery for verification, for example, "An elephant is larger than a mouse." Goldenberg (1989, 1992) demonstrated that patients with left temporo-occipital lesions were unable to take advantage of imagery instructions in verbal learning tasks.

The study of severe neuropsychological patients has been integrated with the study of groups of individuals hypothesized, for different reasons, to have specific difficulties in visuospatial working memory or in mental imagery tasks (for a review, see Cornoldi and Vecchi, 2003). Examples of these groups are blind individuals (e.g., Cornoldi et al., 1991; Cornoldi and De Beni, 1988), children with nonverbal/visuospatial learning disabilities (Cornoldi et al., 1999; Cornoldi and Guglielmo, 2001; Mammarella and Cornoldi, 2005), elderly people (Vecchi and Cornoldi, 1999; Richardson and Vecchi, 2002), and individuals with specific genetic syndromes (Lanfranchi et al., 2004).

With the development of more sophisticated brain-mapping techniques, the study of imagery has taken further steps forward. In fact, from the pioneering work of Roland and Friberg (1985), who studied the variations of cerebral blood flow on the basis of the visualization of familiar routes, a great number of imagery studies have been carried out with neuroimaging techniques. Some of the questions research has tried to answer are: How do differences in brain activation inform us about the nature of different kinds of imagery? What kinds of brain areas are activated during generation, maintenance, and transformation of mental images? Does mental imagery share common cortical structures with perception, memory, or motor control?

Neuroimaging methods can be classified into two main groups: electromagnetic techniques, such as MEG (magneto-encephalography) and ERPs (event-related potentials), which have excellent temporal resolution but poor spatial resolution, and techniques, such as PET and fMRI, which have good spatial resolution and coarse temporal resolution. It is noteworthy that although neuroimaging techniques can identify regions associated with a cognitive task, they cannot determine which of these regions are crucial for performing the task. For this reason, neuroimaging findings may be complemented with data provided by experimental and neuropsychological methods.

A central issue in the field of imagery is whether those visual areas involved when an object is perceived are also involved when an object is imagined. For example, Kosslyn's theory (1994) predicts activation during mental imagery activity in early visual processing regions (i.e., striate and extrastriate cortex). A series of experiments by Kosslyn and colleagues (Kosslyn et al., 1993, 2001; Kosslyn and Thompson, 2003) provided support for similarities between visual perception and visual imagery; other studies, however, have suggested that primary visual cortex is not activated during visual imagery (Roland and Gulyas, 1994; D'Esposito et al., 1997; see Cabeza and Nyberg, 2000 for a review). Roland and Friberg (1985) asked subjects to visualize the successive view along a route in a familiar environment. The task induced blood flow increase in the superior prefrontal cortex and, in particular, in the superior occipital cortex, the postero-inferior temporal cortex, and the postero-superior parietal cortex. These associative regions are also activated during processing of visual information. However, the authors did not find an activation of the primary visual cortex. According to Kosslyn et al. (1995), the right hemisphere is responsible for generating mental images from memory, whereas the left hemisphere is advantaged in the generation of visual mental images (see also Trojano and Grossi, 1994).

Charlot and coauthors (1992) selected high- and low-imagery participants and involved them in a task requiring the conjugation of abstract verbs (verbal task) and in a mental exploration of a memorized spatial configuration (imagery task). Their results revealed different patterns of activation for high (left-sensory motor cortex in the verbal task and left temporo-occipital cortex in the imagery task) and low imagers, who showed less differentiated increase of their cerebral activity. In Mellet et al.'s (1995) study, participants were required to inspect and memorize a map of an island with six landmarks. The cerebral blood flow was recorded as the participants performed either perceptual (the subjects were shown the map and asked to scan from landmark to landmark) or imaginal scanning of the map (performing a mental scan without looking at the map). The results revealed a common network of cerebral areas, in particular, bilateral superior external occipital regions, reflecting the processes involved in the generation and maintenance of visual images, and the precuneus (left internal parietal region), reflecting the scanning process. In this study, the parietal regions were involved in an imagery process with a spatial component. This latter result is consistent with the already mentioned hypothesis (Ungerleider and Mishkin, 1982) of a distinction between a dorsal stream (spatial system), running from the occipital to the parietal cortex, involved in the perception of spatial locations, and a ventral stream (visual system), running from occipital to the infero-temporal cortex, involved in the recognition of objects. The results obtained by Mellet and colleagues (1995; see also Mellet et al., 1996) revealed that the spatial system is engaged in both mental scanning of visual images and mental scanning of mental images.

#### 2.08.4.3 Imagery Value

In the study of the indexes of verbal materials best predicting memory performance, imagery value has usually resulted as the best predictor (Paivio, 1971), whereas the effects of item frequency/familiarity and associative value/meaningfulness resulted in weaker results and were partly explained by imagery value. This result was interpreted by Paivio (1971) as proof of the dual-code theory; in fact, a high-imagery-value item (e.g., the word 'train') evokes both a verbal and an imaginal encoding, and the double encoding enhances enhance the probability to get back the item. On the contrary a low-imagery-value item (e.g., the word 'range') only evokes a verbal encoding and thus has a poorer trace and a reduced probability to be recovered. Paivio (1971) also assumed that pictorial material has, by definition, a high imagery value and thus, if verbalizable, has the highest probability of having a double encoding; in other words, the picture superiority effect (better recall of the verbal label of a presented picture than of the corresponding presented word) should be caused by the same reasons that explain the superior recall of high-imagery words with respect to the recall of low-imagery words. However, this conclusion raises a series of perplexities (for a review, see Cornoldi and Paivio, 1982; Marschark and Cornoldi, 1990) because high-imagery verbal material differs from low-imagery verbal material in many respects only partly related to the use of mental imagery.

Different paradigms have been used to analyze the specific effects of mental imagery on the recall of high-imagery-value materials. For example, in a dual-task paradigm, participants are presented with a main task, which in this case can involve the retention of the high-imagery-value material. Simultaneously, they are also required to perform a secondary task, most of the time tapping one of the working memory components. (Some studies that have employed the dual-task paradigm have been presented in the preceding paragraphs, e.g., Salway and Logie, 1995; Bruyer and Scailquin, 1998). In a series of studies (e.g., Colpo et al., 1977), we simultaneously presented words, either with high or low imagery value, and pictures, and we found that the memory for high-imagery-value words was selectively impaired, suggesting that high-imagery words and pictures relied on the same type of resources.

A different paradigm concerns the manipulation of instructions. In general, specific instructions encouraging the use of mental imagery enhance memory with respect to instructions encouraging the use of a non-imagery strategy (e.g., repetition); furthermore, this effect seems to interact with the imagery value of the material, although the latter effect is not always clear (for a review, see Richardson, 1999).

### 2.08.4.4 Individual Differences in Imagery Abilities

The study of mental imagery has often used an individual differences approach, as already anticipated in the section concerning neuropsychological evidence. Also, within normal populations (i.e., in the absence of severe deficits), imagery ability differences can be observed. Actually, some of the tasks used for measuring spatial abilities require the maintenance and the manipulation of mental images, as in the case of tasks requiring mental rotation or the mental transformation of parts (mental folding, mental assembly, etc.). The traditional preference for imagery transformation tasks over other spatial tasks in the psychometric assessment of spatial abilities seems to result from the fact that the imagery transformation tasks involve a high degree of control and are thus central and related to the central structures of intelligence; however, at the same time, they maintain specific spatial features and are not only theoretically but also empirically distinguishable from other high-control tasks tapping verbal functions (Cornoldi and Vecchi, 2003).

Individual differences found with the use of objective measures are related to independent measures obtained with neurological (e.g., Charlot et al., 1992) and cognitive procedures. An example of this relationship is represented by the ability of solving ambiguous figures (Cornoldi et al., 1996). For example, Mast and Kosslyn (2002) found that the ability of rotating images was highly associated with reports of image reversals subsequent to an 180-degree rotation of a figure, whereas other imagery ability measures were not.

In the mental imagery field, the repertoire of differential measures has been enriched by many other measures, including subjective ones. Despite their methodological limitations, the self-report measures have been largely used and have produced a series of different tools. For example, the VVIQ test (Marks, 1973) requires that a person imagines, with either open or closed eyes, a scenario (e.g., a sunset) and reports how vivid his/her image is. The imagery ability is directly inferred by the sum of the values given to the different activated images. There have been concerns regarding the value of this subjective measure, voiced from different sides, but there is evidence that in some cases it may be a useful method (for a review, see McKelvie, 1995). For example, a VVIQ score may be predictive of the performance in a task requiring the memorization of visual objects. However, there is evidence that in some cases other types of subjective reports may have better predictive power. In particular, Graham and Morris (2003) suggested that a lack of a relationship between subjective measures and performance could be because they tap different components of mental imagery. To investigate this, the researchers administered two spatial tasks and two different self-report questionnaires to a group of subjects. One self-report, the VVIQ, mainly involved subjective visual experiences derived from long-term memory, whereas the other included items of the same kind used in the spatial tasks. They found that only the latter items predicted spatial performance, whereas there was no relationship between VVIQ and objective measures.

## 2.08.5 Educational and Other Applied Implications

The role of mental imagery in human cognition, for example, in reasoning, comprehension, and creativity, has been illustrated in several studies (Paivio, 1971; Richardson, 1999). This evidence suggests that training to effectively use visualization processes could enhance cognitive performance in many areas.

A well-known example of how mental imagery can be used in an educational context is represented by imagery mnemonics. This point was already emphasized by ancient Greeks and Romans, who stressed the importance of using mnemonics to improve learning. However, in the history of culture and education, the attitude toward mnemonics alternated between moments of enthusiasm, resulting from the enhancement of memory, and criticisms, resulting from the artificial connection between memory content and memory cues. For example, Cicero and Giordano Bruno were in favor of mnemonics, but Erasmus and Montaigne were not (Yates, 1966). Despite these different views, there is general agreement that mnemonics enhance memory and that they rely largely on the use of mental imagery (for a review, see Higbee, 1988). One key principle of imagery mnemonics is the creation of interactive images, which facilitates the retrieval of an element when the element imagined in interaction is available.

Mnemonics can be distinguished into two categories according to whether they rely on a specific rule or they require the prior creation of a cues file, and both categories of mnemonics very often rely on the use of mental imagery. Mnemonics based on a rule are of many different types. In the chaining mnemonics, people form a series of interactive images by combining in pairs the sequence of items. For example, given the sequence 'radio, cat, window, salad, etc.,' one could form the interactive image of a radio turned on by a cat, then a subsequent image of a cat jumping onto the windowsill, a window placed above a bowl of salad, and so on.

Another rule-based mnemonic that has received a lot of educational uses is represented by the keyword technique, mainly used for the study of foreign languages. The technique requires people to give a concrete imaginable meaning to the foreign word by associating it with a word in their own language with a similar sound. They then form an interactive image including the images of the new word and the word corresponding to the real meaning of the foreign word. The example given in **Figure 14** shows how a person could remember the Russian word 'likor' for 'battleship'. His first task would be to find an imaginable word similar in sound to the Russian word 'likor,' for example, Lincoln or liquor. The second task would be to create an interactive image including, for example, Lincoln and a battleship. As the two elements are very different in size, the person could use a zooming process to give a name to the small individual represented on the deck of the battleship.

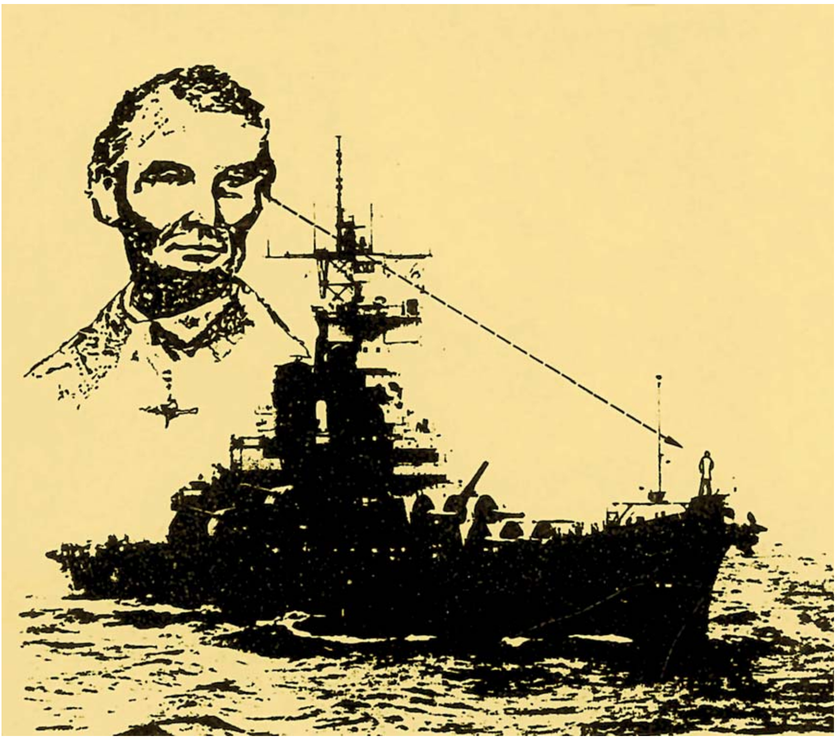

**Figure 14** Example of the use of the key-word technique to learn a foreign word ('likor' for 'battleship').

Despite the fact that imagery mnemonics can be considered artificial and distinguished from mnemonics based on semantic associations, in many cases the two components can act together. The example given in Figure 15 represents this possible synergy. In fact, a child trying to memorize the patterns illustrated in the matrix could simply rely on the semantic associations between items (e.g., a dish and a bowl can stay together), or the more effective rule of categorical clustering (a hen, a duck, a chicken, and a rabbit are all animals). However, the child could also take advantage of the memory of the visual form of the represented objects and the possibility of imagining them in interaction (a farm scenario with the animals, a bowl above a dish, etc.).

Mnemonics based on a cues file requires people to have already created a file containing a series of organized images that will be imagined in interaction with the new to-be-remembered material. At retrieval, the well-known cues file will be used for retrieving the new information memorized in interaction. Expert memorizers have always given preference to this category of mnemonics because it offers the possibility of storing huge amounts of material. There are reports of experts who created files of thousand of cues, either organized around spatial layouts or (more often) organized sequentially in correspondence with the number sequence. The most well known mnemonic based on a cues file is represented by the loci mnemonics, where people use landmarks arranged along a well-known pathway as cues. The example given in Figure 16 is adapted from the illustration given by Lindsay and Norman (1977) in their psychology handbook, where the pathway was in fact the route followed by Donald Norman to reach the Department of Psychology of the University of California at San Diego, starting from his home. The first landmarks selected by Norman were in sequence: (a) his own home, (b) the bay, (c) the train railway, and so on. Having to memorize a sequence of words, Norman could associate them with the sequence of landmarks (e.g., a radio left close to the gate of his home, a cat looking at a boat in the bay, a broken window on a train). If required to remember the sequence of words in perfect order, people using the loci mnemonics have no

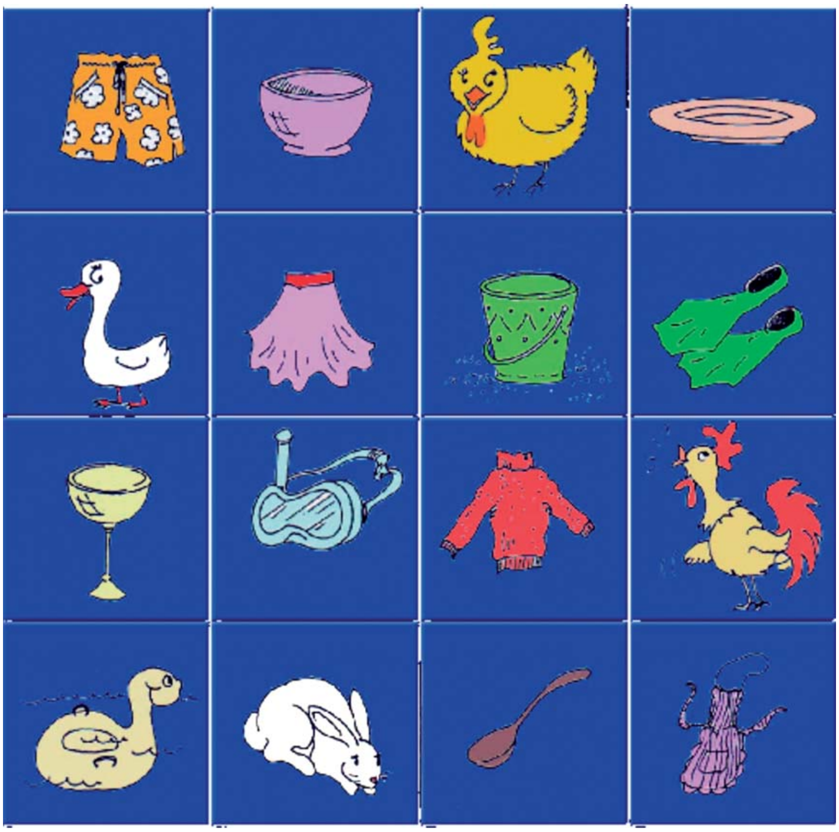

**Figure 15** Example of memory material that can take advantage of both semantic and mental imagery strategies.

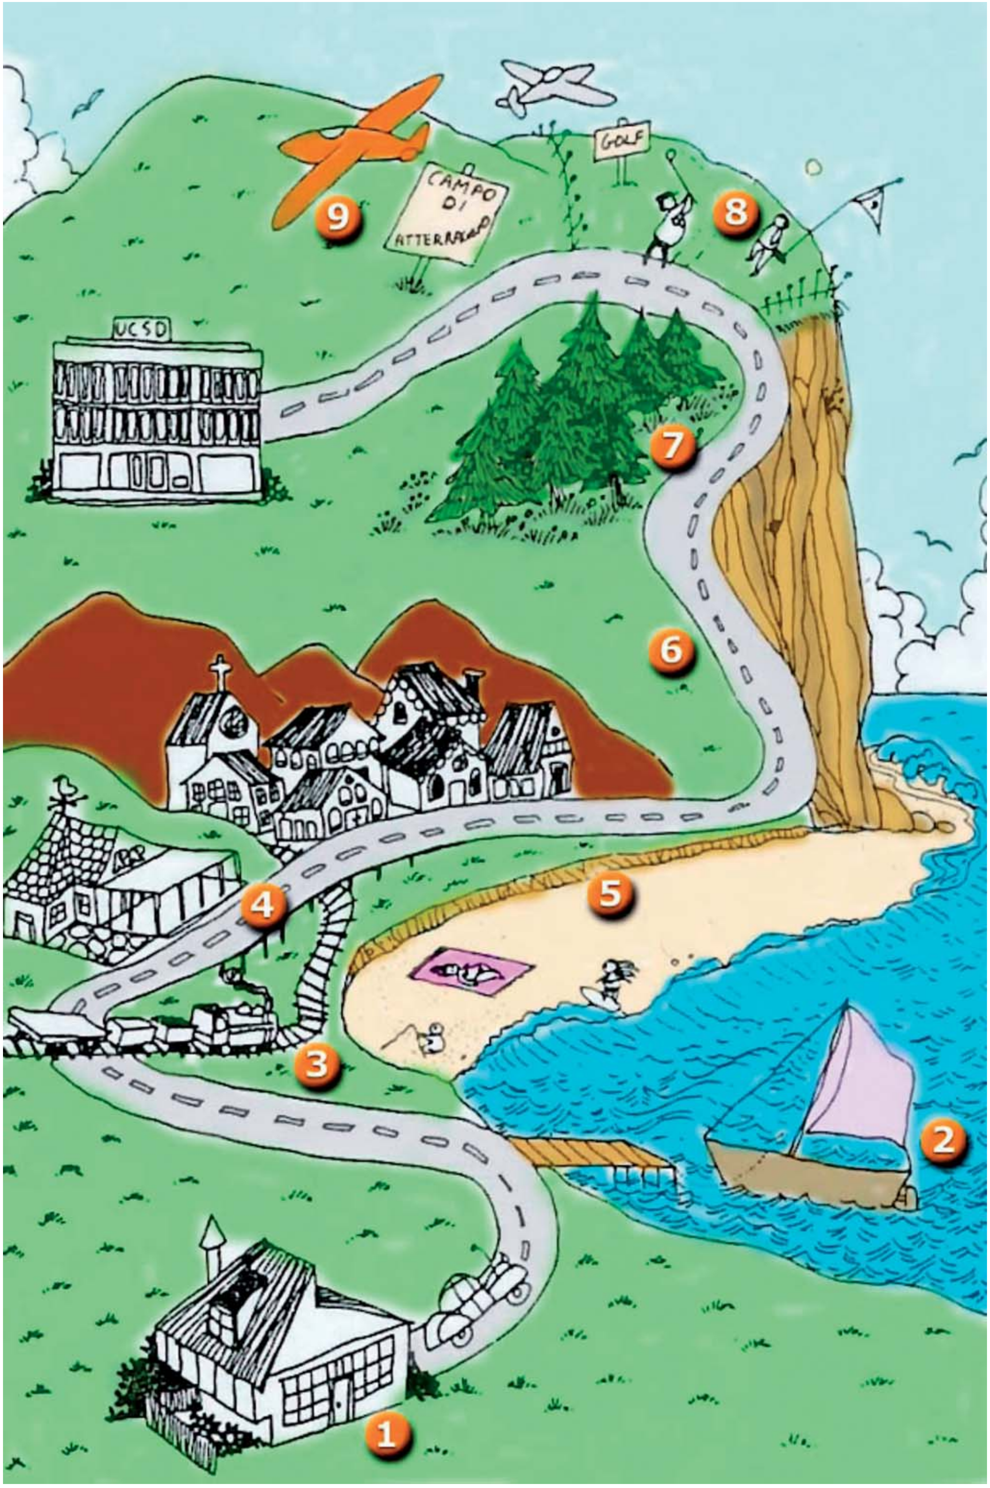

**Figure 16** An example of figure employed for using the loci mnemonic. Adapted from Lindsay PH and Norman DA (1977) *Human information processing,* 2nd edn. New York: Academic Press.

problems in retrieving their well-known route with its landmarks and thus retrieve the elements imagined in interaction with their landmarks.

A critique advanced against the loci and other imagery mnemonics is that they can be successfully used for memorizing isolated arbitrary series of items but do not offer an advantage in memorizing meaningful texts. However, there is evidence that loci mnemonics can also enhance memory for texts, although its advantage is more evident when a text is orally presented than when it is written, because of the competition of visual processes involved in imagining and reading (Cornoldi and De Beni, 1991).

## 2.08.6 Concluding Comments

Mental imagery represents a very relevant part of mental life. Because of its pervasiveness, internal status, and complexity, its study raises a series of methodological problems and requires differentiations and specifications. In this chapter we described mental imagery with reference to different approaches and theories. In particular, we illustrated the debate between prepositional and imagery theorists and the efforts devoted to distinguishing between different imagery processes and representations. The classical problem concerning the extent of the analogy between visual perception and visual mental imagery may find a response in the consideration of the differences from images directly derived from experience and images generated from long-term memory information. Furthermore, the consequences resulting from the use of different types of long-term memory information can be examined within the approach distinguishing between general, specific, and other types of mental images. However, many issues in the field, for example, the dynamic nature of mental images, their role in different life activities (like creative processes, thinking, meditation, and so on), and the study of individual differences, appear still in need of further research developments.

# 2.09 Distinctiveness and Memory: A Theoretical and Empirical Review

**S. R. Schmidt**, Middle Tennessee State University, Murfreesboro, TN, USA

## 2.09.1 Introduction

My memories appear as a varied landscape, with fields and trees and distant mountains. I can distinguish each blade of grass at my feet, I see the individual veins on the leaves on a nearby tree and the brown corrugated grain of the tree's bark. Farther away, the blades of grass are lost in a field of green, and the trees on the hillside are marbled clumps of color. However, I can clearly see a lone tree in the middle of a distant field. On the horizon I can see the blue haze of the mountains, occasionally interrupted with an outcrop of white rock. I know the mountains must be covered with trees, but I cannot separate one from another. The clarity of my memories, like the clarity of my perceptions, appears to be determined by both distance and contrast. In this manner, contrast, or distinctiveness, is a fundamental concept in any theoretical treatment of memory.

Theory and research concerning distinctiveness and memory have long and fascinating histories that have been recounted in detail elsewhere (see Wallace, 1965; Schmidt, 1991; Hunt, 1995). These histories unfailingly begin with Hedwig von Restorff, a post-doctoral assistant in Wolfgang Köhlers's laboratory. von Restorff was one of the first to argue that the Gestalt perceptual principles applied to memory traces (Geissler, 2001). Principles of organization and the perception of figure and ground lend themselves nicely to the clarity of memory for that metaphorical lone tree in the field. von Restorff (1933) argued that "the rules according to which the reproducibility of items is a function of the structure of the list are consistent with the laws governing whether individual parts in the field of vision remain independent or integrated into a perceptible whole." (Von Restorff, 1933: p. 323) The perception of a single "figure in a whole" (or tree in a forest) is impaired because it becomes a part of the whole. The perception of a tree in a field does not suffer from such interference (Von Restorff, 1933: p. 327). Studies of the von Restorff effect and distinctiveness effects in general can be seen as attempts to understand the good memory for the metaphorical lone tree.

In the following pages, I provide a summary of theoretical and empirical treatments of the concept of distinctiveness in memory research. I begin with a few of my own organizational principles, followed by three theoretical perspectives on distinctiveness in memory. Then I provide a rather long catalog of empirical phenomena that roughly fit under the distinctiveness umbrella. I conclude with a cautionary note concerning the usefulness of distinctiveness as a theoretical construct.

## 2.09.2 Organizing Principles

Imagine that I am looking at a giant oak tree at the height of fall colors. My visual field is completely filled with the image of the tree, and every leaf on the tree, save one, has turned bright red. The green leaf stands out in this perceptual field. There is nothing unusual about a green leaf; it gains its distinctive character by virtue of its context. In contrast, I do not recall ever seeing a purple polka-dot leaf on a tree. Perhaps a purple polka-dot leaf on a tree would be distinctive in any context. Note that individual leaves on a tree full of purple polka-dot leaves would not stand out from one another. However, the tree as a whole would stand out in a typically green forest. Thus, when one tries to define the distinctiveness of an experience, one must consider the domain, or to push the metaphor, the field of view.

Toward this end, researchers often distinguish between context-dependent, or primary, distinctiveness and absolute or secondary distinctiveness (Schmidt, 1991). Primary distinctiveness (from W. James's primary memory) is defined relative to the immediate context or, for example, a list of words in a memory experiment. For example, a tall tree in the middle of a field of grass stands out in its immediate context, and a single word printed in red stands out in the context of a list of words all printed in black. Secondary distinctiveness is defined with regard to the previous history of the observer and to experiences stored in long-term or James's secondary memory. Examples of secondary distinctiveness might include seeing a purple polka-dot tree or reading the sentence: The banker floated across the puddle on a newspaper.

This discussion of primary and secondary distinctiveness naturally leads to a discussion of experimental design or, more specifically, list structure. The study of primary distinctiveness requires a within-subjects or mixed-list design. That is, the participants must experience material that stands out within the experimental context. In contrast, secondary distinctiveness can be studied in both mixed-list and between-subjects design. For example, suppose one were interested in the effect of word frequency on memory. In a between-subjects design, one group of participants could view a list of frequent words, while a second group would view a list of infrequent (i.e., distinctive) words. In a within-subjects design, participants would view a mixed list of frequent and infrequent words. Interestingly, the word frequency effect in recall may only appear in mixed-list designs (DeLosh and McDaniel, 1996).

Researchers have also wrestled with the problem of the locus of the effect of distinctiveness in memory research. von Restorff addressed this issue when she stated, "Either similar forces are at work in the 'trace field' as are in perception, *or* [her emphasis] our results are merely the direct results of Gestalt effects in perception" (von Restorff, 1933: p. 323). In modern terms, we might ask whether the effects of distinctiveness result from processing differences during encoding or differences in the stored representations or arise during the retrieval stage. von Restorff concluded that the effects operate on the memory traces, combining representational and retrieval views of distinctiveness. Other researchers have concluded that all three stages contribute to the effects of distinctiveness (see Schmidt, 1991, and Hunt, 1995).

McDaniel and Geraci (2006) argued that the effects of primary distinctiveness typically occurred at the retrieval stage, whereas secondary distinctiveness effects resulted from both encoding and retrieval processes. With manipulations of primary distinctiveness, memory for the nondistinctive surrounding items on a list is not impaired, particularly on measures of recognition memory (Schmidt, 1985). This suggests that the processing of the distinctive item does not distract from the processing of the common items on the list. In addition, the position of the distinctive item within the list does not seem to impact the effect of primary distinctiveness. That is, the distinctive item is well recalled even when it is the first item in the list (Hunt, 1995). In this list position, the distinctiveness advantage must have resulted from the item standing out in memory rather then during its initial presentation. In contrast, with secondary distinctiveness (e.g., bizarre sentences), the presence of the distinctive items appears to impair memory for the common items, and list position is an important factor. For example, McDaniel and Geraci (2006) found that bizarre and common sentences were recalled equally well if the bizarre sentence appeared in the first half of a list. The typical bizarreness advantage was found when the bizarre sentences appeared in the second half of the list. These results demonstrate the importance of encoding processes in supporting the effects of secondary distinctiveness. Retrieval processes also play an important role. For example, the relatively good memory for bizarre sentences is often found in free recall but not cued recall (Einstein and McDaniel, 1987) or serial-order recall (McDaniel et al., 2000).

Despite McDaniel and Geraci hypothesis, few would argue that encoding and perceptual processes are not important in primary distinctiveness. After all, the green leaf on a red tree will not stand out if one is colorblind. That is to say, the features that support trace distinctiveness must be encoded. For example, consider the experiment reported by Van Overschelde et al. (2005). Research participants viewed names of American football teams (e.g., Texas Longhorns). In one condition, this list contained only the names of college teams, and in a second condition, the list contained one college team isolated in a group of professional teams. Only participants with a high knowledge of football, who were thus able to discriminate between professional and college teams, showed a memory advantage for the isolated name. Hunt and Lamb (2001) asked participants to name either a similarity or a difference between adjacent words in a list. In the control list, all the words belonged to the same conceptual category (e.g., tools). In the isolation list, one word was from a different conceptual category (e.g., vegetables) than the other words on the list. The typical isolation effect was found following the same judgments, but not following the difference judgments. Clearly, prior knowledge and encoding strategies play an important role in producing the effects of primary distinctiveness.

## 2.09.3 Theoretical Perspectives

From the discussion in the preceding section, we can see that the domain, the type of experimental design, and the locus of the effect are all central to studies concerning the impact of distinctiveness on memory. In addition, researchers have offered numerous definitions of distinctiveness (see Schmidt, 1991, and Hunt, 2006, for reviews). These include the ideas that distinctiveness is a property of an item, an item in context, a property of a memory trace, a property of a retrieval cue, a property of a cue in a context, a type of processing, and the response of an individual to a stimulus. Definitions of distinctiveness are typically tied to theoretical perspectives, and numerous theories have been proposed. The theories can be grouped into three primary classes: organizational theories, representational theories, and those theories focusing on the affective response of the perceiver. Each of these perspectives is outlined below.

### 2.09.3.1 Organizational Theories

Organizational theories can trace their roots to von Restorff, and thus to Gestalt approaches to psychology. Within this framework, a distinctive item is apart, or in a different category, than its physical or temporal neighbors. Thus, in a list-learning task, the distinctive item changes the organizational structure of the list. Bruce and Gains (1976) used this account to explain clustering of related isolated items in free recall. These results could not easily be explained by increased attention to or rehearsal of (Rundus, 1971) the distinctive items.

Reed Hunt and his associates have offered several elaborations on organizational approaches. These are variously referred to as the distinctiveness hypothesis (Hunt and Mitchell, 1978; Hunt and Elliot, 1980; Hunt and Einstein, 1981; Hunt and Mitchell, 1982), the organization and distinctiveness view (Hunt and McDaniel, 1993), and most recently and generally, as distinctive processing (Hunt, 2006). A common theme running through this research is the focus on individual item and relational processing in memory. For this reason, I refer to this approach as the individual item/relational processing view. Individual item (distinctive) processing serves to distinguish each item form other items in a set. Relational processing highlights features shared by items within a set, helping to delineate the search set. Depending on the nature of the set of items and the retrieval context, each kind of processing can be beneficial to memory performance. Within this framework, "distinctiveness is the processing of difference in the context of similarity" (Hunt, 2006: p. 22). So, for example, in a group of relatively homogeneous items individual item (distinctive) processing would serve to differentiate the items and greatly improve recall (see the discussion of the Hunt and Lamb, 2001 study in section 2.09.2). However, in a list of unrelated items, relational (organizational) processing would benefit recall more than individual item processing.

Organizational approaches have numerous strengths. These include their application to both recognition and recall performance and their explanation for the effects of distinctive items on organizational processes in free recall. In addition, the general framework is applicable to a wide range of phenomena, including the isolation effect, the bizarre imagery effect, the humor effect, the word frequency effect, and the concreteness effect. Each of these effects, and their relation to distinctiveness, is discussed in section 2.09.4. The drawback of this approach is that it treats distinctiveness as an explanation, or a theoretical construct, rather than as an independent variable (Hunt, 2006). As such, Hunt's ideas can be used to explain why a distinctive item is well remembered in a given situation. However, the approach does not specify a direct measure of the distinctiveness of an experience. That is to say, it cannot predict what conditions will produce mnemonic isolation.

### 2.09.3.2 Representational Theories

According to a representational approach, the distinctive item has a memory representation that shares few features with other items in memory. That is, distinctiveness is the converse of similarity as defined by researchers such as Tversky (1977) and Shepard (1987). Thus, unlike Hunt's individual item/relational approach, this approach starts with a specification of what makes an item distinctive, and the focus is less on the processing or organization of an experience and more on static/mathematical ratios. Representational approaches can be traced to Murdock (1960) and his conveyor belt model (Murdock, 1972, 1974). In Murdock's approach, each item is assigned a value along some dimension (e.g., time or size). The distinctiveness of an item is then defined as a function of the sum of the difference between that item and other items on a list. Relative distinctiveness of a set of items is then defined as the ratio of each item's distinctiveness value to the sum of the distinctiveness values of other items in the set. This model has been most successfully applied to the serial position curve (see Neath, 1993), where each item's temporal position was used to calculate item distinctiveness.

Eysenck (1979) also described a representational view of distinctiveness, wherein distinctiveness was defined in terms of sets of overlapping information. Within this framework, three sources of information contributed to recognition memory: information from previous encodings, information from the study-trial encoding, and information in the test trial encoding. "[T]he most important factor in recognition memory is the extent to which the test-trial encoding contains information that is unique to the study-trial encoding" (Eysenck, 1979: p. 111). Recognition performance should then be a ratio of this distinctive information to shared information.

Whereas the Eysenck (1979) and Neath (1993) treatments focused on recognition performance, Nairne et al. (1997; see also Nairne, 2006) extended the framework to recall. Nairne et al. combined uncertainty (perturbation) in serial position information with a metric of positional distinctiveness to predict primacy and recency as a function of presentation rate and retention interval. Nairne (2006) applied the framework to the isolation effect in free recall, providing what is perhaps the most comprehensive coverage of distinctiveness within the representational perspective. This model might be seen as a more formal development of Eysenck's (1979) ideas. Nairne argued that recall is a function of the extent to which a retrieval cue uniquely matches a recall target. Such matches were determined by item similarity, which was defined in terms of shared semantic features. Item distinctiveness was the ratio of the similarity of the cue to the target item to the sum of the similarity of the cue to other possible candidates for recall.

Representational models are often presented in formal mathematical descriptions, providing some precision to their predictions, a true advantage over the verbal descriptions offered by the organizational approach. However, as noted above, most of the formal treatments have been applied to the serial position curve. Applications to other phenomena that fall under the distinctiveness rubric are rare. Schmidt (1996) applied the Murdock (1960) and Neath (1993) frameworks to the typicality effect in free recall and found that they made inaccurate predictions. For example, Murdock's model incorrectly predicted that both very typical and atypical items embedded in a list of moderately typical items should be distinctive and thus well recalled or recognized. In addition, these theories fail to take into account recent developments concerning similarity (e.g., Gati and Tversky, 1984; Murphy and Medin, 1985; Medin et al., 1993). Items should not be thought of as containing a fixed set of features, with each feature having a fixed contribution to item similarity. Rather, feature selection and feature weights are determined by the context in which an item appears, and by the processing strategies brought to the task (see Hunt and McDaniel, 1993; Schmidt, 1996). Given the lack of a firm metric of similarity, it is difficult to construct a ratio of distinctive to shared features.

The representational approaches seem to have particular difficulty dealing with secondary distinctiveness. For example, within Murdock's (1960) theory, the distinctiveness of an item is calculated relative to other items in a list, not relative to the set of all items stored in memory. Yet, secondary distinctiveness is defined in terms of this larger set of information. How then, for example, could one calculate the relative distinctiveness of, say, high- and low-frequency words? Within Eysenck's framework, independent of experimental design, semantic processing leads to more distinctive memory traces than phonetic processing. As predicted, semantic processing leads to better memory than phonetic processing in both within- (Craik and Tulving, 1975) and between-subjects designs (see Johnston and Jenkins, 1971). Similarly, Valentine (1991) described a representational theory in his explanation of a good memory for distinctive faces. Within this view, faces are represented in multidimensional feature space. Typical faces fall in relatively crowded regions of this space containing many exemplars, whereas atypical faces fall in relatively empty regions. Item discrimination processes are thus relatively easy for atypical compared with typical faces. As a result, the discrimination advantage enjoyed by atypical faces should be present independent of experimental design. Thus, from a representational view, one can define distinctiveness in relative terms, in which case the theory cannot be applied to secondary distinctiveness. Or, one can define distinctiveness in absolute terms, in which case distinctiveness should aid memory independent of experimental design. Thus, representational views stumble over the fact that the effects of secondary distinctiveness are confined to within-subjects designs (see Section 2.09.4).

### 2.09.3.3 Affective Response Theories

One can imagine the landscape of everyday memories painted in neutral affective tones. However, some experiences would be painted in the vivid colors of strong emotional responses. These emotionally laden experiences should stand out in memory. The distinctive item, within this framework, is one that leads to a heightened physiological state of arousal or emotion. In Schmidt's (1991) classification, experiences that stood out because of their emotional content were classified as examples of emotional distinctiveness. For example, Hirshman et al. (1989) argued that the bizarreness effect resulted from the surprise experienced by participants at finding a bizarre sentence in a mixed list of bizarre and common sentences. Conversely, some researchers have argued that the effects of emotion on memory should be thought of as von Restorff effects (Loftus and Burns, 1982) or as attributable to distinctiveness (McCloskey et al., 1988; Dewhurst and Perry, 2000).

Numerous researchers have tied von Restorff, isolation, or distinctiveness effects to physiological correlates of increased attention, surprise, or emotion. Researchers within this tradition can probably trace their ideas to the work of Sokolov (1963), James (1890), and ultimately Darwin (1872). The nervous system ignores steady-state information and responds to change. From a Jamesian perspective, our perceptions of these nervous system responses 'are' the emotions we feel. These responses can be seen in indices of the orientation reflex (e.g., increased skin conductance, Gati and Ben-Shakhar, 1990), in the N400 and the P300 cortical responses (Fabiani et al., 2000), and in the release of stress-related hormones (Gold, 1992). Exactly how these responses translate into memory effects varies from theory to theory.

James (1890) argued that an emotional experience may be "accompanied by an extraordinary degree of attention" (James, 1872: p. 671). Similarly, Easterbrook (1959) argued that arousal may lead to a narrowing of attention. Bower (1992; see also Rundus, 1971) argued that an emotional event would disrupt rehearsal processes, leading to decreased rehearsal of surrounding material and increased rehearsal of the emotional item. Burke et al. (1992) suggested that an emotional experience would lead to a shift in the priority of information processing. Thus, one explanation within affective theories of distinctiveness is that outstanding events (Ellis et al., 1971) receive extra attention and processing, and that this extra processing may be at the expense of other stimuli.

Gold (1987, 1992) focused on the neurobiological processes supporting memory. He argued that information storage was influenced by neuroendocrine responses that may promote memory coding. Specifically, stress releases epinephrine, which in turn leads to increased levels of blood glucose in the brain. Serum glucose levels were thought to regulate memory storage processes in an inverted-U-shaped fashion.

Brown and Kulik (1977) developed their flashbulb memory hypothesis, borrowing the potent mechanism from Livingston's (1967a,b) Now Print! theory. According to this view, the response to a significant event follows a three-stage process. First there is the recognition of novelty or unexpectedness (distinctiveness), followed by a test for biological significance, and then the "permanent registration of not only the significant novelty, but all recent brain events" (Brown and Kulik, 1977, p. 76). This is accomplished, according to Livingston, through diffuse action of the reticular formation. MacKay's binding hypothesis (MacKay et al., 2004) provides yet another perspective: in some of the other views expressed above, emotional stimuli soak up encoding resources. Specifically, through the action of the amygdala, the hippocampus binds word meanings to the context in which they occur.

Several researchers have proposed multistage processing of emotional stimuli. For example, Christianson (1992a,b) proposed a two-stage model wherein an emotional stimulus may automatically receive preferential processing, followed by elaborative processing of the stimulus. Fabiani and Donchin (1995) argued that working memory maintains a model of recent experience or context. The P300 response to distinctive stimuli reflects the updating of that model resulting from the necessity reorganizing the experience. If a stimulus requires this update, then it is marked, and the marking can be used to aid retrieval processes.

An obvious criticism of the emotional distinctiveness view is its extensive coverage of responses from the mild surprise of encountering a red word printed in a list of black words to the shock and horror one experiences at the loss of a loved one. Are the mechanisms proposed above (e.g., attention focusing, brain glucose, contextual binding) qualitatively the same across a continuum of emotional reactions, perhaps differing only in magnitude with changes in emotional intensity? Or are qualitatively different memory processes invoked by each of the many emotions? Some researchers have attempted to separate manipulations associated with distinctiveness into different groups. Michelon and Snyder (2006) argued that the N400 cortical response was seen with manipulations of secondary distinctiveness, and the P300 associated with primary distinctiveness. However, only the P300 was consistently associated with good memory performance. Schmidt (2006, 2007) has argued for a categorization of stimuli into those that are distinctive and those that are significant. Within this view, distinctiveness is the result of a mismatch between an experience and memory representations, whereas the significance of an experience results from a match between the experience and previous significant experiences. Only significant stimuli were thought to lead to strong emotional responses and poor memory for surrounding stimuli.

#### 2.09.3.4 Hybrid Theories

Although there is considerable divergence across the three theoretical perspectives described above, there is also commonality. For example, theories of stimulus orientation (e.g., Ohman, 1979) often invoke a feature-matching process similar to representational theories of distinctiveness. Fabiani (2006) and Christianson (1992b) both describe poststimulus elaboration and rehearsal processing that are reminiscent of organizational theories of distinctiveness. Schmidt (1991; Schmidt and Saari, in press) developed the incongruity hypothesis, which contains elements of all three approaches.

According the incongruity hypothesis, each presented item is compared with the contents of working memory. If an item is encountered that contains features that substantially differ from the weighted features in working memory, then the observer orients to the item. This orientation is automatic and leads to the increased storage of features extracted from the item. Because the process is automatic, the incongruent item will not rob attentional resource from other items with the typically slow rates of presentation used in many memory experiments. Some effect may be observed, however, in RSVP tasks (Raymond et al., 1992). In a modification of this view, significant stimuli hold attentional resources during an emotional appraisal process

(Schmidt, 2002b; Schmidt and Saari, in press), disrupting processing of material in the spatial or temporal proximity of the significant item. Further processing of distinctive and significant experiences may occur as a result of controlled elaboration and organizational processes. The first two phases in the incongruity hypothesis clearly place the locus of the effects of distinctiveness on encoding processes. However, Schmidt (1991) also included a retrieval component: "during the memory test (Phase 3), the effect of incongruity on memory will depend on the degree to which stored information supports good memory performance" (p. 537).

There are several strengths of the incongruity hypothesis. First, the framework incorporates research concerning the effects of stimulus contrast on physiological measures of orientation and attention. Second, the framework includes an explanation of the effects of distinctiveness on organization in recall (e.g., Bruce and Gains, 1976). Third, the framework explains why the effects of secondary distinctiveness may be limited to within-subjects designs. However, some have argued that the incongruity hypothesis incorrectly predicts that the effects of primary distinctiveness should be reduced if the distinctive item is in the first serial position of the list (Hunt, 1995; McDaniel and Geraci, 2006). According to this view, the first item in a list cannot be incongruent, and thus should not stand out at retrieval. However, this interpretation of the incongruity hypothesis is overly simplistic. Increased attention to an item through incongruity has its impact on memory by increasing individual-item processing of the item. This increased processing then supports retrieval and discrimination processes, which lead to enhanced memory for the distinctive item. The first item in a list, because of its primacy position, should also lead to orientation and increased attention (Oberauer, 2003) relative to other items on the list. Thus, it is reasonable to assume that the same critical features will be encoded for the distinctive first item as are encoded for a distinctive middle item. In addition, feature selection during the encoding of subsequent list items will be aligned with the contrast to the first item. Memory advantages enjoyed by a distinctive first item should thus be similar to those of a distinctive middle item.

## 2.09.4 Empirical Phenomena

As indicated above, a large number of phenomena have been offered as examples of the effects of distinctiveness on memory, been explained by reference to the von Restorff effect, or been described as the result of distinctive processing. In the following section, I provide a brief description of many of these phenomena and attempt to cast them within the theoretical frameworks outlined above.

### 2.09.4.1 von Restorff's Original Work

von Restorff's (1933) original paper has been summarized elsewhere (Hunt, 1995); in addition, there is a very readable and accessible translation of her paper available online (see Hunt, 1995). However, given that her research is very unlike what most people think of as the von Restorff effect (e.g., Wikipedia, 2006), it is worth recounting some of her original work.

von Restorff described a series of experiments investigating proactive and retroactive interference effects in recall and recognition. In some of her experiments, she employed a collection of diverse objects (e.g., a number, a green square, a letter, a nonsense syllable). Some of the objects were massed, that is, four objects of the same type (e.g., four nonsense syllables) appeared in the list, and others were isolated, in that only one object of a specific type appeared in the list. She demonstrated that memory for isolated items exceeded memory for massed items. In another of her experiments, von Restorff contrasted memory for three lists: one number with nine nonsense syllables, one syllable with nine numbers, and a list of ten heterogeneous items (a number, a syllable, a button, a chemical compound, etc.). The proportion of isolated items recalled greatly exceeded the proportion of common items from the same list. She also demonstrated that isolated numbers or syllables were more likely to be recalled, and were more quickly recalled, than were numbers or syllables from the heterogeneous list. However, the difference between recall of an isolated item and recall of the same item from the heterogeneous list was smaller than the difference between the isolated item and the common items in the same list. Across experiments, she varied the structure of the lists, as well as the position of the isolated item. She concluded that similar list items were absorbed into the memory trace field, whereas isolated items were not. von Restorff reported these effects in recall and recognition, but the effects were larger in recall. Finally, she concluded that both proactive and retroactive interference were the result of these same field effects.

#### 2.09.4.2 The Isolation Effect

Numerous researchers have adapted the design of the second von Restorff experiment described in the preceding section. In these experiments, a single isolated item (e.g., a word printed in red) is placed in a list of otherwise homogeneous items (printed in black). Memory for this item is then compared to memory for the same item in a list of homogeneous items (all words printed in black). Typically, recall of the isolated word would exceed recall of the same word printed in black (Rabinowitz and Andrews, 1973). This design focuses on one of the more striking findings reported by von Restorff and provides a purer measure of isolation. That is, in von Restorff's design, one cannot separate the positive effect of isolation on memory for the isolated item from potential negative effects of isolation on memory for the remainder of the list. In a well-designed experiment, memory for a physically identical stimulus can be either assessed with that stimulus isolated or not, and potential positive and negative effects of isolation can be identified (e.g., Schmidt, 1985). Wallace (1965) provided a detailed review of early isolation effect experiments; Schmidt (1991) provided a brief review of more recent research. Good memory for isolated items can be found with both physical and semantic isolation and is observed on recall, recognition, and even implicit tests (Geraci and Rajaram, 2004) of memory. The presence of an isolated item in a list impairs recall but not recognition of other items on the list (Schmidt, 1985). Because of its central place within distinctiveness research, all three theoretical perspectives described here have been applied to the isolation effect.

#### 2.09.4.3 Bizarre Imagery and the Bizarreness Effect

Memorists have long believed that bizarre imagery is an effective mnemonic device (Yates, 1966). However, experimental tests of the benefits of bizarre imagery led to an inconsistent and confusing array of results. This confusion was greatly alleviated when McDaniel and Einstein (1986) conclusively demonstrated a bizarreness advantage in the recall of sentences. They demonstrated that the bizarreness effect was only obtained when participants experienced both bizarre and common sentences within the same experimental context. Thus was born the distinctiveness interpretation of the bizarre imagery effect.

It is beyond the scope of this chapter to review the vast literature on bizarre imagery effect. Additional coverage can be found in the Mental Imagery chapter in this volume (*See* Chapter 2.08), and a recent review of the bizarreness effects can be found in Worthen (2006). Bizarreness appears to have both positive and negative effects on memory, aiding memory for the bizarre material but interfering with sentence integration (McDaniel and Einstein, 1986) and retention of order information (DeLosh and McDaniel, 1996). As a result, the positive bizarreness effect is usually confined to free-recall tests and not found on cued-recall (see Einstein and McDaniel, 1987, for a review), ordered-recall (DeLosh and McDaniel, 1996), or recognition (McDaniel and Einstein, 1986) tests of memory performance. There are currently two prominent explanations for these effects, one from the organizational and one from the representational perspectives outlined in section 2.09.3. From the organizational perspective, bizarreness encourages individual-item processing at the expense of relational processing and the processing of order information (DeLosh and McDaniel, 1996). In contrast, McDaniel et al. (2000, 2005) have argued against differential processing interpretations of the bizarreness effect. Rather, the bizarreness benefit occurs at retrieval when the set of features used during retrieval "are functionally distinctive in the context of the retrieval set"(McDaniel et al., 2005, p. 271). It is unclear how to reconcile this position with the list order effects reported by McDaniel and Geraci (2006), described in Section 2.09.2.

#### 2.09.4.4 The Humor Effect

Humorous material is often remembered better than nonhumorous material matched in content (Kaplan and Pascoe, 1977; Kintsch and Bates, 1977; Schmidt, 1994; Schmidt and Williams, 2001). Like the bizarreness effect, humorous material only has a mnemonic advantage in mixed-lists designs. Also, similar to the bizarreness effect, the humor effect is eliminated if the humorous material is presented in a block prior to the nonhumorous material in the same list (Guynn et al., as reported in McDaniel and Geraci, 2006). Unlike the bizarreness effect, the humor effect is obtained in cued recall (Schmidt, 1994). This is probably because humorous sentences are easily integrated, whereas bizarreness disrupts sentence continuity. Schmidt (2002a) provided a hybrid explanation of the humor effect. He concluded that humorous cartoons received increased attention and discrimination processes in a mixed list and were given retrieval priority during the memory test.

### 2.09.4.5 The Serial Position Curve and Temporal Distinctiveness

Memory performance for a series of presented items is often a U-shaped function of input position, with participants showing good memory for the beginning and ending of the series and relatively poor memory for the middle positions. This ubiquitous phenomenon has led to numerous explanations, but it is most often cast within the modal model (i.e., Atkinson and Shiffrin, 1968) and the fate of items in sensory, short-term, and long-term memory (Crowder, 1976). However, Murdock (1962) suggested a different cause in his seminal paper on the shape of the serial position curve. He argued that the shape of the curve resulted from retroactive and proactive interference between adjacent items on the list. In addition, Murdock (1960) applied his distinctiveness model to the bowed serial position curve. Recently, researchers have returned to the distinctiveness explanation of the serial position curve (Nairne et al., 1997; Neath, 1993) within the representational view described above. Surprenant (2001) applied this approach to the memory of tonal sequences and, true to the von Restorff tradition, argued that a common theory of relative distinctiveness could be applied to both perceptual and memory phenomena.

The distinctiveness interpretation of the serial position curve also has its opponents. Rouder and Gomez (2001) argued that the temporal distinctiveness parameters used to model the serial position curve were arbitrary. Oberauer (2003) argued that an attentional gradient was necessary to account for the primacy effect. Lewandowsky et al. (2006) argued for an event-based rather then a temporal-based account of the curve. Within this view, the temporal structure of the list (beginning, end, inserted pauses, etc.) provides opportunities for consolidation, rehearsal, and organizational processes. These processes are responsible for the shape of the serial position curve, not temporal distinctiveness per se. Note that one could still use the concept of distinctiveness to explain the serial position curve within this framework. However, item distinctiveness would be event or item based and not tied to the memory representation of the temporal gradient.

### 2.09.4.6 Orthographic Distinctiveness

Zechmeister (1972) was one of the first researchers to report that orthographically uncommon words (e.g., 'llama') are remembered better than words that conform to common English orthography. This effect has been found on recall (Hunt and Mitchell, 1982), recognition (Zechmeister, 1972), and word fragment completion (Hunt and Toth, 1990) tests of memory. However, like many of the effects of distinctiveness, the orthographic distinctiveness effect appears to be confined to mixed-list designs (Hunt and Elliot, 1980). Interestingly, the effects of orthographic distinctiveness are additive with the effects of conceptual distinctiveness (Hunt and Mitchell, 1982; Kirchhoff et al., 2005), and thus orthographic and conceptual distinctiveness may be mediated by different mechanisms (Kirchhoff et al. 2005).

Geraci and Rajaram (2002) argued that the orthographic distinctiveness effect is only obtained on implicit memory tests if the participants are aware of the relation between the test and the encoding task. In addition, orthographic distinctiveness effects were reduced if the participants' attention was divided between two tasks. They suggested that conceptual processing of the relation between the distinctive and common items is important to produce the effect. Geraci and Rajaram concluded that their results were consistent with Hunt's distinctiveness hypothesis, as well as Schmidt's (1991) incongruity idea, and the Fabiani and Donchin (1995) framework described above.

### 2.09.4.7 The Word Frequency Effect

Recall of frequent words usually exceeds recall of infrequent words. In contrast, recognition memory for infrequent words usually exceeds that for frequent words (Gregg, 1976). The word-frequency effect in recognition is often cast within a representational view of item distinctiveness. That is, low-frequency words appear in fewer preexperimental encodings than high-frequency words. In terms of Eysenck's framework described above, it should be relatively easy to discriminate between the low-frequency word's experimental and preexperimental encodings (Brown, 1976; Eysenck and Eysenck, 1980), leading to higher hit rates and lower false alarm rates for low- than for high-frequency words (Rao and Proctor, 1984). Superior recognition of low-frequency words is found in both homogeneous and mixed lists (see Gregg, 1976, for a review), as well as with implicit memory tests (MacLeod and Kampe, 1996). Eysenck and Eysenck (1980) provided support for the distinctiveness interpretation by demonstrating that distinctive processing (e.g., producing an infrequent modifier for the nouns in the study) reduced the word-frequency effect in recognition.

The word-frequency effect in recall has been cast within the individual item/relational processing view of distinctiveness (DeLosh and McDaniel, 1996; Dobbins et al., 1998; Saint-Aubin and LeBlanc, 2005). DeLosh and McDaniel (1996) argued that memory for word order plays an important role in many recall tasks. In addition, encoding "resources are lured to processing and interpreting the individual and idiosyncratic features of unusual items" (DeLosh and McDaniel, 1996, p. 1137). This shift in encoding robs resources from processing order information. In a pure list of high-frequency words, there are greater resources to devote to order processing than in a pure list of infrequent words, leading to the typical recall advantage found for the high-frequency words. However, in a mixed list of high- and low-frequency words, increased processing of the low-frequency words takes place at the expense of the order encoding of both types of words. The low-frequency words received increased individual item processing relative to the high-frequency words, and both types of items suffer from a disruption of order encoding or relational processing. The result is that in the recall of mixed lists, low-frequency words are sometimes recalled better than high-frequency words (Delosh and McDaniel, 1996; Saint-Aubin and LeBlanc, 2005). DeLosh and McDaniel demonstrated this reversal, as well as the predicted effect of mixed lists on memory for order information.

Saint-Aubin and LeBlanc (2005) also compared memory for pure and mixed lists of high- and low-frequency words. They employed relatively short lists of words and a serial order recall task. In their mixed lists, a single high- or low-frequency word was isolated in lists of five words of the other type. My interpretation of the order-encoding hypothesis leads me to predict that a single high-frequency item should be poorly recalled in the context of infrequent words. That is, the infrequent words should rob encoding processes from the high-frequency word. However, the high-frequency words were recalled better than the low-frequency words in this list structure. In addition, there was not a significant effect of word frequency when the lists contained primarily high-frequency items. These results seem to challenge the order-encoding interpretation of the word-frequency effect. Interestingly, Saint-Aubin and LeBlanc (2005) argued that their results supported a distinctiveness interpretation, citing Hulme et al.'s (2004) explanation of the word-length effect. According to Saint-Aubin and LeBlanc, high-frequency words were more distinctive than low-frequency words.

### 2.09.4.8 The Word Length Effect

On immediate-recall tests, recall of short words often exceeds recall of long words. This finding is often interpreted within a working memory model and the role of the phonological loop in immediate recall (Baddeley et al., 1975). However, the word-length effect is also found with delayed tests, and with lists that should exceed the memory span (Russo and Grammatopoulou, 2003), challenging the working memory interpretation of the effect. Three different distinctiveness interpretations of the word-length effect have been offered as alternatives to the working memory hypothesis. Hulme et al. (2004) argued that the word-length effect was in reality an effect of item complexity. Short items are less complex than long items and, thus, are less susceptible to memory errors (Neath and Nairne, 1995). In addition, because short items contain fewer features than long items, they will share fewer features across other list items. As a result, short items have greater item distinctiveness within the Neath representational framework. Hulme et al. used this framework to explain the absence of a word-length effect in mixed lists of long and short words alternating across input positions.

Cowan et al. (2003) also evaluated the word-length effect in mixed lists, but they varied the number of long and short words in the list and compared memory with and without articulatory suppression. The word-length effect was either reversed (without articulatory suppression) or eliminated (with articulatory suppression) when the list was composed of primarily short words. The typical word-length effect was obtained when the list was predominately long words. They concluded that in mixed lists, organizational factors play an important role in recall, invoking the organizational view of distinctiveness.

Hendry and Tehan (2005) investigated the word-length effect in mixed lists and employed both serial recall and recognition measures of memory performance. They observed the typical short word advantage on the recall task, but long words were recognized better than short words. They interpreted their results with DeLosh and McDaniel's (1996) order-encoding hypothesis (see section 2.09.3.1). That is, long words rob encoding resources from the processing of order information, impairing serial recall, but, long words also benefit from increased item processing relative to short words, leading to greater recognition of long words than short words. From this perspective, long words are more distinctive than short words.

### 2.09.4.9 The Concreteness Effect

"Concrete language is remembered better than abstract language in a wide variety of tasks" (Paivio et al., 1994, p. 1196). The concreteness effect is most often interpreted within Paivio's (1971) dual-coding theory, according to which imaginal and verbal processing independently contribute to memory for concrete words, whereas only verbal processing is usually possible for abstract material. The concreteness effect is found in both within- and between-subjects designs (Marschark and Hunt, 1989). Nonetheless, Marschark and Hunt (1989) noted that the concreteness effect was greatly attenuated in free recall and argued that this challenged the dual-coding interpretation. Instead, they cast the concreteness effect within the individual item/relational-processing framework (see also Marschark, 1985, and Marschark and Surian, 1992). Within this view, concrete materials encourage encoding of perceptual attributes of the material that can serve a distinctive function at retrieval.

It is worth noting that both views of the concreteness effect include the role of item distinctiveness (Paivio et al., 1994). What appears to be at issue is whether or not separate memory codes for verbal and imaginal processing is a necessary component of an explanation of the concreteness effect. According to the dual-coding theory, the additive effects of concreteness and relatedness on memory performance implicate independent contributions of the two systems. In contrast, Marschark and Hunt (1989) argued that concreteness effects in recall should only be observed in the presence of relational processing. That is, the distinctive memory representations of concrete words cannot contribute to good memory performance if the search set cannot be identified by appropriate relational information. Paivio et al. (1994) and Richardson (2003) have challenged this assertion by reporting additive effects of concreteness and relatedness. However, ter Doest and Semin (2005) found a concreteness effect on an explicit word stem completion test for a list of related words but not for a list of unrelated words, providing support for the Marschark and Hunt position. Nonetheless, a concreteness effect was observed for the unrelated word list in their free-recall test. Clearly, neither dual coding nor distinctiveness by themselves provides complete explanations of the concreteness effect. Both perspectives rely on other mechanisms (e.g., task-appropriate processing, Hamilton and Rajaram, 2001) to handle the full range of phenomena.

### 2.09.4.10 The Picture Superiority Effect

Under many conditions, including in both mixed- and between-list designs, people remember pictures better than they remember words (see Paivio, 1971, 1986). Research concerning this picture superiority effect parallels research on the concreteness effect in several ways. Like the concreteness effect, early explanations of the picture superiority effect were cast within Paivio's (1971) dual-coding hypothesis. The dual-coding explanation was then challenged by a distinctiveness explanation (Nelson et al., 1976; Nelson, 1979), and the distinctiveness explanation was then given further support by studies employing implicit memory tests (Weldon and Coyote, 1996; Hamilton and Geraci, 2006). Despite these similarities, the concreteness effect has been cast within an individual item/relational processing view of distinctiveness, whereas the picture superiority effect has been cast within a representational view of distinctiveness.

Nelson's (1979) conceptualization of distinctiveness is very similar to that of Eysenck (1979) and other representational views of distinctiveness. "Retention level is assumed to be a direct function of the relatively unique and unified nature of the study trial encoding *and* [author's emphasis] the degree to which the retrieval environment recapitulates this encoding" (Eysenck, 1979: p. 49). From this view, pictures have more unique (distinctive) features than words. Words presented in a list are limited by font and letter constraints that render them visually similar. In contrast, a picture of an object may contain many features that help distinguish it from pictures of other objects appearing on a list. Evidence for this perspective was found in the fact that the picture superiority effect could be diminished, or even reversed, by employing pictures that were visually similar to one another (Nelson et al., 1976). This explanation of the picture superiority effect has faired better than empirical tests of the individual item/relational explanation of the concreteness effect. Perhaps the concreteness effect should be recast within the Nelson/Eysenck view of distinctiveness. That is, perhaps concrete words encourage visual imagery processes, and the resulting images are more distinctive than the verbal representations of abstract words (Hamilton and Rajaram, 2001).

### 2.09.4.11 False Memory and the Distinctiveness Heuristic

Research concerning the distinctiveness heuristic trades heavily on the picture superiority effect. Israel and Schacter (1997) investigated memory within the Deese-Roediger and McDermott false memory paradigm (Roediger and McDermott, 1995; *See* Chapter 2.14). In this paradigm, a list of related words, for example, bed, rest, awake, and dream, is followed by a memory test. Of interest is participants' false memory for a related target word, such as 'sleep' Israel and Schacter compared memory for words spoken and written to words spoken and depicted in pictures. Picture presentation led to lower false recognition than written presentation. The authors argued that distinctive perceptual qualities of the pictures, features not available following written word presentation, served to reduce false memory. Schacter et al. (1999) later developed the idea of a distinctiveness heuristic: "a mode of responding based on participants' metamemorial awareness that true recognition of studied items should include recollection of distinctive details" (Schacter et al., 1999, p. 3). Schacter, Dodson, and associates have provided impressive support for the use of the distinctiveness heuristic (e.g., Schacter et al., 2001; Dodson and Schacter, 2001, 2002).

Hege and Dodson (2004) provided an alternative explanation for the lower false memories for pictures than for words. According to this view, the distinctive nature of pictures leads to impaired relational processing relative to the processing of printed text. As a test of this hypothesis, Hege and Dodson compared both recall and recognition memory following picture and word presentations. On the recall test, participants were asked to report any items related to the studied list, presumably bypassing any use of the distinctiveness heuristic. In support of the individual item/relational view, participants were still less likely to commit false recall of the target items following the picture than following the word presentation. On a follow-up recognition test, participants were instructed to put check marks next to items that actually appeared on the memory lists. Support for the distinctiveness heuristic was found when false recognition was lower for pictures then for words. Additional support for the distinctiveness heuristic was reported by Dodson and Hege (2005). In this study, the researchers varied the rate of presentation of test items on the recognition test. On self-paced tests, pictures lead to lower rates of false memories than words. However, on fast-paced tests (750 ms/item), the pictures and words led to comparable false recognition rates. In contrast, true recognition rates for words and pictures were similar, and both declined equally as the test pace increased. These results provide evidence against the idea that the low rate of false recognition of pictures results from reduced relational processing relative to words. Rather, the authors invoked two-stage theories of recognition (e.g., McElree et al., 1999; *See* Chapter 2.23) and argued that the distinctiveness heuristic is a time-consuming retrieval processes. As a result, lower false memories for pictures than for words only occurs during slow-paced recognition tests.

The distinctiveness heuristic should confound those of us studying distinctiveness and memory for several reasons. First, the idea presupposes that participants have the metamemorial abilities to discern which mnemonic variables are likely to increase and decrease the distinctiveness of memories. Given the literature reviewed here, it is clear that memory researchers do not agree on how variables impact item distinctiveness. Attributing this knowledge to the typical research participant is questionable at best. Second, the argument begins with the explicit assumption that pictures are more distinctive than words. Whereas there is research to support this claim, it is not an incontrovertible fact and, according to Nelson et al. (1976), depends on the pictures. Third, the Dodson and Hege (2005) results seem to undermine the whole enterprise. Not only do these results challenge the idea that words receive greater relational processing than pictures but they challenge the idea that the memory representations of pictures are more distinct than the memory representations of words. More distinctive memories should lead to greater true and lower false recognitions independent of the pace of the recognition test (from a representational view of distinctiveness). Nonetheless, the proportion of both hits and false alarms for pictures were equal to those of words on the fast-paced test. Perhaps the picture superiority effect results from dual coding, and the distinctive memory traces referred to by the distinctiveness heuristic are stored in Paivio's imagery system. During the recognition test, participants may need to access this visual code to aid memory discrimination processes. It is well established that accessing a visual code for verbally presented materials requires time (Paivio and Csapo, 1969). If this dual-coding interpretation is correct, then the picture superiority effect on both true and false memories may tell us more about dual coding than about item distinctiveness.

### 2.09.4.12 Face Recognition

Recognition memory for unfamiliar faces is greatly influenced by face uniqueness (Going and Reed, 1974), distinctiveness (Cohen and Carr, 1975), or typicality (Light et al., 1979). Going and Reed (1974) attributed this effect to the fact that a greater number of eye fixations were devoted to unique than to common visual stimuli. Cohen and Carr (1975) argued that the effect was akin to the von Restorff effect, whereas Light et al. (1979) attributed the effect to interitem similarity. The most comprehensive treatment of the effect of facial distinctiveness on recognition has been offered by Valentine and his associates (Valentine and Bruce, 1986; Valentine, 1991; Valentine and Ferrara, 1991).

Valentine has argued that faces are represented in a multidimensional space, with typical faces represented near the conceptual core of the category and atypical faces located at the categorical fringe. Valentine and Bruce (1986) argued that participants detected that an atypical face was different from the category norm, and this led to distinctive encodings of these faces. However, they concluded that "[t]he exact nature of a mechanism which may give rise to the effect of distinctiveness of encoding is unclear" (Valentine and Bruce, 1986, p. 304). Valentine and Ferrara (1991) were more specific in that they modeled facial recognition within both the McClelland and Rumelhart (1985) distributed memory theory and Nosofsky's (1986) model of item recognition. In the McClelland and Rumelhart theory, connection weights were determined by the difference between an input face and the facial prototype. Within the Nosofsky framework, the atypical face is not given special treatment at encoding. Rather, the distinctive memory representation of the atypical trace aids discrimination processes in recognition memory. Valentine (1991), again adopted a representational view, and argued that distance in the multidimensional space supported discrimination processes in face recognition. Typical faces fall in a crowded region of space, whereas atypical faces fall in less densely populated regions, aiding item discrimination processes in recognition.

It is worth noting that research concerning facial memory relies on subjective ratings of facial typicality or distinctiveness. Memory performance is usually tested over a range of stimuli differing in distinctiveness, and then either memory is correlated with the measure of distinctiveness (e.g., Valentine and Bruce, 1986) or a median split is used to group faces into distinctive and common groups (e.g., Newel et al., 1999). In other words, researchers always seem to employ a mixed-list presentation of common and distinctive items. Valentine's (1991) theory implies that the effects of facial distinctiveness should occur in between-list manipulation of facial type as well. It would be nice to see an empirical demonstration of this prediction.

### 2.09.4.13 The Modality Effect

Auditory presentation of verbal material often leads to superior memory performance than visual presentation. This effect is more robust on tests of immediate memory than on tests of delayed memory (Penney, 1989). The immediate memory modality effect is often attributed to the beneficial effects of a separate auditory sensory store (Crowder and Morton, 1969). However, both the immediate-memory modality effect (Nairne, 1990) and the long-term modality effect (Conway and Gathercole, 1987) have been attributed to item distinctiveness. Conway and Gathercole have shifted their view of the role of distinctiveness in the long-term modality effect. Conway and Gathercole (1987) and Gathercole and Conway (1988) argued that auditory stimuli were temporally more distinct than visual stimuli. Conway and Gathercole (1990) argued for a translation processes, wherein translation from one input domain to another (e.g., voicing a visually presented word) led to a more distinctive memory representation than processing in one domain. Nairne (1990) argued that visual presentation led to primarily modality-independent memory representations, whereas auditory presentation created both modality-independent and modality-specific memory representation. The modality-specific representations available following auditory presentation provide distinctive features to aid memory performance. Nairne's model has been used to explain an impressive range of phenomena, including modality, suffix, and serial position effects, as well as the impacts of articulatory suppression and irrelevant speech on memory performance (see Neath and Surprenant, 2003).

Recent research into the phenomenon of false memory (*See* Chapter 2.14) has led to an interesting twist in the interpretation of the modality effect. Smith and Hunt (1998) found that visual presentation led to fewer false memories in the Deese-Roediger and McDermott paradigm (see Roediger and McDermott, 1995) than did auditory presentation. They also demonstrated that a task designed to increase distinctive processing (pleasantness rating) reduced false memories. They concluded that visual presentation led to more distinctive memory representations than auditory presentation. Gallo et al. (2001) replicated and extended these findings to both within- and between-subject manipulations of modality. Furthermore, auditory presentation only led to greater false memories on visual tests of recognition memory. They concluded that participants use a list-specific heuristic, wherein distinctive visual cues retained from visually presented words aid discrimination between old and new items on the memory test.

It is hard to reconcile these views of the modality effect in false memory with the Conway and Gathercole (1990) and Nairne (1990) explanations of the modality effect in immediate recall. The false memory research is more consistent with the view of the modality effect developed by Penney (1989). She argued for separate streams of processing for visually and auditorily presented information. Visual information led to a rapidly fading visual code and a phonological code, whereas auditory information led to a more persistent acoustic code plus a phonological code. As a result, visual inputs are associated based on simultaneous presentation, whereas auditory information is integrated across time. Similarly, Arndt and Reder (2003) argued that auditory presentation encouraged relational processing across items, whereas visual presentation encouraged individual item (i.e., distinctive) processing (see also, Pierce et al., 2005). Thus, in order to explain enhanced memory following auditory presentation, and lower false memory following visual presentation, the modality effect has been recast from the original representational view to the individual item/relational processing view of distinctiveness.

### 2.09.4.14 Emotional Words

Researchers have long argued that emotional material is remembered better than neutral material (Kleinsmith and Kaplan, 1963, 1964; Maltzman et al., 1966). However, several researchers have noted that the effect may depend on experimental design (Walker and Tarte, 1963). Most of the early research investigating memory for emotional material employed mixed lists of emotional and neutral words. When memory for a homogeneous list of emotional words has been compared to a memory for a homogeneous list of neutral words, the emotional memory effect sometimes disappears (Dewhurst and Parry, 2000; Hadley and MacKay, 2006). Dewhurst and Parry (2000) argued that the mixed-list presentation enhanced the distinctiveness of the emotional words; however, they do not specify how this happens. Perhaps they have in mind a trade-off between individual-item and relational processing.

However, a distinctiveness interpretation of the emotional memory effect is complicated by the fact that not all emotional words have the same impact on memory and attention processes. Words associated with sex and the bathroom have a greater impact on memory than do less offensive words (Manning and Goldstein, 1976), and the emotional memory effect is larger for negative than for positively valenced emotional words (McNulty and Isnor, 1967; Dewhurst and Parry, 2000). Furthermore, Saari and Schmidt (2005) found an emotional memory effect for taboo words in both within- and between-subjects designs. In contrast, with negative affect non-taboo words, an emotional memory effect was only found when mixed-list designs were employed (Schmidt and Saari, in press).

The complex relation between word emotion and memory will likely require a hybrid explanation that includes both a representational view of distinctiveness and shifts in attentional resources. Schmidt and Saari (in press) noted that emotional words often lead to increased attention as measured by the Stroop color-naming task (see Williams et al., 1996, for a review). However, Schmidt and Saari found that emotional Stroop effect was modulated by both list structure and the type of emotional words employed. With taboo words, the emotional Stroop effect was found in both mixed- and pure list designs and was of equal magnitude in both designs. In addition, the memory advantage for taboo words occurred in both list structures but was larger in the mixed list design. This suggests that taboo words attract extra encoding resources in both experimental designs but benefit from item distinctiveness in a within-list design. A different pattern of results was found with nontaboo emotional words. With nontaboo words, the Stroop effect was only found with relatively short interstimulus intervals (ISIs) and when the emotional and neutral words were presented in blocks. The Stroop effect for these nontaboo words was thus probably the result of carryover in the processing of one emotional word to the processing of the next word in the series (see also McKenna and Sharma, 2004). In contrast with the Stroop effect, enhanced memory only occurred in mixed list with these emotional nontaboo words, and the memory effect was independent of ISI or blocking. Thus, increased attention was not related to good memory for the nontaboo emotional words. Instead, these words gained their mnemonic salience from a distinctive retrieval context. Schmidt and Saari concluded that increased attention and a distinctive retrieval context work together to produce enhanced recall of taboo words, whereas with nontaboo emotional words, the emotional memory effect is the result of item distinctiveness. Thus, the results were compatible with the Schmidt (1991) incongruity hypothesis and the Fabiani and Donchin (1995) orientation-distinctiveness view.

### 2.09.4.15 Odor

Several researchers have reported that odor is a very effective retrieval cue (the so-called Proust phenomenon; Chu and Downes, 2002; Herz and Schooler, 2002). However, some researchers have failed to find that odor cues facilitate memory (Bjork and Richardson-Klavehn, 1989). Herz (1997) argued that for an odor cue to be effective, the odor must be salient in the environment. That is, the odor cue must be distinctive, or contextually inappropriate, in the experiment. Thus, the positive effects of odor on memory may be tied to cue-distinctiveness within an Eysenck framework of the effects of distinctiveness on memory.

## 2.09.5 Summary and Conclusions

Based on this review, one is tempted to conclude that the concept of distinctiveness in memory research is amorphous and has been utilized to explain such a wide range of phenomena that it is nearly bankrupt. Within the same phenomenon, completely opposing roles of distinctiveness have been proposed. For example, some researchers have argued that low-frequency words are more distinctive than high-frequency words, whereas others have argued that high-frequency words are more distinctive than low-frequency words (see also the word-length effect). Auditory presentation apparently leads to a more distinctive memory representation than visual presentation, unless of course you are discussing false memory, in which case visual presentation leads to more distinctive memory representations than auditory presentations. Within the same phenomenon, many different distinctiveness interpretations have been offered (e.g., the bizarreness effect, the word length effect, the concreteness effect). And, with conceptually and empirically similar phenomena (e.g., the concreteness effect and the picture superiority effect), distinctiveness explanations have taken different forms.

Schmidt (1991) also noted the varied forms of the distinctiveness hypothesis, leading him to ask: "Can we have a distinctive theory of memory?" (Schmidt, 1991, p. 523). There are several answers to this question. One answer is that the concept of distinctiveness can be used heuristically, or descriptively. In this approach, good memory implies distinctiveness. That is, distinctiveness is not really a theory of good memory but a description of why memory is good. Unfortunately, many researchers continue to use distinctiveness in this manner (see Hunt, 2006, for a similar complaint).

Alternatively, one can look for a coherent structure in the phenomena reviewed in this chapter and use that structure to narrow the theoretical and empirical fields. With very few exceptions, the effects of distinctiveness are modulated by experimental design. The notable exceptions include the word frequency effect in recognition, the concreteness effect, the picture superiority effect, and memory for taboo words. These phenomena occur in both between- and within-subject designs. It is tempting to attribute these select phenomena to mechanisms other than distinctiveness (i.e., familiarity, dual coding, and emotional processing, respectively). The remaining phenomena, those more naturally tied to distinctiveness, either disappear in between-list designs (e.g., bizarre imagery effect) or simply must be studied in within-subjects designs (e.g., the isolation effect and the serial position curve). Any successful theory of distinctiveness must explain the impact of experimental design on the pattern of results.

As another general observation, encoding as well as retrieval processes are nearly always a part of successful explanations of distinctiveness. The word-frequency effect in recognition is the only notable exception to this rule. However, Chunyan et al. (2004) noted an association between the late-positive ERP and the correct recognition of low-frequency words – implicating encoding processes in the word-frequency effect. Diana and Reder (2006) also provided support for the role of encoding processes in the word-frequency effect in recognition. These researchers compared memory following either single-task (study the list) or dual-task (study the list while engaging in an addition task) encoding conditions. Performing the dual task during encoding eliminated the effect of word frequency on hit rates and reduced the effect on false alarm rates relative to single-task performance.

Of the 15 different memory phenomena reviewed herein, ten have been explained by specific reference to representational models. I caution against this view as an exclusive explanation of the effects of distinctiveness on memory. Representational views generally overlook encoding processes, and as I have argued, encoding plays an important role in modulating many of the effects of distinctiveness. Representational theories have defined distinctiveness in terms of a memory (or memory trace plus retrieval cue) representation that shares few features with other memory representations. Support for this assumption is found in the fact that recognition of distinctive items exceeds memory for typical items. Without some independent index of item distinctiveness, this explanation provides little insight into memory processes. (Note that this criticism does not apply to the distinctiveness explanation of the serial position curve, where position or time serves as a parameter in calculating item distinctiveness.) Schmidt (1995) provided evidence against representational approaches to category typicality effects on memory, and his criticism applies to representational approaches to secondary distinctiveness effects in general. Finally, the representational view implies a strong causal link between distinctiveness and memory. According to this view, the psychological space is relatively empty around distinctive items, and each distinctive item in a list should also be off by itself within this space. As a result, it should not matter if a list has 20 such distinctive items or ten common items and ten distinctive items. In both cases, each distinctive item should fall in a relatively empty psychological spatial region, leading to enhanced item discrimination processes relative to the common items found in crowded regions. Thus, distinctive memory representations should enhance memory in both mixed-list and between-subjects designs. In addition, distinctive memories should aid performance on intentional, incidental, and implicit tests of memory. Of the phenomena reviewed above, only the concreteness effect, the picture-superiority effect, and the word-frequency effect in recognition meet these standards. All of the other phenomena require additional explanatory mechanisms.

In order to avoid tautological explanations of memory performance, specific definitions of distinctiveness must be employed. These definitions must be supported by converging evidence. That is, if I say that A is more distinctive than B, and that item distinctiveness supports better memory for A than B, then I must independently demonstrate both halves of this assertion. In addition, theories of distinctiveness should provide specific mechanisms whereby distinctiveness aids memory performance. From the above review, we can see that the list of potential mechanisms is not long. The list includes increased attention (as indexed by neurological or behavioral correlates), increased item processing at the expense of relational processing, feature sampling, ease of discrimination, and retrieval priority.

These observations lead me to conclude that adequate theories of distinctiveness will necessarily be hybrid models of the kind proposed by Schmidt (1991), Christianson (1992a,b), Fabiani and Donchin (1995), Worthen et al. (1998), and some instantiations of the individual item/relational processing framework. Within each of these approaches, there is a clear definition of what is "distinctive" – they describe specific mechanisms whereby distinctiveness enhances memory, they include both encoding and retrieval components, and they can be applied across a range of empirical phenomena. In addition, these theories help to integrate physiological measures of attention and arousal with behavioral measures of attention and memory. The extended power of these approaches is also their drawback, for it is hard to make predictions concerning how distinctiveness should influence memory performance in specific situations.

In summary, the concept of distinctiveness has become chameleonic, as researchers color and stretch it in attempts to gain insight into a broad range of memory phenomena. Three different theoretical perspectives concerning distinctiveness can be identified: organizational theories, representational theories, and affective theories. The definition of distinctiveness, and the explanations for how it influences memory, vary across these perspectives and from one empirical phenomenon to another. As a result, there is a danger that distinctiveness will be relegated to little more than a description of good memory performance.

However, theories that describe specific mechanisms whereby distinctiveness influences performance have been proposed and do explain an impressive range of findings. Hybrid models that include organizational processes, emotional processes, and encoding and retrieval processes, as well as incorporating some of the ideas from representational views, appear the most promising.

# 2.10 Mnemonics: Underlying Processes and Practical Applications

**J. B. Worthen**, Southeastern Louisiana University, Hammond, LA, USA

**R. R. Hunt**, University of Texas at San Antonio, San Antonio, TX, USA

In modern society, we rely on accurate memories to perform a variety of tasks throughout the day. We must remember passwords and user names while using the Internet, account and personal identification numbers for business transactions, and myriad telephone numbers for use both at work and at home. Even a mundane event such as a trip to the grocery store is dependent on accurate memory. Such a trip involves not only remembering what to buy at the store but also how to get to the store, the name and a few personal details of the chatty neighbor who will invariably end up next to us in the checkout line, and where the car is parked when we have completed our shopping. Clearly, we rely heavily on our memory system to negotiate the modern world. However, the reliance on memory for successful adaptation to the environment is not a product of modernity at all. In fact, the development of strategies to enhance memory – referred to as mnemonics – dates backs thousands of years. When all communication relied primarily on the oral tradition, the ancient Greeks and Romans developed strategies for remembering lengthy speeches and poems (Yates, 1966), and medieval lawyers used mnemonics to memorize entire sets of codes and laws (Fentress and Wickham, 1992). In fact, good memory was considered a virtue in medieval Europe, and mnemonic training was fundamental to medieval education (Carruthers, 1990). Thus, it appears that the desire to improve one's memory has a history that long predates the formal study of psychology. In this chapter, we describe some of the most popular and enduring techniques for enhancing memory and discuss the cognitive principles that are believed to underlie each technique.

## 2.10.1 Mnemonic Processes

Although numerous techniques and strategies have been offered to improve memory, the vast majority of mnemonics represent simple applications of basic research findings in cognitive psychology. In fact, the most popular mnemonic techniques are designed to capitalize on a few well-researched psychological processes: organization, elaboration, and mental imagery. Because of their fundamental importance to mnemonic strategies, we briefly discuss each of these processes next.

#### 2.10.1.1 Organization

A major function of mnemonics is organization of to-be-remembered information. It has been clearly established that organized information is easier to remember than unorganized information (Jenkins and Russell, 1952; Bower et al., 1969; Broadbent et al., 1978) and that instructions to organize information enhances memory even in the absence of instructions to memorize (Mandler, 1967). It is also widely accepted that both episodic and semantic information is stored in long-term memory in an organized fashion (e.g., Smith et al., 1974; Collins and Loftus, 1975; Raaijmakers and Shiffrin, 1981; Anderson, 1983; Tulving, 1983). Moreover, examinations of recall output indicate that learners will subjectively organize information that is presented randomly (Bousefield, 1953), even if that information is, on the surface, unrelated (Tulving, 1962). Thus, it is likely that the organization function of mnemonics decreases storage demands by arranging the stimuli in a fashion that more closely matches the preexisting organizational structure of long-term memory. Furthermore, mnemonics that link the to-be-remembered information to the organizational structure of long-term memory may also facilitate retrieval (Baddeley, 1990).

#### 2.10.1.2 Elaboration

A second major process used in the context of mnemonics is elaboration. Although the term is sometimes used synonymously with semantic analysis in textbooks (e.g., Matlin, 2005), an accurate definition describes elaboration more generally as a process of embellishment with additional information (Baddeley, 1990; Anderson, 1995). The advantage of the latter definition is that it allows for a distinction to be made between meaningful and nonmeaningful elaboration. A good deal of research (e.g., Craik and Tulving, 1975; Rogers et al., 1977; Nelson, 1979) supports the notion that meaningful elaboration enhances memory. However, nonmeaningful elaboration can also enhance memory, and under certain conditions, it can do so better than meaningful elaboration (Slamecka and Graf, 1978; Kolers, 1979; Pressley et al., 1987). Thus, it appears that it is the degree of elaboration induced by a mnemonic rather than its meaningfulness that facilitates memory (cf. Craik and Tulving, 1975).

It is also important to note how elaboration facilitates memory. It is believed that elaboration facilitates memory by making memories more discriminable at retrieval by virtue of distinctive processing (Craik, 1979; Lockhart et al., 1976). Distinctive processing is defined as the processing of difference in the context of similarity (Hunt, 2006). As it relates to mnemonics, this suggests that, by way of elaboration, a mnemonic adds uniquely identifying or item-specific information to to-be-remembered items. As a result of additional item-specific information, mnemonic-enhanced memories are more discriminable than memories of unelaborated items at retrieval.

#### 2.10.1.3 Mental Imagery

Some of the most enduring mnemonics involve the use of mental imagery as a form of elaboration. The term mental imagery can be used to refer to any type of mental representation (e.g., Kosslyn et al., 1990; Intons-Peterson, 1992), but in the context of mnemonics, mental imagery is usually visual. A wealth of research (e.g., Paivio et al., 1968; Paivio, 1969; Bower, 1970; May and Clayton, 1973; Richardson, 1978) supports the notion that visual mental imagery enhances memory, and this effect is especially robust when interactive imagery is used (Wollen et al., 1972; Yesavage et al., 1983). Mental imagery is an effective component of mnemonics because it has the potential to enhance both the organization and elaboration of to-be-remembered information. Thus, the use of interactive visual imagery in mnemonics may serve to facilitate the encoding and storage of to-be-remembered information as well as it making the information more discriminable at retrieval.

The use of bizarre mental imagery as a component of mnemonics has been advocated by Greek and Roman orators (Yates, 1966), professional mnemonists (Lorayne and Lucas, 1974; Lorayne, 1990, 1998), and educators (Tess et al., 1999). As a result, the relative effectiveness of bizarre and common imagery has received a good deal of attention from psychological researchers. Empirical research suggests that instructions to use bizarre imagery can lead to better memory than instructions to use common imagery when both types of imagery are used (McDaniel and Einstein, 1986; Cornoldi et al., 1988; Worthen and Marshall, 1996) and either free recall or recognition is tested (Worthen, 2006). However, additional research (Anderson and Buyer, 1994; Weir and Richman, 1996; Worthen, 1997) indicates that the bizarreness advantage is due to the more general process of bizarre elaboration rather than mental imagery *per se*. Regardless, it is likely that the use of bizarre elaboration in the context of a mnemonic makes the to-be-remembered information more discriminable at retrieval.

#### 2.10.1.4 Retrieval Cues

As described earlier, organization, elaboration, and mental imagery are often treated as part of the encoding process. However, one could just as easily suggest that these processes are part of the retrieval process. Indeed, as Tulving (1983) convincingly argued, any distinction between encoding and retrieval processes is purely heuristic. Processes occurring at the time of learning exert their effect on the retrieval process, either as facilitation or interference, and thus no meaningful theoretical dichotomy between encoding and retrieval remains coherent. The challenge is to explain the influence of processing at the time of initial experience on processes required for successful test performance. To this point, we have hinted at the importance of developing cues that are diagnostic of the to-be-remembered information. A more elaborate rendition of this idea is that the processing of the original experience, when reinstated at testing, constrains production to a limited set of items. This idea has been suggested to explain the effect of various encoding manipulations.

An example of this type of approach within the context of mnemonics is research (i.e., Wallace and Rubin, 1991; Rubin, 1995) that has examined the use of rhyme and meaning to cue memory for narratives in the oral tradition. Such research suggests that rhyme and meaning cues work in concert to facilitate memory by constraining the number of stored choices available at retrieval (cf. Rubin and Wallace, 1989). More generally, this notion of constraining choices at retrieval is at the heart of the effectiveness of distinctive processing. As noted by Hunt and Smith (1996), organization serves to specify the episodic context in which to-be-remembered information was embedded. The addition of item-specific information (e.g., a unique cue) along with organizational processing limits the retrieval set to items that both share the unique feature and were present in the specified context. Thus, processes that ostensibly occur during encoding may very well exert their influence by providing diagnostically precise cues at retrieval.

## 2.10.2 Formal Mnemonic Techniques

In this section, we discuss strategies for improving memory that involve highly prescribed instructions. Typically, formal mnemonics involve instructions for associating to-be-remembered information with more well-established stored memories.

#### 2.10.2.1 The Method of Loci

With evidence of its use dating back to circa 500 BC (Yarmey, 1984), the method of loci is perhaps the oldest enduring mnemonic. Believed to have been used extensively by Greek and Roman orators, the method of loci is designed to facilitate serial recall by organizing to-be-remembered information within the context of a well-established visual mental image. As an example, consider a herpetologist who wishes to use the method of loci to help remember the topics to be covered in a talk about venomous snakes in Texas. Specifically, the herpetologist wishes to discuss the five most common venomous snakes of Texas in order of potential dangerousness. From least to most dangerous, the snakes discussed in the talk would include the copperhead, the cottonmouth, the coral snake, the timber rattler, and the diamondback rattler. To use the method of loci to remember the list of species to be discussed, the herpetologist would first form a mental image of a very familiar place such as the layout of his home. The next step would be to form associations between the familiar image and the species of snakes to be discussed by mentally placing a cue representing each species in a separate part of the imagined location. In our example, the herpetologist might imagine the normally blue wooden front door of his house to be made of shiny copper to cue the memory of copperhead. Next, he might imagine a carpet of cotton balls (to cue cottonmouth) leading from the front door into the foyer. Similarly, to cue his memory for the coral snake, timber rattler, and diamondback rattler, the herpetologist could imagine a coffee table made of coral in the living room, a stand of small pine trees lining the stairwell, and an oversized diamond blocking passage at the top of the stairs. Finally, when the topics of the talk need to be recalled, the herpetologist would simply mentally revisit his familiar place and pick up the cues he left behind.

In theory, the method of loci should be an effective mnemonic because it represents an application of all three basic mnemonic processes. First, the to-be-remembered information is organized in a serial fashion by association with a well-established memory. In our herpetologist example, the necessary serial order of the list is maintained by associating the least dangerous species with the entrance to the home and the more dangerous species with more interior locations within the home. Thus, when the herpetologist mentally revisits his mental image at the time of his talk, he will encounter cues in the specified order simply by following the natural layout of his home.

Second, the method of loci provides elaboration of to-be-remembered information via the development of associated cues (e.g., pine trees for a timber rattler) and the use of visual mental imagery. One should also note that imagery used in our example was interactive and bizarre by design. The interactive nature of the imagery is important because it enhances the link between the well-established memory of the familiar place and the less-well-established memory of the to-be-remembered information. The bizarreness of the imagery allows the to-be-remembered information to stand out against the common backdrop and should ultimately lead to a more discriminable memory trace.

The effectiveness of the method of loci as mnemonic technique is supported by anecdotal evidence from professional mnemonists (Lorayne and Lucas, 1974), case studies of exceptional memories (Luria, 1968), and empirical evidence. Regarding the latter, research indicates that the method of loci indeed enhances serial recall (Ross and Lawrence, 1968; Christen and Bjork, 1976; Wang and Thomas, 2000), even after a substantial retention interval (Groninger, 1971; Wang and Thomas, 2000). Furthermore, research has demonstrated that the same loci can be used to learn several different lists without proactive interference (Christen and Bjork, 1976; de Beni and Cornoldi, 1988; Massen and Vaterrodt-Plunnecke, 2006). Some evidence also suggests that mnemonic training with the method of loci can curb some age-related memory differences in elderly adults (Hill et al., 1991; Brooks et al., 1999). Overall, the method of loci is considered along with the peg-word method (described next) to be one of the most effective mnemonics for learning lists (Roediger, 1980). However, when used to learn more complicated verbal material (e.g., prose, discourse), the method of loci is effective when to-be-remembered information is presented orally, but not when information is presented in a written format (Cornoldi and de Beni, 1991; Moe and de Beni, 2005). Additionally, because of its complexity, the method of loci is generally considered an unsuitable mnemonic for the rehabilitation of memory for those suffering from brain injury (McKinlay, 1992; Richardson, 1995).

#### 2.10.2.2 The Peg-Word Method

A mnemonic also designed to enhance serial learning, but with a less-storied history, is the peg-word method. Although its exact origins are unclear, the peg-word method may be a simplification of Grey's (1730) very complicated mnemonic system that involved the transformation of numbers to letters and sounds. Loosely similar to Grey's system, the peg-word method involves learning a list of words that rhyme with numbers to be used as framework with which to organize to-be-remembered items. In a typical rendering, the list of peg words includes bun, shoe, tree, door, hive, sticks, heaven, gate, wine, and hen to represent the numbers 1–10, respectively. To use the peg-word method, one first commits the list of peg words to memory. Then, when a list of items needs to be learned, an interactive visual image is formed between each to-be-remembered item and a peg word. As an example, suppose that an outdoor enthusiast wishes to remember a list of the most crucial items that one would need to survive in the wilderness. According to Bradley Angier's (1956) timeless book *How to Stay Alive in the Woods*, a minimal survival kit would include matches, a compass, a knife, a mirror, and maps. One could remember these items using the peg-word method by creating the following images: numerous matches protruding between two buns like a sloppy match sandwich, an animated compass wearing shoes (perhaps hiking boots!), a tree with a knife embedded in its trunk, a door with a mirror where the window should be, and an animated bee reading a map in front of a hive. When the items need to be remembered, one would simply recall the list of peg words in order. Just as the numbers 1–5 will cue memory for the peg words, the peg words should cue the list of needed items in a specific order.

Like the method of loci, the peg-word method makes use of organization, elaboration, and mental imagery. The association of to-be-remembered items to numbers allows the information to be organized in a specified sequence. The association of the to-be-remembered items to the peg words and the interactive mental image representing that association provides a good amount of elaboration to enhance the discriminability of the memory trace. Moreover, discriminability of the memory trace may be also be enhanced by the nearly inevitable use of bizarre elaboration when using the peg-word method.

Despite the apparent counterproductivity of learning one list (peg words) to remember another list (to-be-remembered items), the usefulness of the peg-word method has received a good deal of empirical support. Research has demonstrated the effectiveness of the method when used by normal and learning-disabled children (Veit et al., 1986; Krinsky and Krinsky, 1996), normal and learning-disabled adolescents (Elliot and Gentile, 1986), college-age adults (Wood, 1967; Bugelski, 1968; Bugelski et al., 1968; Johnson, 1970; Wood and Bolt, 1970; Wang and Thomas, 2000), and older adults (Wood and Pratt, 1987). The peg-word method has also been found to be effective after both short and lengthy retention intervals (Wang and Thomas, 2000). Furthermore, the same list of peg words can be used for numerous lists without interference (Morris and Reid, 1970; Massen and Vaterrodt-Plunnecke, 2006). However, the peg-word method has been demonstrated to be ineffective when used to learn information that is high in category relatedness (Reddy and Bellezza, 1986) or for information that is presented very rapidly (Bugelski et al., 1968). Also, like the method of loci, the peg-word method may be too complex for use with brain-injured learners in rehabilitation settings.

The relative effectiveness of the peg-word method, the method loci, and rote rehearsal in determining serial recall is depicted in **Figure 1**.

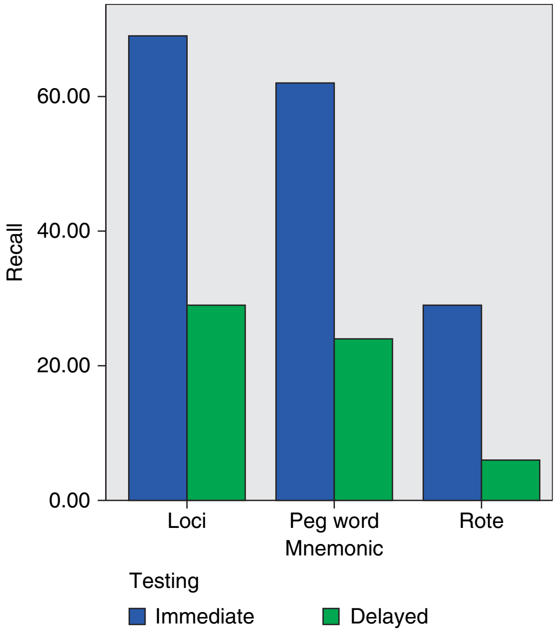

**Figure 1** Percentage of correct serial recall as a function of mnemonic method and retention interval. Adapted from Roediger HL (1980) The effectiveness of four mnemonics in ordering recall. *J. Exp. Psychol. Hum. Learn. Mem.* 6: 558–567.

### 2.10.2.3 The Keyword Method

The keyword method was originally developed by Raugh and Atkinson (1975) as a procedure to facilitate second-language acquisition. The keyword method involves making an association between a to-be-remembered term's meaning and what the term sounds like in one's primary language and then using interactive mental imagery to elaborate on that association. For example, consider an English speaker who is trying to learn the Spanish term queso, which means cheese in English. When pronounced, queso sounds like 'CASE-OH.' Thus, the learner could use the English word case as the keyword for remembering that queso means cheese. Forming a mental image of a briefcase made of cheese (or a briefcase full of cheese) could embellish the association between the keyword and the translation. At recall, the Spanish term queso should cue the keyword (case) and, subsequently, the interactive mental image that combined the meaning of the to-be-learned term and the keyword (i.e., briefcase made of cheese). From a theoretical perspective, the keyword method should be an effective mnemonic because it encourages elaboration during the production or processing of the keyword (depending on whether the learner generates the keyword) and because of its use of interactive mental imagery.

Empirical research has demonstrated the keyword method to be effective in facilitating second-language acquisition both in children (Pressley, 1981; Pressley et al., 1981) and adults (Atkinson and Raugh, 1975; Raugh and Atkinson, 1975; Beaton et al., 2005). The keyword method has also been found to facilitate primary-language vocabulary learning in learning-disabled children (Cundus et al., 1986; Mastropieri et al., 1990), normal children (Levin et al., 1992), and normal adults (Pressley, 1982; Sweeney and Bellezza, 1982; Troutt-Ervin, 1990). Additionally, versions of the keyword method have been used to effectively enhance children's learning of music history (Brigham and Brigham, 1998), adult's memory for artists and their work (Carney and Levin, 1991), the quality of college students' written essays (Rummel et al., 2003), and memory for prose in young, middle-aged, and elderly adults (Dretzke, 1993). However, a growing body of research (Wang et al., 1992, 1993; Wang and Thomas, 1995; Thomas and Wang, 1996) suggests that keyword method does not enhance recall after lengthy retention intervals (for contrary results, see McDaniel and Pressley, 1984; McDaniel et al., 1987). Research also indicates that the keyword method may not be effective for second-language acquisition among experienced foreign-language learners (van Hell and Mahn, 1997). Finally, regarding the keyword method, research (Campos et al., 2004; Beaton et al., 2005) suggests that the effectiveness of the method is dependent on mental-image quality.

### 2.10.3 Organizational Mnemonic Techniques

Organizational mnemonic techniques serve mainly to organize information such that all to-be-remembered information is linked together in memory. Unlike formal mnemonic techniques, organizational mnemonic techniques do not emphasize the establishment of associations between to-be-remembered information and previously stored memories to aid retrieval. Instead, organizational mnemonic techniques emphasize intralist associations and are thus less dependent on extralist cues for successful retrieval. Successful use of an organizational technique should consolidate all to-be-remembered information such that retrieval of one item cues memory for other items. Thus, like a connected chain of paper clips, successful retrieval of one item should result in successful retrieval of all items. However, a major disadvantage of this dependence on intralist cues is that the failure to retrieve a single item of the to-be-remembered information may result in the failure to recover all items cued by the forgotten item (cf. Bellezza, 1981, 1996).

#### 2.10.3.1 Acronyms (Linking by Initial Letter)

The use of acronyms to enhance free or serial recall is a popular mnemonic among college students (Gruneberg, 1973; Stalder, 2005). This method simply involves making a word or pseudo word out of the initial letters of to-be-remembered information. For example, a biology student might use the acronym IPMAT to remember the five stages of cell division (interphase, prophase, metaphase, anaphase, and telophase). Perhaps due to its simplicity and popularity among students, the use of acronyms has been advocated for learning a variety of information, including assessment criteria for psychological disorders (Short et al., 1992; Pinkofsky, 1997; Pinkofsky and Reeves, 1998).

Despite its simplicity and popularity, empirical research investigating the effectiveness of the use of acronyms as a mnemonic has provided minimal support for the method. Although a few studies (Nelson and Archer, 1972; Kovar and Van Pelt, 1991; Stalder, 2005) suggest limited effectiveness of acronyms as mnemonics, the bulk of research (Boltwood, and Blick, 1970; Waite et al., 1971; Perewiznyk and Blick, 1978; Carlson et al., 1981) suggests that acronyms do not enhance recall, especially when they are self-generated (Kibler and Blick, 1972).

#### 2.10.3.2 Linking by Story

Another way to organize to-be-remembered information such that all items are linked together is to form a story that incorporates each item. This method has the same organizational advantage of using acronyms but also includes a high degree of self-generated elaboration. Thus, unlike the use of acronyms, linking by story should result in a memory trace that both consolidates to-be-remembered items and is highly discriminable (cf. Bellezza, 1986).

Early empirical research investigating the linking-by-story mnemonic demonstrated the method to be effective for enhancing both serial (Bower and Clark, 1969) and free recall (Herrmann et al., 1973) of verbal material in college-age adults. Subsequent research has found the method to be useful for improving recall in elderly participants (Hill et al., 1991; Drevenstedt and Bellezza, 1993), memory-impaired participants (Wilson, 1995), and mildly retarded participants (Glidden, 1983). A variation of the linking-by-story method has also been found to improve memory for long strings of digits (Bellezza et al., 1992). Additionally, a study comparing the method of loci, the peg-word method, and the linking-by-story method found linking by story to be the most effective method to enhance free recall (Herrmann, 1987).

#### 2.10.3.3 Categorical and Schematic Organization

The use of categories or schemas to organize to-be-remembered information is often advocated as a mnemonic in textbooks (i.e., Solso, 2001; Matlin, 2005). A category organization involves organizing information in a taxonomic hierarchy whereby abstract category labels are used to organize subordinate exemplars. As an example, consider an angler who wishes to remember a list of items to needed for a fishing trip. The angler must remember the following items: rod and reel, motor key, filet knife, landing net, battery for boat, and plastic bags for storage of fish filets. These items could be organized into three separate categories, each of which subsumes two items. The battery and key would be subsumed under the category label boat items, the rod and reel and landing net would be subsumed under fishing tackle, and the knife and bags would be subsumed under fish-cleaning supplies. With this type of organization, one would need only to remember the category labels, which should cue the specific items to be remembered. As such, the organization of the to-be-remembered items should reduce cognitive load, and with this type of application, the intrusion of categorically related associates would not be necessarily problematic.

A schematic organization involves organizing to-be-remembered information such that spatial relations among items are maintained (Nakamura et al., 1992). Using our fishing-trip example, the needed items could be organized according to where they are to be placed in a boat. For example, the angler might note that the key and battery are in the stern of the boat, the fish-cleaning supplies in the main hatch, and the rod and reel and landing net in the bow of the boat. Thus, the stern, hatch, and bow of the boat would serve to organize and cue to-be-remembered items.

Empirical research using college-age adults (Nakamura et al., 1992) has demonstrated that information organized by taxonomic category and information organized into scene schemas is better recalled than unorganized information. Other research also using college-age adults (Khan and Paivio, 1988) has demonstrated that category organization and script-schema organization leads to equivalent levels of recall. However, it should be noted that categorical and schematic organization is unlikely to enhance recall in young children (Yoshimura et al., 1971).

### 2.10.4 Summary of Mnemonics and Mnemonic Processes

The mnemonics discussed in this chapter represent simple applications of well-established mnemonic processes. All of the mnemonics designed to enhance memory for lists included a procedure designed to enhance the organization of the to-be-remembered information. Moreover, the most effective of these mnemonics involve a combination of organization and at least one form of elaboration (see **Table 1** for a summary). The sole mnemonic discussed here that did not emphasize organization (the keyword method) was designed to enhance memory for paired associates rather than lists and thus would incur fewer benefits from organization. Nonetheless, even this method imposes some degree of organization on to-be-remembered information via the use of interactive mental imagery.

The importance of a combination of organization and elaboration to mnemonic effectiveness is attested by research that has shown that memory is enhanced by procedures that combine relational and item-specific processing (Einstein and Hunt, 1980; Hunt and Einstein, 1981). Relational processing refers to the processing of fundamental similarities among to-be-remembered items. Thus, relational processing is, in essence, organizational processing. Moreover,

**Table 1** Mnemonic Effectiveness as a Function of Processes Involved

| *Mnemonic* | *Organization* | *Elaboration* | *Imagery* | *Effectiveness* |
|---|---|---|---|---|
| Method of Loci | Yes | Yes | Yes | High |
| Peg-Word Method | Yes | Yes | Yes | High |
| Keyword Method | No | Yes | Yes | High |
| Acronyms (without imagery) | Yes | No | No | Low |
| Acronyms (with imagery) | Yes | No | Yes | Limited |
| Linking by Story | Yes | Yes | No | High |
| Category Organization | Yes | No | No | Limited |
| Schema Organization | Yes | No | No | Limited |

Note: Imagery has both organizational and elaborative properties.

relational processing is believed to enhance memory by specifying a common context in which all to-be-remembered items are embedded. On the other hand, item-specific processing – the processing of unique characteristics of individual items – can be induced by elaboration. Thus, by specifying both a common context and uniquely identifying characteristics of individual items, a combination of relational and item-specific information should enhance the discriminability of list items in memory (Hunt and McDaniel, 1993; Hunt, 2006).

Applied to mnemonics, research on relational and item-specific processing suggests that any mnemonic technique that involves a combination of organization and elaboration should facilitate memory. However, a mnemonic that emphasizes only organization or only elaboration is unlikely to result in strong memorial benefits. In support of the latter claim, the use of acronyms may be an ineffective mnemonic because it mainly emphasizes organizational processing with little emphasis on elaboration. As such, acronyms may serve to link to-be-remembered items together, but, without elaboration, individual items are not particularly discriminable in memory. However, the simple addition of elaboration (i.e., mental imagery) to compliment the already existing process of organization significantly increases mnemonic effectiveness of an acronym (Wilding et al., 1986). Similarly, research investigating the mnemonic effectiveness of bizarre imagery as a method of elaboration has found that, in the absence of an organizational scheme, bizarre imagery is no more effective than using common imagery when only one form of elaboration (bizarre or common) is used during learning (Wollen and Cox, 1981; McDaniel and Einstein, 1986). However, if bizarre elaboration is complemented by an organizational scheme (i.e., the method of loci and the peg-word method), the result is a successful mnemonic. Thus, it is likely that the exact nature of the organization and elaboration comprising a mnemonic is far less important than the requirement that some form of both organization and elaboration is used.

## 2.10.5 Practical Issues

A major issue in the application of mnemonic techniques is whether the main components of a given mnemonic should be provided to or generated by the learner. Although basic research (e.g., Bowbrow and Bower, 1969; Slamecka and Graf, 1978) supports the notion that generation enhances memory, the application of this finding within the context of mnemonic research is not without qualification. In terms of simple mnemonic processes (e.g., mental imagery), research (Jamieson and Schimpf, 1980; Ironsmith and Lutz, 1996; Kuo and Hooper, 2004) indicates that self-generated elaboration is more effective than elaboration that is provided. However, provided elaboration can be more effective than learner-generated elaboration if it is in the context of a mnemonic that is difficult to use (Patton et al., 1991) or if it is to be used with learning-impaired populations (Swanson et al., 1988; Canellopoulou and Richardson, 1998).

A more general issue related to self-versus-other generation is whether self-generated mnemonic strategies are more effective than mnemonics devised by others. If, as we have argued, a few basic cognitive processes can account for the effectiveness of formal mnemonics, then one may be inclined to abandon formal mnemonics in favor of self-generated applications of mnemonic processes. This sentiment is reflected in the results of a study by Park et al. (1990), which suggests that memory researchers and other psychologists are more likely to both use and recommend the use of general mnemonic processes (e.g., organization and elaboration) than formal mnemonics.

Although spontaneous use of formal mnemonics is infrequent (Intons-Peterson and Fournier, 1986; Soler and Ruiz, 1996), this does not mean that self-generated mnemonics are more useful. For example, Wang and Thomas (2000) examined the effectiveness of the method of loci, the peg-word method, self-generated organizational and imagery mnemonics, and rote rehearsal in determining serial recall. They found self-generated strategies to be least effective when recall was tested immediately, but as effective as formal mnemonics after a 48-h delay. Similarly, research with elderly participants (Derwinger et al., 2003, 2005) has indicated only minimal advantages of self-generated strategies compared to other-generated strategies even after training. Apparently, the benefits of generation and ease of use associated with self-generated mnemonics is offset by the effort involved with devising a personal strategy.

Taking into consideration research examining self-generated versus other-generated elaboration and, more generally, self- versus other-generated strategies, the most important point seems to be that mnemonics are quite flexible. That is, as long as an appropriate combination of cognitive processes is involved, a mnemonic can be effective regardless of whether it is fully self-generated or other-generated or whether it contains self- or other-generated components. Thus, the decision to use a self-generated or other-generated mnemonic may simply boil down to personal preference. As noted previously by Bellezza (1996), individual differences may play a large role in determining the effectiveness of any mnemonic. Considering that research also indicates that the effectiveness of a mnemonic depends on the demands of the learning situation (Roediger, 1980; Herrmann, 1987), it is likely that there is no single best mnemonic for a given person or even a given situation. As such, the best approach to improving memory across a variety of situations may be to have an assortment of mnemonic techniques at one's disposal.

## 2.10.6 Conclusions

Although a variety of strategies for enhancing memory have been offered throughout history, the most effective mnemonics involve some combination of organization and elaboration. Thus, it is likely that the specific means of encouraging organization and elaboration are less important than the requirement that both processes utilized. Similarly, when a mnemonic emphasizes both organization and elaboration, it can be effective regardless of whether it is devised by or provided to the learner. However, the appropriateness of any given mnemonic will be determined by characteristics of both the learner and the learning situation.

# 2.11 Human Spatial Memory and Navigation

**T. P. McNamara**, Vanderbilt University, Nashville, TN, USA

**J. Sluzenski**, Richard Stockton College of New Jersey, Pomona, NJ, USA

**B. Rump**, Vanderbilt University, Nashville, TN, USA

## 2.11.1 Introduction

Effective navigation abilities are crucial for the survival of almost every living mobile species. They are essential, for instance, for finding the way back to a previously discovered source of food or water, for safely returning home after a sudden change of weather, and for not getting lost in a complex environment such as a cave. For most modern humans, effective navigation skills have become less critical for daily survival, but many common activities, such as getting to work and back home, are nevertheless still characterized by the need to navigate successfully between places.

Successful navigation relies on two capabilities. First, the organism needs to be able to construct enduring internal representations of the locations and identities of significant objects or landmarks in the environment. Second, the organism needs to be able to stay oriented with respect to these represented elements. As the organism moves, the spatial relations between the organism and the elements in the environment constantly change. To remain oriented and to avoid getting lost, spatial updating processes need to be invoked to compensate for those changes.

The goal of this chapter is to review empirical and theoretical advancements in the scientific understanding of human spatial memory and navigation. Our focus is on memories acquired from direct experience, such as vision and locomotion, and on spaces sufficiently large to afford movement, such as translation and rotation, although we also refer to some findings obtained from studies investigating memories of tabletop-sized environments. We are especially interested in the ways memories of familiar environments are used to guide locomotion, reorientation, and wayfinding. Our decision to focus on these topics should not be interpreted to imply that we believe that other types of spatial memories, such as those obtained from language or indirect sources such as maps, are not important or not interesting. Indeed, for modern humans, navigation based on maps and written works, such as guidebooks, may be at least as important as navigation using one's sense of direction and knowledge of the relations between visible and invisible parts of an environment. Because of space limitations, we were forced to trade breadth against depth of coverage and opted to explore a smaller set of topics in detail, at the expense of several topics equal in importance to those covered here (for reviews of greater scope, see Golledge, 1999; Montello, 2005).

This chapter is divided into nine primary sections. We begin by discussing the elemental types of spatial knowledge: object identity, routes, environmental shape, and survey knowledge. In the second section, we investigate classical and current theories of the acquisition of spatial knowledge. The third section discusses properties of spatial knowledge, such as its hierarchical structure and orientation dependence. In the fourth section, we examine the concept of spatial reference systems and the nature of the spatial reference systems used in spatial memory and navigation. We then turn our attention to the processes and representations that underlie the abilities to guide locomotion and to avoid getting lost. In the sixth section of the chapter, we review contemporary theories of spatial memory and navigation, with an eye for similarities. The seventh section examines the development of spatial memory and navigational capabilities. The eighth and penultimate section looks at the brain networks underlying spatial memory abilities. We close the chapter with a summary and prospectus for future research on human spatial memory and navigation.

## 2.11.2 Types of Spatial Knowledge

### 2.11.2.1 Object Identity

The most elemental type of spatial knowledge may be knowledge of the identities and appearances of objects or environmental features (a hill, an intersection of paths, etc.). We use the term object identity to refer to this type of knowledge, recognizing that many entities in an environment that are important for navigation may not be objects in the narrow sense of the term (e.g., path intersection, saddle between two hills). This type of knowledge is sometimes referred to as landmark knowledge (e.g., Siegel and White, 1975), although landmark knowledge is a special case of object knowledge. People know the identities of many objects in their environments that may not serve as landmarks. Landmarks are objects of special significance to spatial memory and navigation (e.g., Couclelis et al., 1987): They are used to indicate the locations of other objects (e.g., the restaurant is in the basement of the Maxwell House Hotel); they may be the goals of navigation (e.g., I am going to Ryman Auditorium); they mark the locations of changes of direction (e.g., turn right at the Gaylord Entertainment Center); and they are used to maintain course (e.g., you will pass Tootsies Orchid Lounge on your right). According to Siegel and White's (1975) theory of the acquisition of spatial knowledge (discussed in the section titled 'Microgenesis of spatial knowledge'), landmark knowledge is the first to be acquired and is the building block of other types of spatial knowledge.

### 2.11.2.2 Route Knowledge

Route knowledge consists of knowledge of sequences of landmarks and associated decisions and actions. Actions specify the steps needed to get to the next landmark on the route (e.g., turn right at the post office and drive three blocks to the Laundromat). According to Siegel and White's theory, route knowledge does not represent distance, temporal duration, or turning angles early in acquisition. Such metric properties are acquired gradually with experience in an environment.

### 2.11.2.3 Environmental Shape

The importance of knowledge of environmental shape was discovered relatively recently. Cheng (1986) found that when rats searched for the known location of food in rectangular enclosures they often committed rotational errors in which they searched the correct location and the incorrect location differing from the correct one by 180° of rotation. For instance, if the correct location was in one of the corners, the rotational error would be the corner diagonally opposite to the correct corner. These errors occurred even when nongeometric featural cues, such as visual or tactile patterns, were available that would allow the rat to distinguish the correct location from the rotational error. Similar findings have been observed in many species, including humans (for a review, see Cheng and Newcombe, 2005). There is ample evidence that people are sensitive to environmental geometry when they learn a new environment (e.g., Shelton and McNamara, 2001;

Schmidt and Lee, 2006) and when they reorient and navigate (e.g., Sandstrom et al., 1998; Hartley et al., 2004; Ruddle and Péruch, 2004).

### 2.11.2.4 Survey Knowledge

Knowledge of the overall configuration of an environment, including knowledge of Euclidean (straight-line) distances and of interpoint directions, defined in a common reference system, makes up survey knowledge. A key feature of survey knowledge is that the spatial relations between locations can be retrieved or inferred even if the organism has never traveled between the locations. Survey knowledge of an environment is often referred to as a cognitive map (a term coined by Tolman, 1948) and likened to physical maps, although such language and parallels imply isomorphisms between the mental and the physical that do not exit. Survey knowledge is considered to be the most sophisticated type of knowledge obtained about an environment (e.g., Siegel and White, 1975). Behaviors taken to be the signature of survey knowledge include the abilities to create efficient routes (e.g., taking shortcuts), to point directly to unseen locations, and to estimate Euclidean distances.

## 2.11.3 Microgenesis of Spatial Knowledge

The process of the acquisition of spatial knowledge of a new environment has been referred to as microgenesis. The classical theory of the microgenesis of spatial knowledge was proposed by Siegel and White (1975) and it remains the dominant theory in the field (Montello, 1998). According to this theory, the identities and appearances of landmarks are learned first, followed by routes between landmarks. Route knowledge is primarily nonmetric early in acquisition, consisting of the order of landmarks and the appropriate actions to be taken at each one in the sequence. Through experience, route knowledge can acquire metric, or at least approximately metric, properties, such as distance, temporal duration, and turning angles. The most sophisticated form of spatial knowledge is survey knowledge, which is assumed to be derived from accumulated route knowledge (e.g., Thorndyke and Hayes-Roth, 1982).

Although this theoretical framework has been enormously influential, it has not received a great deal of empirical support (for reviews, see Montello, 1998; Ishikawa and Montello, 2006). The limitations of the classical theory are apparent in the findings of a recent study published by Ishikawa and Montello (2006). Participants in this experiment were passively transported by automobile along two routes in a private residential area. The routes passed around and over many hills, and afforded few views of distant landmarks. Learning took place over 10 days (once a week for 10 weeks); on the fourth and subsequent days, participants were transported along a connecting route between the two routes and encouraged to learn the spatial relation between them. Participants' knowledge of the routes and their interrelations was tested using landmark recall, direction estimates, route and Euclidean distance estimates, and map drawing.

Performance was above chance on all tasks after the first session, and near perfect on some, such as landmark sequence recall and route distance estimation. Direction estimates and more difficult distance estimates (e.g., Euclidean estimates within the more complex route) were only moderately accurate and improved modestly over the course of learning. However, substantial individual differences were observed. Some participants performed very well after only one or two sessions and maintained high performance levels on all tasks across all sessions. Another subgroup of participants performed poorly throughout the experiment and showed very little learning on the more challenging tasks, even after 12–14 h of exposure to the routes. Only about half of the participants improved monotonically over the course of learning, and those gains were not large.

These findings largely validate the theoretical distinction between route and survey knowledge, as tasks sensitive to route information, such as landmark sequence recall and route distance estimation, produced similar patterns of results, and tasks sensitive to the layout of the routes, such as Euclidean distance estimation, direction estimates, and map drawing, produced results similar to each other but different from the route tasks. However, these results contradict several key predictions of the classical theory. Landmark knowledge and route knowledge were acquired almost simultaneously. Route knowledge seemed to contain some quantitative information from the very beginning. Even at the earliest stages of learning, participants had some knowledge of the spatial layout of the routes. Finally, although some participants gained more accurate knowledge of the layouts of the routes over the course of learning, few of them could be characterized as having gained accurate survey knowledge of the environments (see also, Gärling et al., 1981; Golledge, 1993).

The evidence on spatial knowledge acquisition is most consistent with Montello's theoretical framework (Montello, 1998; Ishikawa and Montello, 2006). According to this theory, the process of acquiring knowledge of the spatial structure of large-scale environments consists of incremental accumulation of metric knowledge, instead of stage-wise transitions between qualitatively distinct types of spatial knowledge. Spatial knowledge is never limited solely to nonmetric information. This theory emphasizes the importance of knowledge integration – combining knowledge about separately learned places into more complex hierarchically organized representations – in spatial knowledge acquisition. However, even this theoretical framework does not predict or explain the large individual differences observed by Ishikawa and Montello.

## 2.11.4 Nature of Spatial Knowledge

### 2.11.4.1 Fragmented

Spatial knowledge is typically fragmented, in the sense that it consists of a patchwork of detailed knowledge of some areas and only sparse knowledge of other, possibly neighboring, areas (e.g., Lynch, 1960; Appleyard, 1970). Survey knowledge never has the property of being of uniformly high fidelity for all familiar areas.

### 2.11.4.2 Distorted

A second key property of spatial knowledge is that memories of spatial relations, such as distances, angles, and orientation, often differ from the physical values in systematic and predictable ways (e.g., Tversky, 1992, 2000). As discussed in several sections of this chapter, such distortions have played a prominent role in the development of theories of spatial memory.

Estimates of Euclidean distances are greater when locations are separated by a barrier or boundary (e.g., Kosslyn et al., 1974; Newcombe and Liben, 1982; McNamara, 1986) and tend to increase with the clutter between the locations (e.g., Thorndyke, 1981). Boundary effects occur even when the boundaries are subjective (e.g., McNamara et al., 1989; Carbon and Leder, 2005). Estimates of route distance increase with the number of turns (e.g., Byrne, 1979; Sadalla and Magel, 1980) and the number of intersections (e.g., Sadalla and Staplin, 1980). Distance estimates are also asymmetric under certain circumstances (e.g., Sadalla et al., 1980; McNamara and Diwadkar, 1997; Newcombe et al., 1999). In particular, distances from less salient locations or objects to more salient locations or objects (i.e., landmarks or reference points) are underestimated relative to the reverse. Angles of intersection between roads are remembered as being closer to 90° than they are in reality (e.g., Byrne, 1979; Tversky, 1981; Moar and Bower, 1983; Sadalla and Montello, 1989). Disparate regions of space, such as states or continents, are remembered as being aligned with each other, and individual regions of space are remembered as being oriented with canonical reference axes (e.g., Stevens and Coupe, 1978; Tversky, 1981). For instance, people believe that North America and South America are vertically aligned, even though the east coast of the U.S. is roughly aligned with the west coast of South America, and that the Bay Area of Northern California is oriented north-south, even though it actually is oriented along a north-west/south-east axis (Tversky, 1981). These biases produce systematic errors in judgments of the relative directions between objects and cities.

### 2.11.4.3 Hierarchical

There is strong evidence that memories of the locations of objects in the environment are organized categorically and hierarchically, such that a region of space may be represented as a whole, containing other regions and locations, and as a part, contained in larger regions. One indication that spatial memories are hierarchical is that judgments of the spatial relations between cities or objects are affected by the spatial relations between superordinate regions (e.g., Stevens and Coupe, 1978; Tversky, 1981; McNamara, 1986). For instance, in Stevens and Coupe's (1978) experiments, Reno was judged to be northeast of San Diego, even though it is actually northwest. According to hierarchical models of spatial memory, this error occurs, at least in part, because people represent Reno in Nevada, San Diego in California, and Nevada east of California. These spatial relations imply that Reno should be east of San Diego. Other evidence consistent with the hierarchical representation of space includes the effects of boundaries on distance estimations (cited previously), the effects of region membership on judgments of orientation (e.g., Wilton, 1979; Maki, 1981) and proximity (e.g., Allen, 1981), and errors in estimates of latitude, bearing, and distance at global scales (e.g., Friedman and Brown, 2000; Friedman et al., 2002; Friedman and Montello, 2006).

Even stronger evidence for hierarchical representations can found in studies in which task performance is shown to depend on the structure of explicit hierarchical models of spatial memory (e.g., Hirtle and Jonides, 1985; Huttenlocher et al., 1991; McNamara, 1986; McNamara et al., 1989). For instance, McNamara et al. (1989, Experiment 1) required subjects to learn the locations of objects in a large room; the objects were unrelated, and there were no physical or perceptual boundaries in the space. After learning, subjects were asked to recall all of the objects several times, to estimate distances between pairs of objects, and to take part in an item recognition test in which the measure of interest was spatial priming (e.g., McNamara et al., 1984). The latent hierarchical structure in each subject's recall protocols was modeled with the ordered-tree algorithm (e.g., Reitman and Rueter, 1980). An example is illustrated in **Figure 1**. Distance estimations and spatial priming were conditionalized on whether pairs of objects were in the same or different subtrees (e.g., ruler–coin vs. envelope–truck), controlling for Euclidean distance. Different subtrees were assumed to correspond to different subjective regions of space. Subjects underestimated distances between pairs of objects in the same subjective region relative to pairs of objects in different subjective regions, and spatial priming was greater between pairs in the same subjective region than between pairs in different subjective regions. Additional analyses showed that spatial priming increased with the depth at which object pairs were clustered (e.g., ruler–coin vs. ruler–pen vs. ruler–screw). These findings provide strong evidence that spatial memories are organized hierarchically, even when the layout lacks explicit perceptual organization.

The hierarchical structure of spatial memory affects navigation behavior, at least in virtual environments. Wiener and Mallot (2003) found that people minimized the number of region boundaries

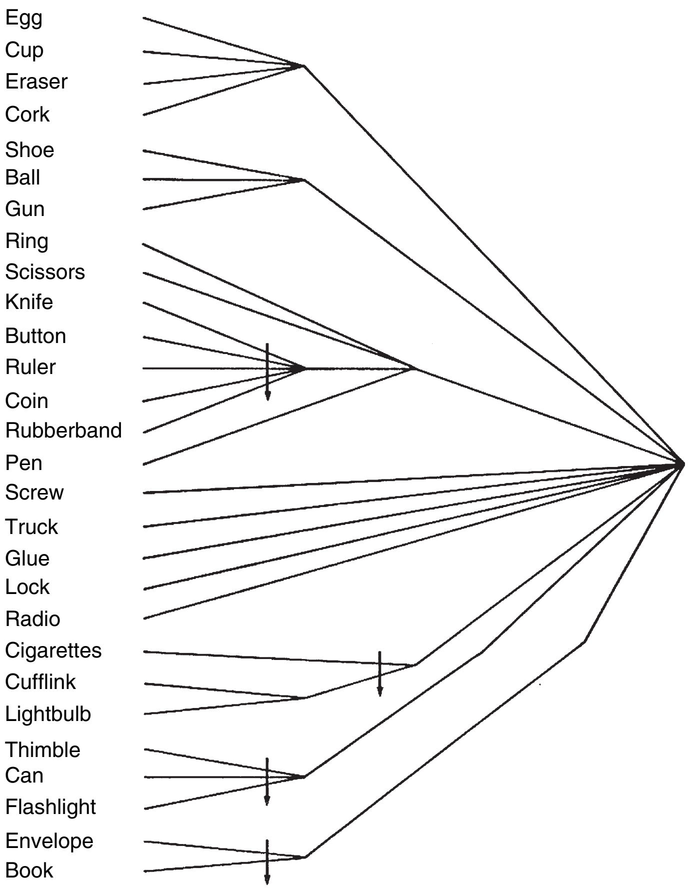

**Figure 1** Ordered tree generated from recall protocols for a single participant. Reprinted with permission from McNamara TP, Hardy JK, and Hirtle SC (1989) Subjective hierarchies in spatial memory. *J. Exp. Psychol. Learn. Mem. Cogn.* 15(2): 211–227.

crossed when navigating to a goal location and that they tended to choose paths that permitted the quickest access to the region containing the goal location. Wiener et al. (2004) showed further that subjects learned environments faster and searched more efficiently when environments were divided into regions than when they were not. This improvement was on the order of a factor of 2. Their results also revealed that navigation strategies seemed to depend on the alignment of the dominant reference directions between different levels of the hierarchical mental representation (see also, Werner and Long, 2003; Werner and Schindler, 2004). (The concept of spatial reference directions and axes will be explored in detail in the section 'Spatial reference systems'.)

### 2.11.4.4 Orientation Dependent

It is well documented that long-term spatial memory is orientation-dependent (see McNamara, 2003, for a review). People recall and recognize interobject spatial relations more efficiently from some perspectives than from others. These privileged perspectives are usually aligned with (parallel or orthogonal to) experienced points of view (e.g., Shelton and McNamara, 2001) but also may be aligned with salient intrinsic axes of the array of objects (e.g., Mou and McNamara, 2002; Mou et al., 2007). Typical results are illustrated in **Figure 2**. There is evidence that spatial memories also may be viewpoint-dependent (e.g., Easton and Sholl, 1995; Waller, 2006; Valiquette and McNamara, 2007). Behaviorally this means that performance is better when the test perspective matches the location of the observer at the time of learning in addition to his or her orientation.

Orientation-independent performance has been observed in several published investigations of spatial memory (e.g., Evans and Pezdek, 1980; Presson and Hazelrigg, 1984; Presson et al., 1989; Sholl and Nolin, 1997, Experiments 3 and 4; Richardson et al., 1999, real-walk condition). McNamara (2003) discusses possible limitations of these studies in some detail. One important feature of those studies (with the exception of Evans and Pezdek's) is that only two orientation conditions were compared: The perspective parallel to and in the same direction as the learning view (0°) and the perspective differing by 180°. This fact may be important because task performance for the imagined heading of 180° is often much better than performance for other novel headings, and can be nearly as good as that for the learning view (e.g., Hintzman et al., 1981; Mou and McNamara, 2002). The cause of this effect is not known, but people may sometimes represent, at least partially, the spatial structure of the layout in the direction opposite to the learning view (Mou et al., 2004). It is also possible that people are able to capitalize, under certain conditions, on the fact that arrays of objects may have high self-similarity under rotations of 180° (e.g., Vetter et al., 1994). Investigations of the orientation dependence of spatial memories are at a distinct disadvantage if only the learning view and its opposite are compared.

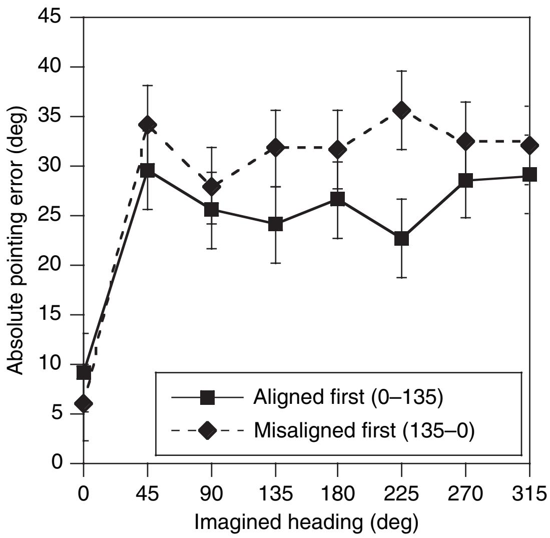

**Figure 2** Results of Shelton and McNamara's (2001) third experiment. Participants learned the layout of seven objects in a room from two points of view (counterbalanced across participants): One view (0°) was aligned with salient environmental reference frames (e.g., walls of the room, square mat on which the objects were placed), and the other (135°) was misaligned with these features. Absolute pointing error in subsequent judgments of relative direction is plotted as a function of imagined heading, separately for the two learning-order groups. Results show that participants represented the layout using a single reference direction parallel to the aligned view and demonstrate the importance of environmental frames of reference in the selection of reference directions in memory. From Shelton AL and McNamara TP (2001) Systems of spatial reference in human memory. *Cogn. Psychol.* 43(4): 274–310.

## 2.11.5 Spatial Reference Systems

Spatial reference systems are essential for the specification of location and orientation in space. The location of Murfreesboro, Tennessee, for example, can be specified by describing its position with respect to the boundaries of the state (e.g., Murfreesboro is in the center of Tennessee), by providing coordinates of latitude and longitude on the surface of the earth (e.g., Murfreesboro is located at 35°55′ N and 86°22′ W), or by describing its position relative to an observer (e.g., Murfreesboro is 31 miles to the first author's left as he writes this paragraph). People represent in memory the spatial properties of many familiar environments. Just as spatial reference systems are required to specify the locations of objects in physical space, so too spatial reference systems must be used by human memory systems to represent the remembered locations of objects in the environment.

A spatial reference system is a relational system consisting of reference objects, located objects, and the spatial relations that may exist among them (e.g., Rock, 1973, 1992; Talmy, 1983). The reference objects may be any objects whose positions are known or established as a standard and may include the observer, other objects in the environment, abstract coordinate axes, and so forth. Note that, according to this definition, a reference frame consisting of orthogonal axes is just one of many types of spatial reference systems. Many schemes for classifying spatial reference systems have been proposed (e.g., Hart and Moore, 1973; Paillard, 1991; Pani and Dupree, 1994; Levinson, 1996; Tversky et al., 1999). For the purposes of understanding the use of spatial memories in navigation and other actions in space, it is useful to distinguish egocentric and environmental reference systems (e.g., Klatzky, 1998). In this chapter, we consider environmental and allocentric reference systems to be equivalent.

Egocentric reference systems specify location and orientation with respect to the organism, and include eye-, head-, and body-based coordinate systems (e.g., Andersen et al., 1997). Returning to the previous example, the description of Murfreesboro's location relative the first author of this chapter uses an egocentric reference system.

Environmental reference systems define spatial relations with respect to elements of the environment, such as the perceived direction of gravity, the sun's azimuth, landmarks, or the walls of a room (e.g., Wehner et al., 1996). Abstract reference systems, such as coordinates of latitude and longitude, also qualify as environmental reference systems. An important subcategory of environmental reference systems are intrinsic reference systems. Intrinsic reference systems can be centered on an object (e.g., Rock, 1973; Marr, 1982). In such cases, the objects usually have inherent facets, such as natural fronts, backs, tops or bottoms, that can be used to define reference axes. The human body is a paradigmatic example. Intrinsic reference systems can also be defined by features of a collection of objects (e.g., Tversky, 1981; Mou and McNamara, 2002). The rows and columns formed by chairs in a classroom constitute an intrinsic reference system. Intrinsic reference systems also may be defined by less explicit perceptual organization, such as an axis of bilateral symmetry or the mutual alignment of several objects (e.g., Mou et al., 2007). An example is illustrated in **Figure 3**.

The primate brain represents the locations of objects in space using egocentric and environmental reference systems (e.g., Andersen et al., 1997; Snyder et al., 1998; Matsumura et al., 1999), and human navigation depends on both egocentric and environmental representations of the environment. Actions such as walking through doorways and other apertures, staying on paths, and avoiding obstacles require the computation of precise self-to-object spatial relations to guide locomotion (e.g., Rieser and Pick, 2006). But planning a route to a distant goal, and maintaining a sense of orientation in large-scale environments, would seem to require enduring representations of the locations of objects relative to other objects (e.g., Loomis and Beall, 1998). Contemporary theories of human spatial memory and navigation specify roles for both egocentric and environmental representations of space, and will be reviewed in detail in the section titled 'Models of spatial memory and navigation'.

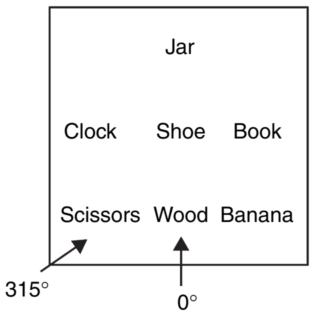

**Figure 3** Layout used by Mou and McNamara (2002). Zero degrees is an axis of bilateral symmetry, increasing the salience of that axis and therefore the probability that it will be selected as a reference direction, even if participants study the layout from a different direction such as 315°. Reprinted with permission from Mou W and McNamara TP (2002) Intrinsic frames of reference in spatial memory. *J. Exp. Psychol. Learn. Mem. Cogn.* 28(1): 162–170.

The concept of spatial reference systems proves useful for accounting for two key properties of spatial knowledge. The orientation dependence of spatial memories indicates that the spatial layout of an environment is mentally represented using a dominant reference direction (e.g., Shelton and McNamara, 2001). Interobject spatial relations that are specified with respect to this reference direction can be retrieved, whereas other spatial relations must be inferred (e.g., Klatzky, 1998), introducing costs in latency and errors. The preferred directions in judgments of relative direction, for example, correspond to intrinsic directions in the layout that are experienced or are highlighted by instructions or layout geometry (e.g., Shelton and McNamara, 2001; Mou and McNamara, 2002; Mou et al., 2007). These preferred directions correspond to the dominant reference directions. A simple model of this form that accounts for orientation dependence in judgments of relative direction is illustrated in **Figure 4**.

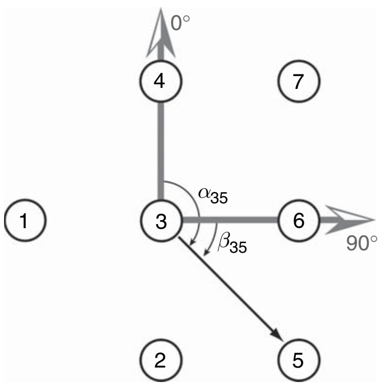

**Figure 4** Schematic depiction of an orientation dependent model of enduring spatial memory. Circles symbolize the represented objects. Interobject spatial relations are symbolized by vectors; for simplicity, only the spatial relation between objects 3 and 5 is represented. Grey arrows symbolize reference directions in the representation. The angular relation from object 3 to object 5 is represented with respect to the 0° ($\alpha_{35}$) and the 90° ($\beta_{35}$) reference directions. Because the direction from object 3 to object 5 relative to 0° is explicitly represented in memory, a task such as ''Imagine you are standing at 3 and facing 4. Point to 5'' is relatively easy, because that direction can be retrieved from memory. A task such as ''Imagine you are standing at 3 and facing 7. Point to 5'' in contrast, is relatively difficult, because the spatial relation between objects 3 and 5 is not represented relative to 45° and, therefore, must be inferred, which produces measurable performance costs. An important feature of the model is that it uses an environmental reference system, yet produces orientation-dependent performance.

The second key property explained by spatial reference systems is the hierarchical structure of spatial knowledge. This property may result from the use of spatial reference systems at multiple scales (e.g., Poucet, 1993). A region of space that can be viewed in its entirety from a single vantage point with minimal locomotion (vista scale as defined by Montello and Golledge, 1999) may be represented in a locally defined spatial reference system. Spatial reference systems used in neighboring regions of space may be interrelated in higher-order reference systems in which the local reference systems serve as elements. For instance, the spatial layout of each of the rooms in a house may be specified in a spatial reference system unique to the room. These spatial reference systems may serve as elements in a higher-order reference system defining the spatial relations among the rooms.

Reference systems within the same level and between levels of the hierarchy need not use common reference directions; that is, conceptual north in one region may or may not correspond to conceptual north in a neighboring region. The acquisition of skills attributed to the possession of survey knowledge, such as pointing accurately to unseen targets, may occur when the reference directions in such locally defined reference systems become integrated in such a way that all are aligned (Montello and Pick, 1993). Werner and colleagues (Werner and Long, 2003; Werner and Schindler, 2004) have shown that misalignment of reference directions in such a reference system hierarchy impairs way-finding performance and produces less accurate knowledge of interobject directions. Experiments reported by Wang and Brockmole (2003a) provide evidence that people maintain orientation with respect to a single reference system as they navigate. They had participants walk from a room in a building on a college campus to the outdoors and then back inside to the room. When oriented with respect to the room, participants lost track of their orientation with respect to the campus, and when oriented with respect to the campus, they lost track of their orientation with respect to the room (see also, Wang and Brockmole, 2003b).

## 2.11.6 Navigation and Spatial Updating

The processes and representations used in human navigation can be divided into three categories. Navigation that depends solely on the organism's history of self-movement is referred to as path integration, or dead reckoning. By integrating velocity or double integrating acceleration with respect to time, an organism can estimate its displacement from a starting location (e.g., Gallistel, 1990). Cues to velocity or acceleration can be internal (e.g., proprioception, efference copy, vestibular cues) or external (e.g., optic or acoustic flow); however, to the extent that external cues are used, path integration is limited to situations in which external cues do not provide information about the organism's position in the environment (Philbeck et al., 2001). Wayfinding (or piloting), by contrast, refers to navigation that depends jointly on an enduring external or internal spatial representation (a map or cognitive map, respectively) and the observation of objects whose locations are specified in the spatial representation (e.g., Gallistel, 1990). The key feature of wayfinding is that the organism uses a representation of the layout of an environment and its perception of objects in that environment to find or orient with respect to objects that cannot be observed. Both path integration and wayfinding may require the organism to pass through apertures (e.g., doorways), follow paths, avoid obstacles and hazards, and so forth. This form of navigation has been referred to as steering (e.g., Rieser and Pick, 2006). Steering requires an organism to guide locomotion in relation to the perceived locations of objects but does not rely on an enduring external or internal spatial representation of the environment.

In general, as an organism locomotes through an environment, it must keep track of its location with respect to objects in the immediate environment and to unseen portions of the environment, to avoid obstacles, to remain oriented, and to navigate to distant goals (Loomis and Beall, 1998; Montello, 2005). These processes are referred to as spatial updating. Experimental research on human navigation has typically been aimed at trying to uncover the mental representations and processes used in spatial updating more broadly, and with the exception of work on path integration, does not divide neatly into categories corresponding to the three types of navigation.

Path integration is often investigated with triangle completion, or return-to-home tasks. An illustrative study was reported by Klatzky et al. (1990). Blindfolded participants were guided along paths of varying complexity and then required to walk back to the starting points. The paths consisted of one to three linear segments, separated by turns. The dependent variables were the angular turn participants made toward the origin and the distance they walked toward it. Participants' errors on both measures were low for the one-leg path and increased with the increasing number of segments. In general, path integration in humans is only moderately accurate and becomes less so as path complexity increases (e.g., Loomis et al., 1993, 1999; Cornell and Heth, 2004; Foo et al., 2005).

Nonvisual spatial updating has also been investigated in tasks that require the participant to keep track of multiple objects simultaneously. For example, Rieser et al. (1986) asked participants to study the locations of five objects in a room and then point to them while blindfolded. Participants were subsequently escorted to a novel position from which they had to point to the objects again. Locomotion resulted in small, nonsignificant updating costs relative to baseline (e.g., Rieser, 1989).

The results from these and similar paradigms suggest that humans are capable of relatively efficient updating when they move without vision, provided that the movement trajectory is not very complex. The increase in error for more prolonged movement is compatible with the assumption of an updating process that does not operate with perfect accuracy and accumulates error over the course of movement.

Spatial updating necessarily involves computations that compensate for the changes in observer–environment relations caused by locomotion. A number of studies have been conducted to identify which of the cues that are normally associated with physical locomotion are sufficient for efficient spatial updating. Purely imaginary locomotion typically produces inefficient spatial updating (e.g., Rieser et al., 1986; Rieser, 1989; but see, Wraga, 2003). Optic flow appears to be insufficient for efficient spatial updating (e.g., Chance et al., 1998; Klatzky et al., 1998; Péruch et al., 1997; but see Kearns et al., 2002; Riecke et al., 2002). A prerequisite for efficient updating seems to be that the person's physical position changes (Ruddle and Lessels, 2006). Whether this position change is accomplished through passive transport, which primarily provides vestibular cues, or through active movement, which provides additional proprioceptive and efferent cues, does not matter in many circumstances (e.g., Wang and Simons, 1999; Wraga et al., 2004). There is, however, evidence that those additional cues become beneficial when the movement trajectory is more complex (e.g., Sholl, 1989; Yardley and Higgins, 1998; Waller et al., 2004).

Evidence indicates that spatial updating during physical locomotion has two properties commonly attributed to automatic processes. First, it seems to require little attentional effort (e.g., Amorim et al., 1997; Wang, 2004). Second, the changes in observer–environment spatial relations produced by physical locomotion are difficult to ignore (e.g., Farrell and Robertson, 1998; Farrell and Thomson, 1998; Wang and Simons, 1999; May and Klatzky, 2000; Waller et al., 2002). For example, in Farrell and Robertson's experiment, participants were required to rotate to a novel orientation, but point to objects as if they were still facing their initial orientation. Performance was as poor in this ignore-rotation condition as in the imagined rotation condition, indicating that participants were unable to voluntarily refrain from updating.

Another important property of automatic processes is their relative insensitivity to processing load. The evidence on the capacity limits of spatial updating is mixed. Results of at least one study indicate that spatial updating deteriorates in accuracy as the number of objects increases (Wang et al., 2006), whereas findings from other studies indicate that spatial updating is capacity-free (Rieser and Rider, 1991; Hodgson and Waller, 2006). This pattern of results has led some researchers to distinguish two forms of updating, one that occurs on-line and relies on working memory and another that occurs off-line and relies on long-term memory (e.g., Amorim et al., 1997; Cornell and Greidanus, 2006; Hodgson and Waller, 2006). This distinction is embodied in several theories of spatial memory and navigation (discussed in the section titled 'Models of spatial memory and navigation').

A common interpretation of the advantage in spatial updating produced by physical locomotion in the absence of vision (e.g., walking while blindfolded) relative to imagined locomotion is that body-based information facilitates the transformations needed to update observer–environment spatial relations (e.g., Rieser, 1989; Chance et al., 1998; Farrell and Robertson, 1998). This facilitation may result from the transfer of learned relationships between action and perception to relationships between action and representations (e.g., Rieser et al., 1995; Pick et al., 1999; Rieser, 1999; Rieser and Pick, 2006). The idea is that people learn the consistent covariations between their actions and the resulting changes in the appearance of the environment. This tight coupling of action and perception is proposed to be the basis for a coupling of action and representation. When a person moves without vision, he or she can use the learned covariation between biomechanical cues from locomotion and the changes in environmental flow to update the self-to-object relations at a representational level. It is argued that, by utilizing this learned covariation during locomotion, people can access the changing self-to-object relations directly rather than having to go through effortful cognitive computations.

An alternate account posits that the difficulty of updating after imagined movements results from interference that is caused by a conflict between the awareness of one's physical position in an environment and the discrepant position one has to adopt in imagination (e.g., May, 1996, 2004). May (2004) has proposed that interference arises from conflicts between object location codes at the sensorimotor level, which are specified relative to the physical position, and object location codes at the cognitive level, which are specified relative to the imagined position. Consistent with this hypothesis, pointing to objects from imagined facing directions is worse when people are oriented than when they are disoriented (e.g., May, 1996; Waller et al., 2002). The interference hypothesis is also supported by the finding that performance in both imagined rotations and imagined translations degrades monotonically as a function of object-direction disparity (May, 2004), which is defined as the magnitude of the difference between (1) the direction of the to-be-retrieved object relative to the imagined position and (2) the direction of the to-be-retrieved object relative to the physical position. To account for the finding that imagined rotations are more difficult than imagined translations (e.g., Rieser, 1989; Presson and Montello, 1994), even when object direction disparity is equated, May (2004) proposed a second source of interference that only applies to imagined rotations. This second source of interference, referred to as head-direction disparity, reflects conflicts that arise from having to specify an object direction relative to an imagined heading that is different from one's physical heading (e.g., Mou et al., 2004).

May (2004) has also shown that providing participants with additional time between the presentation of the to-be-imagined position and the presentation of the target object improved overall performance, but did not mitigate the effect of object-direction disparity in either imagined rotations or imagined translations. This finding indicates that the spatial transformations required for effective spatial updating cannot be performed efficiently in working memory, even if they are somehow facilitated by physical locomotion.

In summary, extant findings indicate that spatial updating during imagined locomotion is difficult in part because knowledge of object locations relative to the actual position interferes with knowledge of object locations relative to the imagined position.

But in addition, imagined spatial updating does not benefit from facilitative transformations provided by physical locomotion.

## 2.11.7 Models of Spatial Memory and Navigation

Cognitive models of spatial memory and navigation attempt to explain how the spatial structure of an environment is represented in memory and how memories of familiar environments are used to guide navigation. All of the models employ both egocentric and environmental representations of space, and although there are important differences between models in the nature of those representations and in the ways they are used to maintain orientation and guide navigation, the models are fundamentally quite similar.

These models include an egocentric system that computes and represents self-to-object spatial relations needed for spatially directed motor activity, such as walking, reaching, and grasping. In the models proposed by Burgess and colleagues (e.g., Burgess, 2002; Burgess et al., 2001; Byrne et al., 2007), Mou and colleagues (Mou et al., 2004, 2006) and Waller and Hodgson (2006), spatial relations represented in this system are transient and decay rapidly in the absence of perceptual support or deliberate rehearsal. In Sholl's model (Sholl and Nolin, 1997; Sholl, 2001; Holmes and Sholl, 2005) and in Wang and Spelke's model (2002), this system is dynamic but can represent more enduring egocentric self-to-object spatial relations. Recent evidence implicates the role of a transient egocentric system in spatial updating, but this evidence is far from definitive (Mou et al., 2006; Waller and Hodgson, 2006).

The second major system in all of the models is an environmental (allocentric) system. Wang and Spelke's model is perhaps the most unusual, in that the environmental system in this model only represents environmental shape. It is difficult to reconcile this aspect of the model with the abilities of people to judge interobject distances and directions using long-term memories of the layouts of environments. The other major difference among models, at least among those which specify the nature of the reference systems used in the environmental system, is whether the spatial reference system is orientation-dependent or -independent. Mou and McNamara argue that the environmental system uses an intrinsic reference system (as discussed in the section titled 'Spatial reference systems'). Sholl, in contrast, claims that an orientation-independent reference system is used, at least in well-learned environments. Sholl's model would seem to have difficulty accounting for the large body of evidence demonstrating orientation-dependent performance in spatial memory tasks, even for well-learned environments, as reviewed previously.

Finally, Wang and Spelke's model includes a third system in which the appearances of familiar landmarks and scenes are represented. These representations are viewpoint-dependent and can be conceived of as visual-spatial snapshots of the environment (e.g., Diwadkar and McNamara, 1997; Wang and Simons, 1999; Burgess et al., 2004). Valiquette and McNamara (2007) recently attempted to find evidence for such a system and to determine whether it could be distinguished from an environmental system. They asked participants to learn the locations of objects in a room from two points of view, one of which was aligned with salient environmental frames of reference (the mat on which the objects were placed and the walls of the room), and the other of which was misaligned with those same frames of reference (i.e., a view from the corner of the room). Participants then took part in judgments of relative direction (e.g., 'Imagine you are standing at the shoe, facing the lamp; point to the banana') and old–new scene recognition. Performance in judgments of relative direction was best for the imagined heading parallel to the aligned learning view and no better for the imagined heading parallel to the misaligned learning view than for unfamiliar headings. This pattern of orientation-dependent performance replicates previous findings (e.g., Shelton and McNamara, 2001; Valiquette et al., 2007). Performance in scene recognition, however, was equally good for the two familiar views and better for familiar than for novel views (see also Waller, 2006). These findings are consistent with a model in which interobject spatial relations are represented in an environmental system using intrinsic reference systems, as specified in Mou and McNamara's model, and visual memories of landmarks and scenes are stored in a viewpoint-dependent system, as specified in Wang and Spelke's model.

This viewpoint-dependent system may account for the effectiveness of the look-back strategy in wilderness navigation (e.g., Cornell et al., 1992). Routes often look quite different coming and going, leading to navigational errors on the return trip. The look-back strategy involves occasionally stopping and turning around to view one's route in the opposite direction while navigating in unfamiliar wilderness environments. These look-back views may be stored in the viewpoint-dependent system and support place recognition when returning.

Spatial updating in these models takes place at two levels. Self-to-object spatial relations are continuously and efficiently updated in the egocentric system as a navigator locomotes through an environment. This updating process supports steering and interactions with objects in the environment. At the same time, the navigator must update a representation of his or her position in the environment, to remain oriented and to locate distant goals. This updating process takes place in the environmental system. According to Mou and McNamara, navigators update their position with respect to the intrinsic reference system used to represent the spatial structure of the local environment. Sholl's model is the most explicit about the environmental updating process. In this model, the egocentric system is referred to as the self-reference system, and it codes self-to-object spatial relations in body-centered coordinates, using the body axes of front–back, right–left, and up–down (e.g., Franklin and Tversky, 1990; Bryant and Tversky, 1999). The engagement of the self-reference system with the physical environment determines the position of a representation of the self-reference system in the environmental system. As a person moves in the environment, the axes of the representational self-reference system are moved to the corresponding new position in the environmental system representation.

To a significant degree, these models primarily describe the perceptual-cognitive architecture of the human spatial memory and navigation system. For this reason, they have varying amounts to say about the various topics covered previously in this chapter. All are intimately concerned with object location, survey knowledge, spatial reference systems, and spatial updating. But none of these models has much to say about route knowledge, the microgenesis of spatial knowledge, or the nature of spatial knowledge (e.g., distortions). An important direction for future research will be to extend these models to account for a broader array of findings in the spatial memory and navigation literature.

## 2.11.8 The Developmental Foundations of Navigation

Decades of research have revealed a host of burgeoning spatial abilities during the first few years of life. These developments are most likely intimately coupled with changing motor abilities (for discussion, see Campos et al., 2000) and, toward the end of infancy, symbolic capabilities such as language. In this section, we focus on the development of rudimentary abilities necessary for navigation (for a recent and more comprehensive review, see Newcombe and Huttenlocher, 2006). Specifically, we discuss the development of two of the elemental types of spatial knowledge: object location (including landmarks) and environmental shape. Route and survey knowledge follow later in development (e.g., Allen et al., 1979) and most likely depend on these earlier abilities. In addition, we consider what children's responses in various situations reveal about early use of egocentric and environmental spatial frames of reference.

### 2.11.8.1 How Children Use Objects and Landmarks

In the first months of life, infants can locate objects through response learning, which involves learning the association between a bodily response (e.g., an eye movement or a reach) and a particular position in space. For example, an infant may learn that lying in her crib she can turn her head to the left to see a colorful toy. Response learning illustrates a very simplistic egocentric reference system – one that does not take self-movement into account. In order to locate objects after movement through space, infants must be capable of what Rieser (2000) has called dynamic spatial orientation, which requires awareness of one's changing orientation with respect to the world.

Early studies have suggested limitations on the infants' ability to keep track of an object's location during self-movement. Acredolo (1978) examined 6-, 11-, and 16-month-olds in the following task. Infants first learned that an auditory cue signaled an interesting event in one of two windows (either on the left side of the room or on the right side of the room for each infant). Infants were then carried on a semicircular path to the opposite side of the room. Only 16-month-olds looked toward the correct window when the cue sounded, whereas younger infants continued to look toward the egocentric side on which the event had occurred earlier. Similar results were obtained by Bremner and Bryant (1977), who found that 9-month-olds continued to search for an object on the egocentric side of a table after being moved to the opposite side of the table.

These initial studies seemed to suggest that sometime during the second year there is a transition from response learning (not taking movement into account) to spatial updating (taking movement into account). However, it is likely that even very young infants use spatial updating when simple forms of movement, such as rotation about the trunk or tilting with respect to gravity, are involved (e.g., Rieser, 1979; Landau and Spelke, 1988). Furthermore, Newcombe and Huttenlocher (2000) have argued that spatial development is most likely characterized by an increased weighting of relevant cues rather than by the appearance of wholly new abilities (for evidence in older children, see Hund and Spencer, 2003). As infants become more mobile and can perform more complex actions in larger environments, cues such as self-movement and landmarks become increasingly relevant.

Early studies have also examined infants' ability to use landmarks as direct cues to locating objects. A direct landmark is one that is either contiguous with or adjacent to some target, thus serving as a beacon for the target location. (Because no coding of distance or angular information is necessary, use of direct landmarks is technically associative rather than spatial in nature.) In contrast is an indirect landmark, which is distant enough from a target that both are not visually available at the same time; consequently, in order to use an indirect landmark a viewer must represent the spatial relations between it and the target location. Acredolo and Evans (1980) explored the landmark use of 6-, 9-, and 11-month-olds. The task was similar to that used by Acredolo (1978) in that infants were carried to the opposite side of the room before searching for an event in a left or right window. Nine- and 11-month-olds clearly benefited from the presence of a landmark that surrounded the correct window, whereas 6-month-olds did not. A consistent finding was that of Bremner (1978), who found that 9-month-olds who moved to the opposite side of the table were more likely to search on the correct side for an object if the left and right hiding places were noted by a black cover and a white cover. Such findings seemed to indicate that, before they are capable of spatial updating, infants are able to use direct landmarks to locate targets. Additionally, when landmarks are highly salient, even 6-month-olds sometimes use them in locating target objects or events (Rieser, 1979; Lew et al., 2004).

Toward late infancy, humans show evidence of using landmarks in the surrounding environment in complex ways. Newcombe et al. (1998) examined children between the ages of 16 and 36 months in a task that required them to locate a toy in a long rectangular sandbox. Success required distance coding (in the continuous space of the sandbox) rather than the categorical coding involved in many earlier studies (e.g., at the left or right window). The children searched either with a circular curtain surrounding them (thus, with no indirect landmarks visible) or without the curtain (thus, in full view of surrounding landmarks in the room). After children watched an experimenter hide a toy in the sand, they moved to the opposite side of the box to perform the search. Children older than 22 months were more accurate when indirect landmarks were visible, whereas the youngest children performed the same whether the landmarks were visible or not. These data suggested that toward the end of infancy children begin to use indirect landmarks to guide navigation (see also DeLoache and Brown, 1983; Bushnell et al., 1995).

While Newcombe et al. (1998) argued that the indirect landmarks aided children's search, it is also possible that children were using the shape of the room (see discussion in section titled 'How children use environmental shape'). Consistent with this latter argument is a recent study by Nardini et al. (2006), who found that 3-year-olds were able to use the shape of the room during a search task that involved indirect landmarks, but not until 5 years did children seem to use the actual landmarks. In fact, there is recent evidence to indicate that young children do not represent landmarks in an environmental reference system.

In a series of experiments, Gouteux and Spelke (2001) examined preschoolers' ability to search for a target that was hidden inside one of several identical landmarks within a room. When landmarks were identical, the configuration (a triangle in some experiments and a rectangle in others) was the only available spatial information. The critical trials took place after children were disoriented within the search space. Across all experiments, children failed to use the configuration specified by the arrangement of landmarks. In contrast, when landmarks were differentiated, children were successful in locating the target. Gouteux and Spelke (2001) noted that the landmarks could have served as beacons for the target location rather than as cues to reorientation within the space.

Lee et al. (2006) explored this latter possibility. Four-year-olds searched for an object among three landmarks that formed an equilateral triangle – thus, the geometric information alone was uninformative; two of the landmarks were identical. As in Gouteux and Spelke's (2001) experiments, children were disoriented before beginning their search. Children successfully retrieved objects that were hidden at the distinctive landmark; however, when objects were hidden at one of the two identical landmarks, children searched at each of those two landmarks with equal frequency. Lee et al. (2006) argue that children can use landmarks as beacons for target locations, but do not use them to reorient to the locations of other landmarks (see also, MacDonald et al., 2004). These findings are consistent with researchers who have argued that humans keep track of discrete objects egocentrically (Wang and Spelke, 2000; Wang et al., 2006). Once these egocentric relations are disrupted, humans cannot use individual objects to reorient to the locations of other objects. The validity of this claim has been a matter of dispute in the adult literature (see discussion in section titled 'Models of spatial memory and navigation'). However, children at least do seem to have difficulties remembering the locations of objects with respect to other objects.

### 2.11.8.2 How Children Use Environmental Shape

When toddlers and older children see an object hidden in one corner of a rectangular space and then undergo a disorientation procedure, they search equally in the correct corner and in the geometrically equivalent corner (Hermer and Spelke, 1994; Learmonth et al., 2001, 2002; see for a discussion Cheng and Newcombe, 2005). Since there is no spatial information available other than the shape formed by the walls of the room, these data clearly demonstrate that, by the time they can walk, humans use the shape of extended surfaces to reorient when lost and to locate desired objects. Furthermore, children's use of geometric information in extended surfaces generalizes to situations in which they are translated outside of the space before searching (Lourenco et al., 2005) and to spaces that are not rectangular (Huttenlocher and Vasilyeva, 2003; Hupbach and Nadel, 2005). Finally, the knowledge of geometric shape must be stored in an environmental reference system, since the disorientation would have disrupted any self-to-surface representations. The shape of extended surfaces, in contrast to object location, seems readily represented in an environmental reference system early in development.

When geometric information is ambiguous, combining that information with other sources of information can be a powerful tool. One question is whether children can combine information about the shape of a room with featural information, unlike rats and other species, which cannot combine these two sources of information (see discussion in the section titled 'Environmental shape'). Hermer and Spelke (1994) examined 3- and 4-year-old children in the following task. Children watched as an object was hidden in a corner of a rectangular room, were disoriented, and then were allowed to search for the object. The researchers found that when one of the walls was blue, making the correct choice of corner unambiguous, young children did not search with greater frequency in the correct corner. Since adults have no difficulty combining the geometry of the room with landmark information, Hermer and Spelke (1996) hypothesized that humans use language capabilities to solve such a task, a hypothesis supported by Hermer-Vasquez et al. (2001). In this study, adults who performed a verbal shadowing task while searching for an object that was hidden in one of four corners were less likely to use relevant landmarks in the room.

There is some controversy over the claim that geometric shape of space cannot be used in combination with landmarks without the aid of language (Learmonth et al., 2001, 2002; Hupbach and Nadel, 2005; see for a discussion Cheng and Newcombe, 2005). However, there is a considerable amount of support for the claim that geometric information, at least in some situations, is processed independently from other spatial cues. One particularly important variable seems to be the size of the room (Learmonth et al., 2002). In spaces that afford only minimal locomotion, children are more likely to ignore featural information and rely solely on the shape of the room. The reasons for this finding, whether they relate to limited locomotion, the proximity of landmark information, or both, are not yet clear (see for discussion Newcombe and Huttenlocher, 2006).

## 2.11.9 Cognitive Neuroscience of Spatial Memory

Our goal in this section is to review some of the primary findings that have emerged from decades of research on the neural bases of spatial memory. Recently there has been a growing focus on understanding how egocentric and environmental reference systems operate in parallel and interact with each other. First we discuss how the hippocampal and parietal cortices subserve spatial memory. Next we turn to a discussion of the parahippocampal cortex, which has been the focus of recent growing interest in its role in navigation and its possible role in hippocampal–parietal interactions.

In now classic research with rats, O'Keefe and Dostrovsky (1971) demonstrated the existence of place cells in the hippocampus, which fire selectively based on the position in the environment that the animal occupies, independently of the animal's facing direction. O'Keefe and Nadel (1978) argued that these cells serve as the basis for an environmental spatial reference system, or the cognitive map. Ekstrom et al. (2003) have provided the first demonstration of place cells in the human hippocampus, confirming what was long hypothesized from several lines of research with humans. This literature has shown that the human hippocampus is involved in performance on a variety of spatial tasks (e.g., Maguire et al., 1997; Holdstock et al., 2000; Kesner and Hopkins, 2001; Stepankova et al., 2004). In particular, the hippocampus seems to be crucial for performance on spatial tasks that require learning the relations among external landmarks, i.e., tasks that cannot be solved using egocentric responding (Astur et al., 2002; Bohbot et al., 2004; Parslow et al., 2004; Shelton and Gabrieli, 2004).

Recently discovered grid cells in adjacent entorhinal cortex (Hafting et al., 2005) may serve a function complementary to place cells. Grid cells respond whenever the animal is in a position that coincides with a vertex in a grid of equilateral triangles that spans the surface of the environment. The grid is initially anchored to landmarks in the environment, although the cells continue to fire even in the dark. Thus, the cells may serve as the neural basis for an environmental reference system, in conjunction with the place cells, and also facilitate path integration within that environment.

In contrast to individuals who have endured damage to hippocampal regions, those with lesions to parietal regions sometimes exhibit severe difficulty navigating through immediate space, often failing to avoid obstacles (e.g., Stark et al., 1996). Such findings have led researchers to postulate that the parietal cortex is critically involved in action and, specifically, in representing self-to-surface relations (see for discussions Andersen et al., 1997; Colby and Goldberg, 1999).

Recently there has been a growing emphasis on how the parahippocampal cortex (PHC) serves spatial functioning. PHC is ideally situated for combining information from parietal and other temporal areas and also projects to entorhinal cortex, a primary input region for the hippocampus. As noted by Epstein:

> . . . the anatomical data suggest that a pathway from parietal cortex to parahippocampal cortex to the hippocampus may be critical for processing navigationally relevant spatial information. (Epstein, 2005: 971)

Neuroimaging studies have shown the PHC to be involved in a wide range of navigation tasks (e.g., Aguirre et al., 1996; Maguire et al., 1996; Mellet et al., 2000; Shelton and Gabrieli, 2002). In addition, humans who have endured damage to this area exhibit impairments in spatial tasks such as route learning and scene recognition (e.g., Bohbot et al., 1998; Aguirre and D'Esposito, 1999; Barrash et al., 2000; Luzzi et al., 2000; Epstein et al., 2001).

The posterior region of the PHC has been the focus of increasing interest due to its dedication to the perception of spatial scenes. In a functional magnetic resonance imaging (fMRI) investigation, Epstein and Kanwisher (1998) found that this area responds more to scenes than to houses, faces, or objects, even during passive viewing. Further experiments revealed that this area responds just as strongly to empty rooms as to scenes with multiple objects. Additionally, this region responds more to coherent scenes than to those in which the component parts are fractured and rearranged. Based on this set of findings, Epstein and Kanwisher called this region of cortex the parahippocampal place area (PPA). Both neuroimaging and lesion studies suggest that the PPA's role is one of encoding (Brewer et al., 1998; Epstein et al., 1999, 2001). Epstein et al. (2003) conducted a study indicating that the region processes geometric information in background elements, in particular. These researchers found that the PPA responds as much to changes in entire scenes as it does to changes in viewpoint of the same scene, suggesting that the PPA processes scene information in a viewpoint-dependent (egocentric) manner. However, there is evidence that over time the way the PPA processes particular scenes may become more viewpoint-independent (Epstein et al., 2005).

One notable finding that has contradicted studies on the PPA was that by Maguire et al. (1998). These researchers found activations of the right PHC when subjects navigated through and learned a series of rooms with salient objects in a virtual reality environment. However, they did not find any medial temporal involvement when participants performed the same task with a series of empty rooms distinguished from each other only by their different shapes. They hypothesized that the parahippocampal region is involved in object-location binding, not analysis of the geometry of the scene. Consistent with this view is the recent finding that monkeys with lesions to the PHC are impaired in the formation of object–place associations (Malkova and Mishkin, 2003; see also Parkinson et al., 1988) and the finding by Bohbot et al. (1998) that humans with lesions to the right PHC are impaired in a spatial task that requires memory for object locations. The contradictory findings may have to do with functional differentiation within the PHC, with the PPA serving a specialized purpose of geometrical analysis and other regions involved in binding object information to the geometry.

## 2.11.10 Summary and Prospectus

Learning a new environment typically begins by learning routes from place to place; even in large-scale outdoor environments, navigation usually takes advantage of trails of some kind. People quickly acquire knowledge of the identities of important objects, or landmarks, and the sequential order of landmarks on routes. Route knowledge has at least quasi-metric properties very early during acquisition. Humans and many other organisms seem to be very sensitive to the shape of the immediate environment and to depend on environmental shape to reorient. With extensive experience in an environment, people sometimes acquire knowledge of its overall layout, or survey knowledge. The acquisition of spatial knowledge is best characterized as the incremental accumulation of quantitative spatial relations. Spatial knowledge does not seem to be limited to qualitative, nonmetric information at any point during acquisition.

Humans represent the locations of objects in space using egocentric and environmental (i.e., allocentric) reference systems, and navigation almost certainly depends on both egocentric and environmental representations of the environment. There is evidence that the process of learning a new environment involves interpreting the spatial structure of that environment in terms of an environmental spatial reference system. Interobject spatial relations seem to be specified with respect to a small number of reference directions. This aspect of the mental representation produces one of its key properties, orientation dependence: interobject spatial relations can be utilized more efficiently from perspectives aligned with the dominant reference directions in memory. These reference directions are typically parallel to points of view experienced during learning, but also may be determined by instructions and by properties of the environment, such as the mutual alignment of several objects or geographical slant. The use of spatial reference systems at multiple scales may explain why spatial knowledge is hierarchically organized.

Effective navigation in a familiar environment depends on the abilities to avoid obstacles and stay on course, to use one's history of self-movement to keep track of one's position, and to use mental representations of the layout of the environment to estimate the positions of objects that cannot be observed. Collectively, these abilities – steering, path integration, and wayfinding, respectively – are referred to as spatial updating. A prerequisite for efficient updating seems to be that the navigator's position in space changes. Imagined spatial updating is difficult and error-prone. An important source of this inefficiency seems to be conflicts that are created by having to imagine a position in the environment that is different from one's physical position in that environment. Physical locomotion in the absence of vision mitigates this interference and also seems to benefit from body-based information, which facilitates the transformations needed to update observer–environment spatial relations. But even physical nonvisual updating breaks down with prolonged movement over complex trajectories.

Contemporary models of spatial memory and navigation specify roles for three types of spatial memories: Egocentric self-to-object spatial relations used for steering and path integration, viewpoint-dependent representations of landmarks and scenes used for place recognition, and environmental representations of object-to-object spatial relations used for wayfinding and some forms of path integration. There are differences among the models in the properties of each of these representational systems and in the manner in which they are used in navigation. For instance, in some models, the egocentric system computes and represents transient representations, whereas in other models, these representations are more enduring. In one model, the environmental system only represents the shape of the environment and is used for reorientation, whereas in the others, it represents object-to-object spatial relations and is used for virtually all locomotion in familiar environments. Despite these differences, however, the models are quite similar in terms of their overall architecture.

The development of these capabilities begins with simple forms of egocentric spatial coding, such as learning the association between a bodily response and a location in space, and of spatial updating, such as compensating for trunk rotation. During the second year of life, children begin to be able to use landmarks in more sophisticated ways and to update after complex movements, developments that are coincident with (and certainly related to) their increased mobility. By the time children can walk, they can use environmental shape, as defined, for example, by the shape of a room, to locate a desired object. This knowledge must be represented in an environmental frame of reference because it survives disorientation, which destroys self-to-object spatial relations. Toddlers appear to have difficulty under some conditions using featural cues or landmarks to find a desired object after having been disoriented. The ability to effectively use such cues does not develop until well into the school-age years.

Research on the neural basis of spatial memory and navigation in humans has isolated the hippocampus, the parietal cortex, and the parahippocampal cortex as especially important brain areas. The hippocampus seems to be critically involved in the formation of long-term representations of the spatial structure of the environment using environmental frames of reference. The parietal cortex is involved in representing the locations of objects in the egocentric reference systems needed for sensorimotor mappings and in coordinating these representations. The parahippocampal cortex is involved in navigation, and its posterior regions seem to play an important role in representing landmarks and scenes.

The scientific understanding of human spatial memory and navigation has advanced enormously since Tolman (1948) presaged the distinction between route and survey knowledge with his categorization of spatial memories into strip maps and comprehensive maps. Significant progress has been made in understanding the nature and acquisition of spatial memories, how remembered spatial relations are used to guide navigation, properties of spatial updating processes, the development of early navigational capabilities, and areas of the brain involved in spatial memory and navigation. But of course much remains to be discovered. Many important avenues of future research are indicated by the findings reviewed in this chapter. A few especially promising ones, to our minds, include the following.

There is abundant evidence of the hierarchical organization of enduring spatial memories, but the processes involved in the formation of such representations are not well understood. Of special interest are the mechanisms used to establish correspondences between representations that use different reference directions and the spatial updating processes used to switch from one hierarchical level to another. The relative importance of egocentric and environmental representations in various spatial tasks, their dynamical properties, and the processes by which egocentric representations in sensorimotor systems are transformed into environmental representations, and vice versa, are largely unknown. Much remains to be learned about how children come to represent spatial relations among landmarks in ways that effectively support navigation. Recent investigations of spatial updating in adults suggest that steering depends on a transient egocentric system, whereas wayfinding depends on an enduring environmental system. Relatively little is known about the nature and the development of these capabilities in children. Finally, research on the neural basis of human spatial memory and navigation has isolated a network encompassing, at minimum, the parietal cortex, the hippocampus, and the parahippocampal cortex. The nature of the representations in these areas and the interactions among them need to be explored in greater depth.

We look forward, with optimism, to seeing the empirical and theoretical fruits of these efforts to understand how people remember where they have been and how they find their way home.

# 2.12 Forgetting

**J. S. Nairne and J. N. S. Pandeirada**, Purdue University, West Lafayette, IN, USA

## 2.12.1 Introduction

As Ebbinghaus observed in his famous monograph, "Left to itself every mental content gradually loses its capacity for being revived, or at least suffers loss in this regard under the influence of time" (1885/1964: 4). To most, forgetting is a scourge, a nuisance, a breakdown in an otherwise efficient mental capacity. The momentary loss of information is a regular part of the human experience, but normal forgetting, even when permanent, is misconstrued as a malfunction or breakdown. We forget for adaptive reasons, and understanding the characteristics of forgetting ultimately tells us a great deal about why and how we remember.

In this chapter we offer a general tutorial on the psychology of forgetting. Our focus will be on its empirical characteristics and proposed theoretical underpinnings, as revealed primarily through laboratory studies with healthy human participants. Excellent reviews on abnormal forms of forgetting, such as those that occur in brain-damaged patients, and on forgetting in nonhuman populations can be found elsewhere in this series. We begin the chapter with a brief discussion of the adaptive value of forgetting, followed by an examination of its functional and mathematical characteristics. Next, we discuss possible causal mechanisms in some detail – why do we forget? Finally, we end by reconsidering the meaning of forgetting and its proper role in modern memory theory.

## 2.12.2 Forgetting and Its Adaptive Value

At face value, memory seems to be about recovering the past, recapturing or reviving previous experiences. Yet, it is unlikely that memory actually evolved for this specific purpose. The past can never occur again, at least in exactly the same form, so there is limited adaptive value in developing a system that carries around intact records of prior experiences. Instead, memory has value because it allows us to use the past in the service of the present, to decide on an appropriate plan of action now or in the future (Suddendorf and Corballis, 1997; Tulving, 2002). Intact records of the past are relevant in some situations, but not in others. For example, we might need to remember the specific location of a food source, but we need not remember every instance in which a particular food type was consumed (we need to remember only that it was edible). As Lewis Carroll famously quipped, "it's a poor sort of memory that only works backwards."

Recognizing that memory's primary function is to deal with the present, or perhaps to anticipate the future, informs how we need to think about forgetting. Obviously, if nature did not 'design' memory to reproduce the literal past, then it is not surprising that we sometimes have difficulty reproducing it. The veridical details of an event tend to be ignored by our memory systems, which choose instead to process and store inferences or connections that are likely to benefit future responding (Bartlett, 1932; Schacter and Addis, 2007). Even when the details of an event are correctly stored, there is little reason to anticipate that those details will be stored indefinitely. In fact, it is easy to make the case that forgetting is a highly adaptive feature of cognition (Bjork and Bjork, 1988, 1996; Altmann and Gray, 2002). Having an intermediate, rather than complete, retention of the past may improve our ability to use inferential heuristics (Schooler and Hertwig, 2005), maximize our ability to detect causality (Kareev, 2000), and even maintain a sense of sanity in an ever-changing world (Luria, 1968).

More to the point, a well-designed memory system can be expected to show sensitivity to the likelihood that a past event will be needed, or appropriate, to a future situation. It makes no sense to retain long-defunct telephone numbers, or high school locker combinations: These are more apt to produce needless clutter than potentially useful records. Moreover, once an event occurs in the present, the likelihood that it will occur again (at least in a similar form) changes predictably with time. If a predator appears in your environment at time $t$, then the chances that it will appear again are usually greater at time $t+1$ than at time $t+2$. As it turns out, the function relating event recurrence with time typically takes a negatively accelerated form, just like the classic forgetting function (Anderson and Schooler, 1991). What we normally think of as forgetting, therefore, may simply represent memory's sensitivity to the statistical structure of events in the environment. We forget an item's occurrence with time because, in fact, that item is less likely to occur again with time.

## 2.12.3 The Characteristics of Forgetting

The fact that forgetting takes on a characteristic form is *prima facie* evidence that a psychological process is at work. We do not forget things randomly; rather, the loss of information proceeds in an understandable

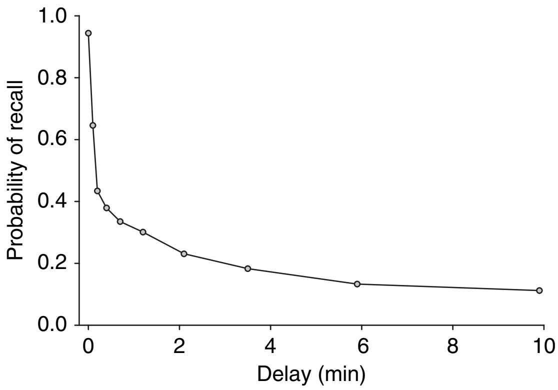

**Figure 1** Probability of correctly recalling a word as a function of time. Data from Rubin DC, Hinton S, and Wenzel AE (1999) The precise time course of retention. *J. Exp. Psychol. Learn. Mem. Cogn.* 25: 1161–1176.

and predictable fashion. A typical retention function is shown in **Figure 1** and it contains a stark empirical regularity: There is a negatively accelerating downward loss in retention over time. We forget rapidly at first and then retention slowly levels off. This general pattern occurs regardless of the quantity or quality of the information learned and the retention measure employed.

Ebbinghaus is usually credited with the first empirical demonstration of the forgetting function (although see Galton, 1879). Using his famous savings method, Ebbinghaus recorded the amount of time spent relearning an earlier memory series (usually consisting of nonsense syllables). In one case, he learned eight series of 13 syllables each (to a criterion of two errorless recitations) and then attempted to relearn the same material after one of seven delays ranging from 1 h to 31 days. The percentage savings, calculated as the difference in time spent during initial learning and relearning expressed as a percentage of the original learning time, dropped systematically over delay in a form resembling that shown in **Figure 1**. He expressed some surprise at the form of forgetting, particularly the lessening effect shown at the later delays. Forgetting "in the latter intervals is evidently so slow that it is easy to predict that a complete vanishing of the effect of the first memorization of these series would, if they had been left to themselves, have occurred only after an indefinitely long period of time" (Ebbinghaus, 1885/1964: 76). The question of whether information, once encoded, ever truly vanishes completely (in the absence of relearning or reexposure) remains an issue of concern today (Bahrick, 2000; Wixted, 2004a).

### 2.12.3.1 Forgetting's Mathematical Form

Psychologists have struggled to characterize the forgetting function in more precise mathematical terms. Ebbinghaus suggested a type of logarithmic function, but many candidates are viable. Linear functions can probably be ruled out, along with simple exponentials, but it is possible to salvage most functions with the right set of assumptions. Psychologists usually choose power – logarithmic, exponential power – or hyperbolic functions, but the decision is often driven by theoretical rather than empirical concerns. At present, despite over a century of effort, no firm consensus on the matter has arisen, although currently many researchers lean toward some kind of power function (e.g., Wixted and Carpenter, 2007).

The failure to reach consensus about forgetting's mathematical form is understandable; the enterprise is fraught with difficulties. For example, one needs criteria for choosing one function, or forgetting model, over another. It is possible to evaluate competing functions simply on the basis of a goodness-of-fit measure, which has typically been the criterion of choice (e.g., Anderson and Schooler, 1991; Wixted and Ebbesen, 1991; Rubin and Wenzel, 1996). However, goodness-of-fit measures usually ignore other important factors, such as the complexity of the function and its psychological viability (Roberts and Pashler, 2000; Pitt et al., 2002; Lee, 2004). There are also serious measurement concerns. The assessment of forgetting requires tracking performance through different points along the measurement scale. Can we really be certain that a drop in retention from, say, 90% correct to 80% correct means the same thing psychologically as a drop from 20% to 10%?

There is also enormous imprecision in the existing data. Forgetting experiments are hard to conduct. Longitudinal studies require testing the same individual at different retention intervals, which is practically difficult and can introduce a testing, or repeated retrieval, confound. In fact, repeated testing of the same information can actually improve overall performance under some conditions (e.g., hypermnesia, Roediger and Challis, 1989). Cross-sectional studies present similar practical difficulties and provide no assurances that the average retention estimates for the different groups accurately represent how forgetting proceeds in an individual (Rubin and Wenzel, 1996; Chechile, 2006). The net result is that most studies report only a handful of retention intervals and, for obvious reasons, the longest sampled retention interval rarely provides any true estimate of memory's permanence. Some memories may remain intact over a lifetime (Bahrick, 1984, 2000) which, in turn, places important constraints on the retention functions that can apply (Wixted, 2004a; Chechile, 2006). Similarly, one cannot ignore performance when the retention interval approaches zero (i.e., immediate testing); some functions are ill-defined at this point, and it is conceivable that special short-term or working memory systems complicate the retention function at very short retention intervals (Chechile, 2006).

There is also the issue of the proper retention measure. As noted, Ebbinghaus measured retention through savings in relearning, but there are many other measurement tools. One can assess memory through proportion correct recall, the d′ discriminability index in recognition, or through various indices of priming in implicit or indirect retention measures. The retrieval environment can also be enriched through the introduction of retrieval cues or degraded through the presence of other concurrent tasks. In addition, it is unclear whether delay should be defined as the simple passage of time, time calculated in terms of some kind of relative index (Bjork and Whitten, 1974; Baddeley, 1976), or perhaps the number or quality of intervening events (Waugh and Norman, 1965). Time and events are usually confounded because the passage of time is highly correlated with the number of intervening events (Chechile, 1987).

Despite these difficulties, when an empirical forgetting function is obtained it virtually always resembles the one shown in **Figure 1**. We forget rapidly at first and then retention slowly levels off. Empirically, the proportional rate of forgetting also slows over time, as aptly expressed in Jost's famous law of forgetting: "Given two associations of the same strength, but of different ages, the older falls off less rapidly in a given length of time" (Jost, 1897: 472). Younger memory traces, at least on average, are more vulnerable to the deleterious effects of time than older traces. Note that Jost's law conflicts with simple exponential forgetting functions, which assume constant proportional loss. In an exponential function, the proportional rate of loss remains constant (retention falls by 50% between $t$ and $t+\text{k}$, where k corresponds to the function's half-life), so associations of equal strength, regardless of their age, should decline subsequently at the same rate. They do not, and this places important constraints on the possible mechanisms that underlie forgetting.

## 2.12.4 Determinants of Forgetting Rates

It is possible to reconcile Jost's law with exponential forgetting if we assume that forgetting rates vary with degree of original learning (Simon, 1966; Wixted, 2004a). For example, if well-learned information is forgotten more slowly than poorly learned information – that is, if the half-life of a memory trace varies with the degree of initial learning – then Jost's law still holds. The possibility that we lose information at a rate determined by its initial strength itself seems imminently reasonable, even intuitive, but it has received little empirical support in the laboratory. Variables that affect acquisition – e.g., word frequency, meaningfulness, similarity, and so forth – typically have little, if any, impact on subsequent forgetting rates (Underwood, 1964; Keppel, 1968).

Slamecka and McElree (1983) allowed the degree of original learning to vary and then assessed retention across several delays. In each case, despite wide differences in original acquisition level, nearly equivalent forgetting slopes were obtained. Importantly, this conclusion held across different retention measures, including free recall, cued recall, category recall, gist recall, and recognition (see **Figure 2**). The same conclusion holds when different mnemonic components or processes are assessed. McBride and Dosher (1999) used Jacoby's process dissociation technique to examine forgetting functions for conscious and automatic components of memory, as a function of the depth of initial processing (semantic vs. graphemic); similar forgetting rates were found for each component, despite differences in the overall level of availability. Even individual difference variables, such as age (Salthouse, 1991) and neurological status (Christensen et al., 1998), commonly fail to produce stark differences in either the form or the rate of forgetting.

These data, among many others, suggest that acquisition and forgetting are not merely two sides of the same coin; rather, variables that affect acquisition may not affect the forgetting process. Forgetting proceeds in its characteristic way, regardless of the retention measure or initial acquisition level, much like the action potential of a neuron, once generated, travels forward in a characteristic (all-or-none) fashion. Of course, this conclusion must be hedged a bit for all the methodological considerations that have been listed; plus, controversies have raged over how to measure the loss of information over

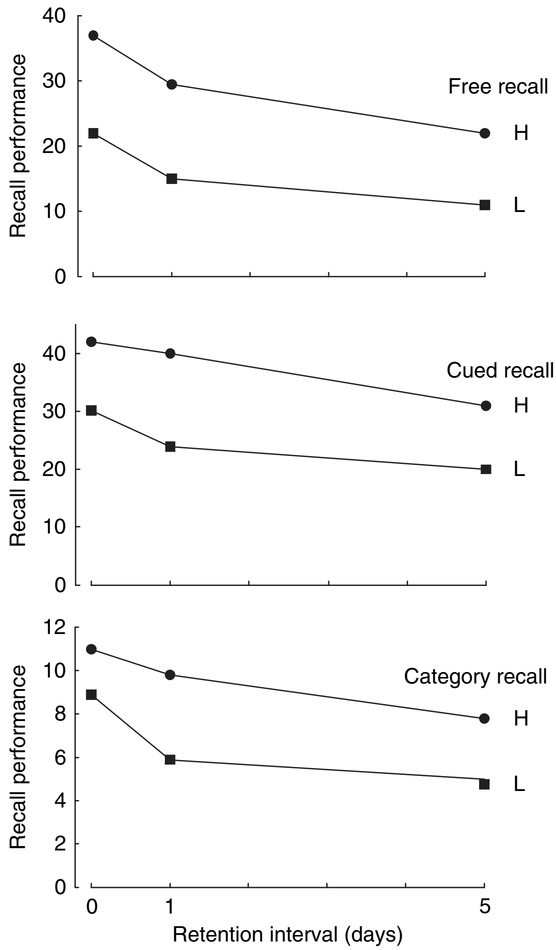

**Figure 2** Forgetting functions obtained for high (H) and low (L) degrees of original learning as revealed for three different retention measures. After Slamecka NJ and McElree B (1983) Normal forgetting of verbal lists as a function of their degree of learning. *J. Exp. Psychol. Learn. Mem. Cogn.* 9: 384–397.

time properly (e.g., Slamecka, 1985; Bogartz, 1990; Loftus and Bamber, 1990). Still, it is generally conceded that forgetting rates remain invariant as acquisition variables, mnemonic processes, and measurement vehicles are manipulated, although exceptions can be found in the literature. For example, McDonald and colleagues (2006) recently found evidence for acquisition-based heterogeneity in forgetting when a novel statistical procedure, multilevel modeling, was applied to the retention data and certain other methodological concerns, such as the mnemonic strategy adopted by the participant, were controlled. The debate continues, as it has for the past century.

## 2.12.5 Mechanisms of Forgetting

It may be difficult to characterize the forgetting function completely, but every researcher recognizes that memory changes systematically with time. As noted earlier, there are excellent reasons to believe that forgetting is adaptive and, more importantly, that the forgetting function mimics the way events occur and recur in the natural world. Consequently, it is reasonable to search for a mechanism, or set of mechanisms, that affects the availability of learned material. Of course, any acceptable theoretical account of why we forget must come to grips with the regularity of the forgetting function itself. One cannot simply argue, for example, that forgetting is cue-dependent – that is, we forget in the absence of an appropriate retrieval cue – without also explaining why the form of forgetting is so regular and predictable.

Historically, researchers have appealed to three primary causal mechanisms to explain forgetting: autonomous decay, interference from other acquired information, and altered stimulus conditions (McGeoch, 1932; Bower and Forgas, 2000). There is a fourth mechanism, active inhibition induced by retrieval, that has been proposed more recently (Bjork and Bjork, 1992; Anderson, 2003), although it, too, has some interesting historical antecedents (e.g., Freud's concept of repression). Each of these mechanisms is discussed in more detail in the sections that follow.

### 2.12.5.1 Decay

When memory theorists use the term *decay*, they mean forgetting that occurs spontaneously with the passage of time. Decay is assumed to be autonomous, which means that its progression does not depend on some other active mnemonic process (such as the acquisition of new information). Of course, everyone believes there must be some kind of neurological underpinning for the decay process, such as a metabolic process that erodes or overwrites synaptic connections, but the mechanism itself is left unspecified. The natural process of radioactive decay is sometimes used as a rough analogy, in which a constant proportion of radioactivity is lost in a fixed unit of time.

To make a principled empirical argument for decay, it is necessary to show that forgetting proceeds in the absence of other activities, such as rehearsal or interference. As we discuss in the next section, newly established memories are quite susceptible to interference from other learned material, so it is necessary to control, if possible, for this factor. Rehearsal also needs to be ruled out, because repetition presumably counteracts the deteriorating effects of the decay process. One needs to create, in essence, a kind of mental vacuum in which time, and little else, is allowed to vary. If information is still forgotten in its characteristic way, then a time-based process, decay, must be responsible.

Various strategies have been employed to detect decay. Most have relied on a dual-task methodology in which the participant is asked to perform an attention-demanding task while simultaneously retaining critical target memories. For example, Reitman (1974) instructed participants to retain groups of words while detecting the occurrence of a tone signal in background noise. The tone detection task was assumed to be sufficiently dissimilar to the words to prevent interference, which typically depends on similarity, and sufficiently taxing to prevent rehearsal (although see Roediger et al., 1977). Similarly, Cowan and colleagues (1997) had people compare the frequencies of two tones separated by delays while performing a silent visual tracking task. It is difficult, perhaps impossible, to rehearse a pure tone, and the intervening visual distractor task seemed unlikely to produce interference, so any decline in the tone task was attributed to decay. In both of these cases, retention performance did decline with delay, implicating decay (although see Cowan et al., 2001).

Note that each of these paradigms investigated retention over the short term, that is, over a time-course of seconds. In fact, the concept of decay is rarely used to explain long-term forgetting, due in large part to the seminal arguments of John McGeoch (1932). Among other things, McGeoch noted that memories often remain highly available or even improve over time, a fact that seems fundamentally incompatible with decay. For example, when people are given repeated opportunities to recall earlier-presented material, they will often recall items on the second or third attempt that they failed to recall initially, a phenomenon known as reminiscence (Ballard, 1913). The Pavlovian phenomenon of spontaneous recovery, in which an extinguished conditioned response recovers after a period of rest, is another case in point (for empirical evidence of spontaneous recovery in human participants, see Wheeler, 1995).

McGeoch (1932) further noted that when the passage of time is held constant, the amount of forgetting depends on the specific activities that occur during the delay. After learning a list of verbal items, if one group of participants rests and a second group learns another list, recovery of the initial list will be sharply impaired in the second group (Müller and Pilzecker, 1900). Moreover, the amount of forgetting will depend on similarity between the original material and the interpolated material (see Osgood, 1953). Forgetting is correlated with the passage of time, McGeoch argued, but the relationship is not causative. It is the events that happen 'in time' that produce forgetting, not time itself.

In the case of short-term retention, however, the situation is somewhat different. Decay remains quite popular among theorists in this arena because short-term retention is thought to tap special storage systems. In the working memory model of Baddeley and Hitch (1974), for example, information is retained for brief intervals in the service of more complex forms of processing (e.g., language), and special 'activity traces' are assumed to be stored in various loops, buffers, and sketchpads (Baddeley, 2000). In the absence of rehearsal, which serves a refreshing function, these traces decay autonomously. Most working memory theorists accept that short-term forgetting can occur as a consequence of other means, such as interference, but decay is assigned an important and even pivotal role (e.g., Page and Norris, 1998).

Memory traces may indeed decay in some circumstances and not in others. There could be something special about short-term activity traces, those engendered and maintained by special short-term memory systems, but the concept remains controversial. For example, Nairne (2002b) has shown that each of McGeoch's main arguments against decay in long-term memory apply equally well to immediate retention: Short-term retention can decline, remain the same, or even improve over time depending on the circumstance. To illustrate, in a study by Turvey et al. (1970), different groups of people were asked to count backward as a distractor activity for group-specific intervals prior to recall (e.g., one group counted for 10 s, another for 15 s, and another for 20 s). Equivalent amounts of forgetting were found across groups in this between-subject design (0.33, 0.30, and 0.30, respectively) (see also Greene, 1996). Moreover, on a critical trial all groups were switched to the same 15-s distractor period. Retention performance dropped in the 10-s group (from 0.33 to 0.20), stayed roughly constant in the 15-s group (0.30 to 0.28), and improved in the 20-s group (0.30 to 0.38). Note that the passage of time – and therefore the opportunity for decay – was equated across the groups on the critical 15-s trial, yet performance depended significantly on the timing of prior trials.

Space does not permit a complete review of all the relevant studies. Suffice to say that the correlation between time and forgetting is far from perfect even when retention is tested over intervals lasting seconds. Importantly, however, such findings by themselves do not rule out the concept of decay. It is still possible that memory traces decay with time, but particularly supportive retrieval environments can counteract the loss. In the Turvey et al. (1970) study, for instance, moving from a 20-s distractor-filled retention interval to a 15-s interval may have helped the participant discriminate to-be-remembered items from information recalled on prior trials (Nairne, 2002b). Similarly, the emergence of newly recalled items on a second or third recall attempt could simply reflect participants' ability to use recalled items as cues to help them recall new items. The state of the trace could still be degraded at time 2 relative to time 1, but a more supportive retrieval environment at time 2 nets improved recall.

At the same time, recognizing that retention cannot be predicted from the state of the memory trace, without considering the retrieval environment, seriously undermines the theoretical utility of decay. Appealing to decay as the source of forgetting is like appealing to strength as the source of remembering. As Endel Tulving (1983) has argued, memory traces "do not have strength independently of the conditions under which they are actualized" (Tulving, 1983: 240–241). Thus, losing trace features over time may or may not impair retention; it will depend on the particular features that are lost and their compatibility with the retrieval cues present at the time of retention testing (Nairne, 2002a).

### 2.12.5.2 Interference: Trace Degradation

The second, and more popular, interpretive tool used to explain forgetting is *interference.* The concept of interference is multifaceted, having several distinct meanings, but the important common denominator is the occurrence of other mnemonic events. We forget because other events interfere with the storage or recovery of target memories. Unlike decay, the interference perspective assumes that if one could create a mental vacuum – that is, if you could measure the state of a memory trace over time in the absence of other mnemonic events or activities – there would be no decline in the integrity of the trace. Forgetting occurs because other events or activities, particularly ones that are memory-based, happen 'in time.'

There are two ways that interference is thought to operate. First, newly learned material can overwrite, erase, displace, or otherwise degrade an existing memory trace. The details are usually left unspecified, although it is generally assumed that similarity between original and new learning increases the extent of the interfering effect. As noted above, many studies have shown that if the retention interval is held constant, the nature of the activities that occur between study and test importantly determines what and how much is forgotten. In a classic study by Jenkins and Dallenbach (1924), for instance, people recalled more information if they slept through a retention interval than if they remained awake; the assumption here is that sleep protects one from the potentially damaging effects of interpolated interference. Comparable findings occur even for amnesic subjects: After hearing words or stories, if amnesic patients are allowed to spend a retention interval in a dark and quiet room, their subsequent retention is vastly improved relative to an interference control (Cowan et al., 2004).

Moreover, in an interesting parallel to decay, some researchers assume that the damaging effects of interference depend on the passage of time as well. Rather than exerting a negative effect, however, memory traces are assumed to become less vulnerable to the effects of interference with time because of a trace consolidation process. The notion that memory traces consolidate is widely accepted by neuroscientists, partly because retrograde amnesia, the loss of memories formed prior to brain damage, shows a distinct temporal gradient (Ribot, 1881). A blow to the head is more likely to lead to the loss of recently formed memories than to the loss of memories from the more distant past. Presumably this pattern occurs because the older traces have consolidated and, as a consequence, are less susceptible to interference. As Wixted (2004a,b) has recently observed, exactly the same reasoning can be applied to general mnemonic principles such as Jost's law: Given two traces of the same strength, but of different ages, retention of the older one will fall off less rapidly in a given length of time, presumably because the older trace has sufficiently consolidated.

In the laboratory, however, the concept of consolidation has a more checkered past. In fact, it has been largely rejected by memory theorists for decades because laboratory-based experiments typically fail to show convincing temporal gradients. It is possible to obtain robust retroactive interference – the term used to describe interference arising from events occurring after the target memory is established – when the interfering event occurs days or even weeks after the original encoding, a period far exceeding any reasonable consolidation time. Moreover, the interference that is obtained after a short delay, when consolidation processes are presumably active, is usually comparable in size to the interference obtained after lengthy delays (see Wickelgren, 1977, for a review).

In fairness to consolidation theory, though, the fact that robust retroactive interference occurs after a long delay does not rule out a consolidation process, for much the same reason that retention after a lengthy delay does not rule out a decay process. As discussed in the next section, interpolated learning can easily decrease the accessibility of a fully formed memory trace by impairing the diagnostic value of an associated retrieval cue. Moreover, Wixted (2004b) has recently challenged the accepted dogma concerning temporal gradients, arguing that traditional retroactive interference designs introduce methodological problems that cloud interpretation. Also, some clinical cases indicate that consolidation may last a relatively long time (Dudai, 2004).

Still, it is important to recognize that consolidation, even if empirically verified, can never stand as a completely adequate account of forgetting (see also Meeter and Murre, 2004). Consolidation theory, like decay theory, essentially reduces to a set of claims about how the integrity of a memory trace changes with the passage of time. As noted, memory traces do not have retention strength outside of the conditions under which they are accessed. For any given trace, degraded or otherwise, there are presumably retrieval conditions that will promote or hinder successful retrieval. To explain forgetting or retention adequately, one needs to consider the state of the memory trace as well as the conditions present at the time retrieval is attempted (Tulving, 1983).

### 2.12.5.3 Interference: Cue Impairment

We mentioned earlier that interference is thought to operate in two ways. The first, just discussed, is the degrading effect that new learning can have on the integrity of an existing trace. The second route places the locus of interference not in the trace itself, but in its eliciting retrieval cue. Psychologists generally assume that remembering is cue-driven. Memories are not thought to arise spontaneously; instead, they are activated by the presence of associated retrieval cues. For decades, the empirical paradigm of choice among researchers was paired-associate learning in which participants are asked to associate target words (e.g., 'town') with cue words (e.g., 'cart'). The advantage of paired-associate learning is that it allows the experimenter to test the integrity of a specific memory by cuing the participant with its associated retrieval cue. The ability to reproduce the target word in the presence of its linked cue is used as the index of retention. When people fail to produce the appropriate response, given the presence of the retrieval cue, then obviously forgetting has occurred.

Once again, forgetting in such a context could occur because the integrity of the target memory has been degraded, either through a decay process or as a by-product of subsequent activity. However, it is also possible that the cue–target association is impaired, leaving the integrity of the target trace intact. In such a case, forgetting occurs because the retrieval cue is unable to elicit or reproduce a previously associated target memory. There are two reasons why the effectiveness of a retrieval cue can become impaired. First, as suggested by early interference theorists (e.g., Melton and Irwin, 1940; McGeoch and Irion, 1952), subsequent activity might lead to 'unlearning' of the cue–target association. Suppose, for example, that after learning an association between 'cart' and 'town', the cue 'cart' is subsequently associated with other targets (e.g., 'block' or 'train'). During this relearning phase, 'cart' occurs in the absence of 'town' and, therefore, the 'cart–town' association extinguishes, much like the process of extinction in Pavlovian conditioning (Pavlov, 1927).

The second and more commonly accepted mechanism for cue impairment is target competition. Even in the absence of unlearning, if a retrieval cue becomes linked to several targets, its ability to elicit any one of those targets lessens. So, if 'cart' is associated initially with 'town,' but then is later paired with 'block' or 'train,' the probability that 'town' will be produced with 'cart' on demand declines (see **Figure 3**). This characteristic of retrieval cues is known by several names, including *response competition, cue distinctiveness,* the *fan effect* (where 'fan' refers to the number of associated target responses), and *cue overload.* Historically the term 'response competition' was used in conjunction with 'unlearning' to form the two 'factors' of the famous two-factor theory of forgetting (McGeoch, 1942; Postman, 1961). Currently, the more popular moniker is *cue overload*, for reasons that will be discussed momentarily.

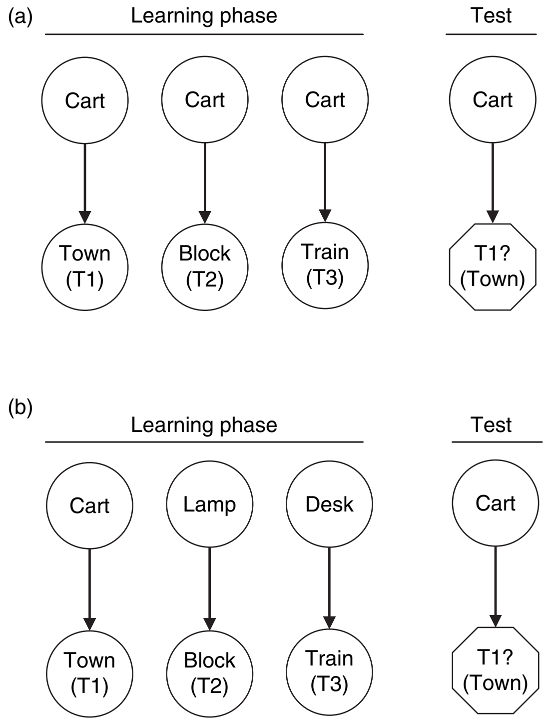

**Figure 3** Illustration of a cue overload situation. In (a) the retrieval cue is linked with several targets, whereas in (b) it is associated only with one target. The predictive value of the cue in situation (a) is lower than in (b) due to cue overload.

The basic phenomenon of cue overload is well supported empirically. For example, as the number of study items from a particular category increases, the category name becomes a less effective cue for eliciting any one item in particular (Tulving and Pearlstone, 1966; Roediger, 1973). Cue overload explains the list length effect as well: recall of any given item from a memory list declines as the length of the list increases. The list length effect occurs, presumably, because people use some representation of the list itself as a cue and it becomes 'overloaded' (i.e., less diagnostic of any particular item) as the number of items subsumed under the list cue increases (Watkins and Watkins, 1975). More directly, it is well established that increasing the number of associated responses to a given target – that is, increasing the cue's associative 'fan' – slows down people's ability to verify any particular cue–target pairing (Anderson, 1974; Anderson and Reder, 1999).

*Cue overload* is the preferred term partly because the locus of interference is believed to lie primarily in the target selection phase rather than in competition among already selected responses. Although this distinction may seem somewhat arbitrary, or at least model-specific, its roots lie in classic work by

Barnes and Underwood (1959) on the modified modified free recall test (MMFR). In an MMFR test, people are asked to recall any or all response terms that have been associated with a cue. There is no requirement to recall a specific response term which, in turn, presumably eliminates any response competition (because any and all responses can be produced). Significant interference is still obtained in the MMFR test – that is, one's ability to recall 'town' to 'cart' remains impaired if other responses have been associated with the cue – and this fact was used by interference theorists to support the concept of unlearning (Postman, 1961). Modern theorists rarely invoke unlearning *per se*, choosing to argue instead that new associations essentially block or impair access to old ones during the target selection phase, or that the recall of one item leads to inhibition or suppression of the other (see Anderson and Neely, 1996, for a review).

Ascribing interference effects to cue impairment – specifically, the ability of a cue to produce a specific target – has considerable advantages. For example, it enables the theorist to explain both retroactive and proactive interference with a single mechanism. As discussed earlier, retroactive interference occurs when newly learned material acts retroactively to impair earlier learning; proactive interference occurs when information learned at time 1 interferes with the ability to access information learned at time 2 (see **Figure 4**). Underwood (1957) provided convincing evidence that much of what is forgotten in standard verbal learning experiments can actually be attributed to proactive interference (i.e., prior learning). **Figure 5**, which is based on data compiled originally by Underwood, shows proportion correct recall of a serial list, tested after an unfilled 24-h interval, as a function of the number of lists learned previously in the experimental context. When the critical list is the only list learned, about 80% of the material will be retained after 24 h; as the potential for proactive interference increases – that is, as the number of prior lists learned increases – delayed retention drops precipitously.

The robust nature of proactive interference is troubling for most of the forgetting mechanisms we have discussed. Why should learning 'cart–town' at time 1 impair one's ability to recover 'cart–block' learned at time 2? Certainly neither decay, nor overwriting, nor unlearning can explain the phenomenon because each is ascribed to things that happen after the point of acquisition. Significant proactive interference is found on an MMFR test as well (Koppenaal, 1963),

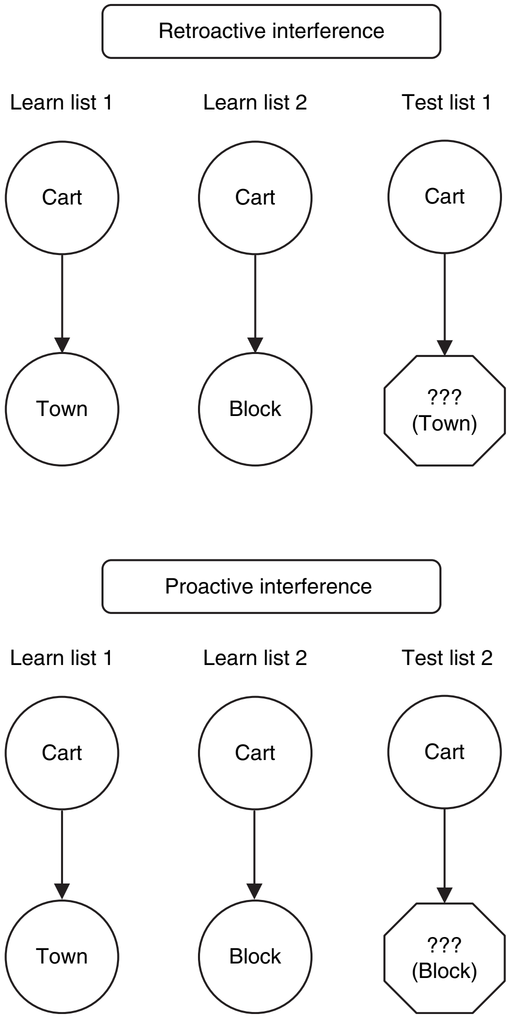

**Figure 4** Representation of experimental settings revealing retroactive interference and proactive interference.

which rules out historical versions of response competition. The only viable forgetting mechanism is cue overload: As the number of targets associated with a cue increases, the ability of the cue to access any particular target declines. Note there is nothing about the order of acquisition that is inherent in the concept of cue overload, although the availability of particular cue–target associations does change in complex ways with time and testing method (see Postman and Underwood, 1973).

### 2.12.5.4 Cue Availability

In addition to interference from events that happen in time, forgetting can also arise from altered stimulus conditions, that is, when "the stimuli necessary to

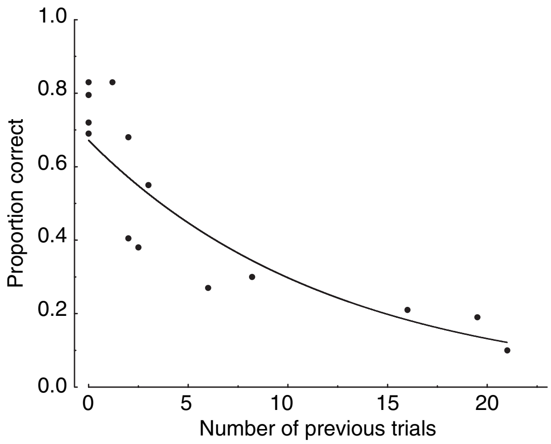

**Figure 5** Proportion of correct responses plotted as a function of the number of previous trials. Data were collected from 14 different studies. After Underwood BJ (1957) Interference and forgetting. *Psychol. Rev.* 64: 49–60.

elicit the originally learned acts are not effectively present" (McGeoch, 1942: 501). Endel Tulving (1974) coined the term *cue-dependent forgetting* to describe the situation. Put simply, if you have learned to associate the target 'town' with the retrieval cue 'cart,' then in the absence of 'cart' you are unlikely to remember 'town.' In this case, there is no degradation or impairment of the target trace, nor any impairment in the cue-target association: We forget simply because we lack the right retrieval cue.

Cue-dependent forgetting helps to explain why memories that seem to have been lost can reappear at a later time. To use the terminology of Tulving and Pearlstone (1966), information can be 'available' in memory, in the sense that the encoded information remains intact somewhere in the memory system, but not 'accessible.' Accessibility requires an appropriate retrieval cue which may be absent at time 1 but may reappear at time 2. Of course, the fact that forgetting proceeds in such a regular fashion, with such a characteristic retention function, suggests that the appearance of retrieval cues may be time-locked. Indeed, psychologists have used the concept of context, which is assumed to change systematically over time, to explain the regularity of forgetting. During presentation, information becomes associated with the context which then changes in accordance with the flow of normal activities (see Estes, 1955; Mensink and Raaijmakers, 1988; Brown et al., 2000, for some specific theories on how context changes). (Note that the examples discussed so far involve external cues (e.g., presenting a cue previously associated with a target), but cue-dependent forgetting can also be demonstrated with internal cues (e.g., mood state; Bower, 1981). In this case, an internal stimulus (such as a mood state) acts as the functional retrieval cue.)

Accepting that remembering (and forgetting) is cue-dependent encourages us to specify the conditions that determine (1) when relevant retrieval cues will be available and (2) the effectiveness of those cues when present. Psychologists have spent decades investigating the second point and have reached consensus that retrieval cues are effective to the extent that they 'match' the contents of the original encoding. The encoding specificity principle, first articulated by Tulving and Thomson (1973), states that retrieval cues will be effective in eliciting targets if and only if the information about them and their relation to the to-be-remembered target is stored at the time of encoding. Thus, the conditions of encoding will uniquely determine whether any given cue will be effective in recovering a prior target episode. Retrieval cues will work if and only if they match, and consequently are a part of, the original encoding complex.

The encoding specificity principle asserts that preexisting associations between cues and targets, such as the semantic relationship between 'bloom' and 'flower,' cannot be used *a priori* to predict the effectiveness of one cue for another. This runs counter to intuition because one would normally expect a strong associate to elicit the target naturally, allowing it to be confirmed easily as a member of the study list. Yet, Tulving and Thomson (1973) showed that a weak associate to the target 'flower,' such as 'fruit,' can actually be a better cue than the strong associate when conditions promote the encoding of the weak associate during study. It follows as well that retention will depend on the match between the retrieval cue and the target memory, as encoded, rather than on the cue and target as originally presented. Presenting the same nominal cue at test will not necessarily be effective. It will depend on whether the participant interprets the retrieval cue at test in the same way that he or she interpreted the cue during the original encoding.

Virtually all psychologists recognize the importance of matching the encoding and retrieval environments, to assure the availability of an appropriate cue, but some have questioned the role of the match *per se*. For example, Nairne (2001, 2002a) has argued that it is the diagnostic value of the retrieval cue that really matters. Rather than a passive matching process, retrieval is better characterized as an active selection process wherein cues are used to pick and choose from among viable retrieval candidates. Matching the retrieval cue with the original encoding context, as encoded, can be expected to increase the diagnostic value of the cue in most situations, but it is easy to conceive of situations in which increasing the match will not improve retention, or perhaps even lower it. For example, if features are added to the cue that match the target exactly, but also match additional non-target items, then the difficulty of the target selection process can increase and performance decline.

The situation is somewhat akin to the relationship between stimulus intensity and the perception of brightness. It is generally the case that increasing the intensity of a light source makes things look brighter, but what mainly determines brightness perception is relative intensity information. It is the number of photons falling in a given spot relative to the number falling in surrounding spots that determines how bright the central spot appears. In fact, it is possible to increase the absolute light intensity falling on the spot and make it look darker (as long as light intensity in the surround is greater still). In discussing brightness perception, it is misleading to focus on light intensity *per se* because our visual system tends to throw away absolute information in favor of relative comparisons. Similarly, for retrieval, it is misleading to focus on the absolute match between a retrieval cue and an encoded target when it is actually the diagnostic value of the cue – the relative match – that really matters (see Nairne, 2002a).

### 2.12.5.5 Retrieval-Induced Inhibition

One interesting feature of the forgetting mechanisms that we have discussed so far is their passive nature. Things happen to the memory trace which yields it less recoverable: It decays, it is degraded by subsequent events, the cue–target association is extinguished by new learning, or the memory target exists in an unrecoverable state because an appropriate retrieval cue is lacking. Yet from an adaptive perspective, it seems likely that our memory systems may have evolved active mechanisms to inhibit or suppress information in specific situations in which that information is not needed. Inhibitory processes certainly play an important role in the nervous system, particularly in neural communication, so it is not a stretch to assume that inhibition is vital to memory processing as well. We might also assume that the effects of inhibition, when it occurs, must be temporary given the continuously changing nature of our processing goals (MacLeod and Macrae, 2001).

To be clear, in modern memory theory the concept of inhibition is synonymous with suppression. When a memory trace is inhibited, it is not degraded, damaged, or impaired, it is simply rendered temporarily unavailable by an active suppression process. Importantly, suppression of this sort differs from the retrieval blocking produced as a consequence of cue overload. In cue overload, competition among viable targets produces a 'winner' and unselected targets suffer as a consequence, but there is no need to assume suppression of the 'losers.' Likewise, recall is often claimed to have inhibitory properties (Roediger, 1974, 1978) because the act of recalling one item can lower the probability that other items will also be recalled; however, this kind of 'output interference' is generally assumed to result from biased sampling rather than from suppression. Once an item is recalled, the probability that it will be sampled again increases (it is primed) which, in turn, lowers the probability that other targets will be sampled. Note that inhibition might well occur as a by-product of cue overload, or biased sampling in recall, but it is not needed to produce forgetting in these instances.

As it turns out, the best evidence for inhibition comes from an empirical procedure known as the *retrieval practice paradigm* (Anderson et al., 1994). Here, people first learn lists of category-exemplar pairs (e.g., 'fruit–banana,' 'drink–scotch') and are then asked to practice retrieval of half of the exemplars from half of the list categories. Practice takes the form of completing stem-recall tests ('fruit-or____?') which people are required to complete several times. Last, after a short delay, a final category cued recall test is given for all of the exemplars (see **Figure 6**). There are two main findings of note: First, recall of the practiced exemplars is superior to that of the unpracticed exemplars; second, recall of the unpracticed exemplars from the practiced categories is impaired relative to exemplars from the unpracticed categories. Thus, practicing the recall of 'fruit–orange' impairs recall of the unpracticed exemplar 'fruit–banana,' below the baseline recall level for exemplars from the unpracticed categories. This impairment is known as *retrieval-induced forgetting* and is thought to accrue from an active inhibitory process.

Of course, there are other interpretations of these findings. For instance, one could appeal simply to retrieval blocking. Practicing 'fruit–orange' increases the strength of the cue–target association which, in turn, should bias the system to sample 'orange' in the

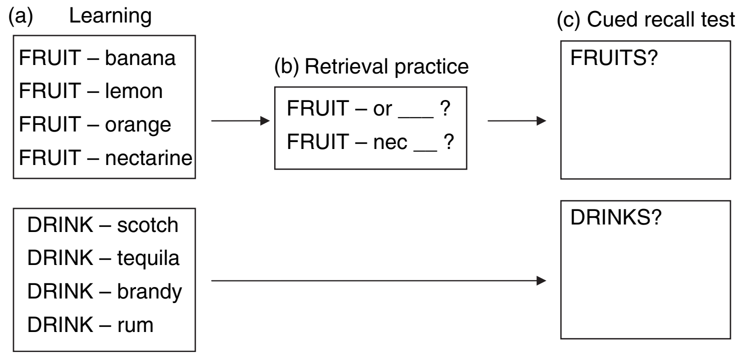

**Figure 6** A simplified version of the retrieval practice paradigm. (a) Elements of two different categories are learned. (b) Half of the elements from one category are subject to a retrieval practice phase–cued word stem completion. (c) After a distractor period, participants respond to a cued recall test with the category name; participants are required to recall all the information learned in (a).

presence of 'fruit' to the exclusion of other exemplars. What supports the presence of active inhibition is the finding that the impairment is cue independent, that is, recall of 'orange' is impaired even when queried with cues unrelated to the category cue 'fruit' (see Anderson, 2003). In retrieval blocking, the impairment results from competition among targets elicited or matched by a given cue which, in turn, should lessen if 'orange' is cued by a target that is less overloaded. As a result, the retrieval practice paradigm seems to create a target that is truly suppressed, leading to impairment regardless of how the target is queried at the point of test.

As noted earlier, the idea that our memory systems may have developed mechanisms for actively suppressing information makes considerable adaptive sense. For any given constellation of retrieval cues, there is likely to be a wide array of potentially recallable responses, so it is in our interest to reduce irrelevant clutter. A telephone, for example, potentially elicits dozens of numbers to call, but we focus on the number at hand and push the remaining numbers out of mind (Levy and Anderson, 2002). A similar task faces us in perception: We must focus our attention on relevant portions of the sensory/perceptual message and block out the irrelevant ones. In memory, as in perception, it is adaptive to exercise cognitive control in our efforts to prioritize functioning. Inhibition – i.e., active suppression – is undoubtedly a useful weapon in the arsenal of cognitive control.

### 2.12.5.6 Motivated Forgetting

Proposals about inhibitory control in memory retrieval lead one naturally to the concept of repression, Freud's proposed defense mechanism (Freud, 1915). Although exactly what Freud meant by repression is open to some interpretation (Boag, 2006), it is generally conceived as a mechanism for preventing anxiety-inducing memories, usually traumatic, from entering the sphere of conscious awareness (Gleaves et al., 2004). Motivated forgetting of this sort seems adaptive: Unpleasant or traumatic memories can interfere with normal functioning, and the associated stress reactions can lead to long-term health consequences as well.

Adaptive speculations aside, is there solid empirical evidence for repression? Unfortunately, most of the relevant data are anecdotal. For obvious reasons, laboratory-based investigations of trauma-induced memory suppression are virtually impossible to conduct. The case for repression continues to rest largely on the many reports of trauma-based amnesia, and subsequent recovery during therapy, that have been obtained in clinical settings. Some relevant survey data and/or clinical cases exist as well, during which people with known histories of sexual abuse have reported periods of amnesia for their abuse (e.g., Williams, 1994; Schooler et al., 1997). However, perhaps not surprisingly, few in the scientific community find these data to be particularly convincing (e.g., Kihlstrom, 2004).

The clinical data are controversial for several reasons. First, in therapeutic settings it is often difficult to verify whether the traumatic event actually occurred or occurred in the form revealed by the recovered memory. Therapists usually do not seek independent corroboration of their clients' reports, again largely for ethical reasons (Shobe and Kihlstrom, 2002). Second, many psychologists believe that therapist–client interactions are particularly prone to the inducement of false memories, perhaps because prior abuse is believed by many to be an important determinant of psychological problems. This is not to imply that false recovered memories are purposely implanted by the therapist, but they can occur as an unintentional by-product (e.g., Porter et al., 1999).

Finally, even if the traumatic event did occur, and the recovered memory is accurate in all details, this does not mean that an active repression process has produced the forgetting. As documented in this chapter, there are many reasons why people forget, and normal forgetting processes could easily account for many, if not all, of the verifiable cases of repressed memory. Just because a memory is traumatic does not mean that it is insensitive to decay, interference, or cue-dependent forgetting. In fact, given that many clinically relevant instances of abuse are thought to occur during childhood, or are accompanied by considerable emotional distress, it is perhaps not surprising that relevant retrieval cues are sometimes lacking at later points in time. Inhibitory mnemonic processes probably do exist, as evidence from the retrieval practice paradigm has shown, but whether there are special inhibitory processes (i.e., repression) that apply when memories are traumatic or emotionally tinged remains speculative at best.

## 2.12.6 Conclusions

Forgetting occurs when we fail to recover information that has been experienced previously. As noted initially, the common tendency is to label forgetting as a nuisance (or worse), but the process itself is actually quite adaptive. Imagine entering the parking garage after work and simultaneously recovering the locations of all of your previous parking spots. In his famous case study of the Russian journalist S., who was plagued by an inability to forget, Luria (1968) describes the torment S. experienced daily. S. had great trouble reading books, for example, because words and phrases so flooded his mind with previous associations that he was unable to concentrate. To avoid a truly cluttered mind, it is reasonable to assume that forgetting is a design feature of memory, that is, a cognitive capability that was selected for and maintained during the evolutionary history of our species.

Given the role that forgetting plays in normal functioning, it is reasonable to assume as well that there are many routes to forgetting. In the bulk of this chapter, we discussed a variety of forgetting mechanisms, everything from decay to interference to inhibition (summarized in **Table 1**). Each mechanism carries some weight of evidence and continues

**Table 1** Summary of the mechanisms of forgetting presented in the chapter

| *Mechanism* | *Source* | *Process* | *Effect* |
|---|---|---|---|
| Decay | Time | Autonomous process | Traces, or trace features, are permanently lost with time |
| Consolidation | Time | Autonomous process | Memories become more resistant to forgetting with time |
| Interference | Other acquired information | Trace degradation (Retroactive interference) | Newly acquired information damages the integrity of existing memory traces (e.g., overwriting) |
| | | Cue impairment (Retroactive interference) (Proactive interference) | Other acquired information impairs the ability of a cue to produce a specific target due to the unlearning of preexisting associations between the cue and the target, or to target competition resulting from the association of the same cue with several targets (cue overload) |
| Cue availability | Altered stimulus conditions | Absence of an effective retrieval cue | The cue needed to elicit the originally learned information is not available |
| Retrieval-induced inhibition | Retrieval of other information | Active inhibition process | Temporary inhibition of information in situations in which it is not needed or when it competes with other target memories |
| Motivated forgetting | Repression | Active repression | Prevents anxiety-inducing memories, usually traumatic, from entering the sphere of conscious awareness |

to have many advocates. It would be improper to conclude that any one of these mechanisms is 'the' forgetting mechanism because different situations will undoubtedly demand different forgetting solutions. In some circumstances, important information needs to be suppressed temporarily; in others it may be in our interest to forget things permanently (or nearly so).

Whatever the mechanism, however, it does remain a challenge for memory theorists to explain the regularity of the forgetting function. As documented earlier, the function relating recovery to time is very regular in form (see **Figure 1**). Attributing forgetting to interference from subsequent events, or to the action of cue overload, does little to explain why the forgetting curve is consistently negatively accelerated. Forgetting may indeed be cue-dependent, but then what determines the availability of appropriate cues? As the forgetting curve informs, forgetting is by no means a random occurrence.

Lastly, it is worth noting that forgetting can never be measured directly: We can only measure what has been 'remembered,' at a particular time, given a particular context. And, as we have described, what appears to have been forgotten may, in fact, turn out to be recoverable at another time or in a different context. To the extent that our memory systems are designed to use the past, in combination with the present, to generate adaptive behavior, then the variability of memory is hardly surprising. Stored information should be retrieved when it is necessary and not otherwise. In this sense it is a mistake to speculate about the ultimate 'cause' of forgetting, or to consider forgetting as a breakdown in normal functioning, because our memory systems are not designed to recover stored information at will: Recovery will depend on the situation and, more importantly, on the particular adaptive problem at hand.

# 2.13 Inhibitory Processes

**K.-H. Bäuml**, Regensburg University, Regensburg, Germany

## 2.13.1 Introduction

### 2.13.1.1 Retrieval Competition

In the course of a day, we encounter a huge number of experiences that we encode and store in our memory. Some of these experiences may be unique and lead to the encoding of very distinct features. Most of the experiences, however, will share certain features with other experiences, thus leading to the encoding of common features in our memory. In his morning lecture, a professor, for instance, may encode many distinct features of each participating student while, for all students, encoding the common feature of participating in this particular course of study. The encoding of this common contextual feature can create a problem for the professor's memory when later asked about the names of the participating students. Typically, the larger the number of students who were present in the lecture, the poorer will be the professor's recall for any one particular name. The reason for this retrieval problem is retrieval competition.

Retrieval competition means that memories that share a common cue – be it a contextual, semantic, or emotional cue – compete for conscious recall once the cue is provided and, as a result, show both reduced recall performance and increased response latencies (**Figure 1(a)**). Corresponding evidence has been provided by a number of studies in quite different experimental paradigms. In single-list paradigms, for instance, memory for target information has been found to decline and to be slowed down when the number of list items increases, which is known as the list-length effect (Watkins, 1975). In multiple-list

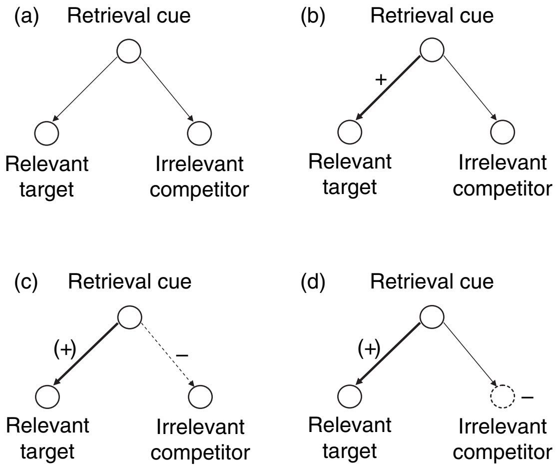

**Figure 1** (a) Retrieval competition. Relevant target and irrelevant competitor material are connected to the same retrieval cue and compete for conscious recall once the cue is provided. For both materials, the competition reduces recall probability and increases response latency. (b) Blocking. Strengthened target information blocks access to nonstrengthened competitor information. Blocking occurs at test when the strengthened material is recalled first and hinders subsequent recall of the nonstrengthened material. Blocking does not affect the competitor's retrieval route and does not affect its memory representation. (c) Route deactivation. Deactivation of the retrieval route between cue and competitor information (with possible simultaneous enhancement of retrieval route between cue and target). Route deactivation takes place at a pretest encoding or a pretest retrieval stage and reduces chances of the retrieval cue to make competitor information recoverable. (d) Item suppression. Deactivation of the memory representation of the competitor information (with possible simultaneous enhancement of retrieval route between cue and target). Item suppression takes place at a pretest encoding or a pretest retrieval stage and reduces chances to recover the competitor information, regardless of which retrieval cue is provided.

paradigms, it has been shown that both the prior and the subsequent encoding of additional lists of items can impair memory for the target list, which is known as proactive and retroactive interference (Müller and Pilzecker, 1900; Underwood, 1957; for a summary, see Crowder, 1976).

Retrieval competition provides a challenge for the goal-directed use of memory. Indeed, in daily life, relevant and irrelevant information often share a common cue. This may be the case for the more relevant and more irrelevant things that occurred to us in the office, the expired and current passwords of our computer, or the past and current address of a friend's home. When trying to recall the relevant or current information, remembering then may fail because the irrelevant or out-of-date information is retrieved. Effective updating should reduce accessibility of the irrelevant memories and simultaneously enhance that of the more relevant information.

It is an old and prominent idea that, in our memory, inhibitory processes operate to serve the function of goal-directed remembering, reducing the accessibility of irrelevant information and enhancing that of the more relevant information. In this chapter, I summarize results from a number of experimental paradigms in which the action of inhibitory processes serving memory's goal-directed use has been suggested. While there is consensus in the literature that inhibitory mechanisms operate to overcome retrieval competition and enhance the processing of relevant information, different conceptions about inhibitory mechanisms exist. In fact, some researchers speak of inhibition whenever a mechanism reduces accessibility of irrelevant information, be it directly or indirectly. Others speak of inhibition only if a mechanism affects the irrelevant information directly, be it through deactivation of the information itself or through deactivation of some of its retrieval routes.

The goal of this chapter is not to discuss which mechanism reflects real inhibition and which does not. Rather, the goal is to indicate which of the suggested mechanisms operate under what conditions. As it turns out, different mechanisms operate in different experimental contexts, providing us with a detailed picture of how reduced accessibility of irrelevant information is achieved in memory. Before reviewing these results, some of the most important conceptions of inhibitory processes suggested in the past decades are outlined. After becoming familiar with these conceptions, I turn to determining which of the inhibitory processes operates in which experimental context.

### 2.13.1.2 Inhibitory Mechanisms

Three primary inhibitory mechanisms have been suggested to serve the goal of effectively separating relevant from irrelevant information and enhancing memory for the first at the expense of the second. The three mechanisms are blocking, route deactivation, and item suppression.

1. Blocking

As described in section 2.13.1.1, when memories share a common cue, they compete for conscious recall once the cue is provided and show reduced recall performance (**Figure 1(a)**). Such retrieval competition has been shown to be strength dependent. That is, if material that is strongly represented in memory and material that is weakly represented share the same retrieval cue, there is a tendency for the stronger material to be recalled first (Rundus, 1973; Raaijmakers and Shiffrin, 1981; Wixted et al., 1997). Thus, if relevant material, like the current computer password, is represented more strongly in memory than irrelevant material, that is, the expired password, the difference can induce a competition bias at test favoring the early recall of the (stronger) relevant information – the current password. By involuntarily sampling the already recalled material repeatedly, this early recall of the relevant information then can block subsequent recall of the (weaker) irrelevant information – the expired password – and make it inaccessible (**Figure 1(b)**). Such blocking of irrelevant information has repeatedly been regarded as an important example of inhibition in human memory (Melton and Irwin, 1940; McGeoch, 1942; Rundus, 1973) and is a core feature of many computational models (Raaijmakers and Shiffrin, 1981; Mensink and Raaijmakers, 1988).

A crucial feature of blocking is that there is no direct effect of inhibition on the irrelevant material itself and no direct effect on the retrieval routes between the irrelevant material and its cue(s). Rather, the inaccessibility of the irrelevant material (the expired password) arises as a by-product of the strengthening of the relevant material (the current password), which, as a result of biased competition, favors recall of the stronger relevant material and blocks recall of the weaker irrelevant material. Because blocking typically operates at test, its effect should be visible in memory tests in which there is the opportunity for strength-dependent retrieval (i.e., in free recall tasks and in cued recall tasks in which more than one item is connected to the cue). In contrast, blocking should play only a minor role, if any, in memory tests in which item-specific probes are provided as retrieval cues, such as recognition tests or implicit memory tests. In all these tests, strength-dependent competition should be greatly reduced or eliminated.

2. Route deactivation

A more direct way to induce inaccessibility of irrelevant material would be to not only strengthen the relevant material but also weaken the retrieval route between the irrelevant information and its cue, so that retrieval of the irrelevant information becomes less effective (Melton and Irwin, 1940; Geiselman et al., 1983; **Figure 1(c)**). Applied to the computer password retrieval problem, this would mean that, rather than blocking retrieval of the expired computer password, an inhibitory mechanism would directly weaken the connection of the expired password's memory representation to the common password cue. Such route deactivation might operate while the new password is encoded, or it might operate after the encoding of the new password, for instance, when retrieving the current computer password. Because the retrieval routes to the irrelevant information would be affected directly, the effect of such a mechanism should be visible in a number of memory tests and should arise not just in free recall tasks but in all forms of cued recall as well. On the other hand, because the representation of the irrelevant material itself would not be affected, only minor, if any, forgetting of the irrelevant information should be observed in recognition tasks.

The strengthening of relevant information creates a difference in relative strength between relevant and irrelevant information and thus can lead to blocking. Route deactivation also creates a difference in relative strength, which may be particularly strong, if not only the retrieval routes for the irrelevant material are reduced but retrieval routes for the relevant material are simultaneously enhanced. Therefore, route deactivation may trigger blocking at test as an additional mechanism, an effect that should be largely restricted to free recall tasks.

3. Item suppression

Blocking and route deactivation reflect mechanisms that, following Tulving and colleagues' terminology (Tulving and Pearlstone, 1966; Tulving and Psotka, 1971; Tulving, 1974), result in loss of retrieval access to inhibited items rather than in loss of the items' availability. A loss in availability would imply that the memory representation of material is affected itself so that memory for the material is impaired regardless of which retrieval cue is provided. It has repeatedly been suggested that inhibitory processes may affect the item representation itself (Postman et al., 1968; Anderson and Spellman, 1995; **Figure 1(d)**). Applied to the computer password retrieval problem, for instance, this would mean that, rather than blocking the expired computer password or reducing its connection to the common password cue, the memory representation of the expired password would directly be suppressed. Such suppression might operate while the new password is encoded, or it might operate after the encoding of the new password, for instance, when retrieving the current computer password. Due to the direct effect on the memory representation of the irrelevant information itself, item suppression would reflect a strong form of inhibition and should be visible over a wide range of memory tests, including recognition tasks and tasks that employ so-called independent probes, that is, probes not used until the test phase of an experiment.

Like route deactivation, a side effect of item suppression is that a difference in relative strength between relevant and irrelevant material is created, particularly if there is simultaneous strengthening of the relevant information. In memory tests that are sensible to strength-dependence effects, this difference can trigger blocking as an additional inhibitory mechanism. In free-recall tasks, item suppression, therefore, may reduce accessibility of irrelevant material very effectively.

In sum, although blocking, route deactivation, and item suppression can all serve the goal of reducing accessibility of irrelevant material and enhancing that of relevant information, the three mechanisms differ in the way the inaccessibility is achieved. In blocking, the inaccessibility arises because of the difference in relative strength between target and competitor information, with early recall of the stronger target information blocking recall of the weaker competitor information; in route deactivation, inaccessibility arises because of the direct deactivation of the retrieval route between the cue and the irrelevant information; and in item suppression, inaccessibility arises because of the direct deactivation of the memory representation of the irrelevant material itself, which, following Tulving's terminology, represents some form of information unavailability.

The difference in how inaccessibility is achieved in the three inhibitory mechanisms has implications for the range of memory tests in which the effects of inhibition can be observed. Blocking represents the weakest form of inhibition. Because it does not affect the irrelevant material directly, its effects should arise only in memory tests that leave sufficient room for strength-dependent retrieval, like free-recall tasks. By directly affecting the retrieval routes to the irrelevant material, route deactivation represents a stronger form of inhibition, the effects of which should be observable in free-recall and cued-recall tasks. Item suppression, finally, represents the strongest form of inhibition that affects the memory representation of the inhibited item itself and thus should create effects across a wide range of memory tests. Also note that route deactivation and item suppression can trigger additional blocking at test, thus creating a situation in which two inhibitory processes may operate in concert.

The next section examines the role of the three suggested inhibitory mechanisms in experimental paradigms that are often assumed to involve inhibition: strength-induced forgetting, retrieval-induced forgetting, directed forgetting, think/no-think impairment, and part-list cuing impairment. At the end of the section, current knowledge about the developmental trajectory of inhibition in the single paradigms is reviewed. In the conclusion, finally, the results are summarized and a taxonomy of the inhibitory paradigms is suggested.

## 2.13.2 Inhibitory Paradigms

### 2.13.2.1 Strength-Induced Forgetting

A simple way to emphasize memory for relevant material is to present the relevant information repeatedly or longer and the less relevant information less often or for a shorter time period. This is common use in textbooks or talks, in which important information is typically repeated in several places, and it is typically employed by students preparing for an exam, when they spend more time on the seemingly relevant material than on the seemingly irrelevant material.

Strengthening the memory representation of relevant information – be it through repeated or longer study – should lead to different memory performance for the relevant and irrelevant information, simply because of the resulting difference in (absolute) memory strength between the two types of information. The effect of strengthening or inhibition that we observe in experiments, however, is often larger than we might expect on the basis of the encoding difference, suggesting that additional processes enhance accessibility of the relevant material and reduce it for irrelevant material. This point has been demonstrated in a number of experimental paradigms, discussed next. In these paradigms, a subset of the material to be learned is strengthened, and its effect on later memory for the strengthened and nonstrengthened material is examined.

#### *2.13.2.1.1 The mixed-list paradigm*

In the mixed-list paradigm, participants are presented a list of items such as unrelated words. Strengthening effects are then examined by providing a longer presentation time for a subset of the material or by presenting a subset of the material repeatedly (e.g., Tulving and Hastie, 1972; **Figure 2**). For instance, half of the items of a list may be shown for 6 s and the other half for 2 s, or half of the items may be shown twice and the other half once. Memory performance for the two types of items is compared with two pure-list baseline conditions in which there is no such partial strengthening and all material is studied in the same way (i.e., all items are studied for 6 s or all items are studied for 2 s). Memory is typically assessed by means of a free-recall test, a cued-recall test, or a recognition test.

On the basis of the encoding difference between strong and weak items, strong items should show better memory than weak items. In particular, strong items in mixed lists should show the same memory performance as strong items in pure lists, and weak items in mixed lists should show the same performance as weak items in pure lists. The general idea of retrieval competition and blocking, as outlined above (in sections 2.13.1.1 and 2.13.1.2), however, suggests otherwise, at least in free-recall tasks. Partial strengthening in the mixed-list paradigm should introduce a competition bias, leading to early recall of the strengthened items, which then may block subsequent recall of the nonstrengthened items. As a result, on average, strong items in mixed lists should show better performance than strong items in pure lists, and weak items in mixed lists should show poorer performance than weak items in pure lists. Such effects should be present in free-recall tasks, but they should be absent in recognition tasks, in which no such competition bias is expected.

Indeed, free-recall experiments have shown that, in mixed lists, strengthened items are better recalled than nonstrengthened ones and that this effect is not only a result of the difference in the items' absolute memory strength but is also attributable to their difference in relative strength. Recall of strong items was consistently found to be higher in mixed lists than in pure lists, and recall of weak items was

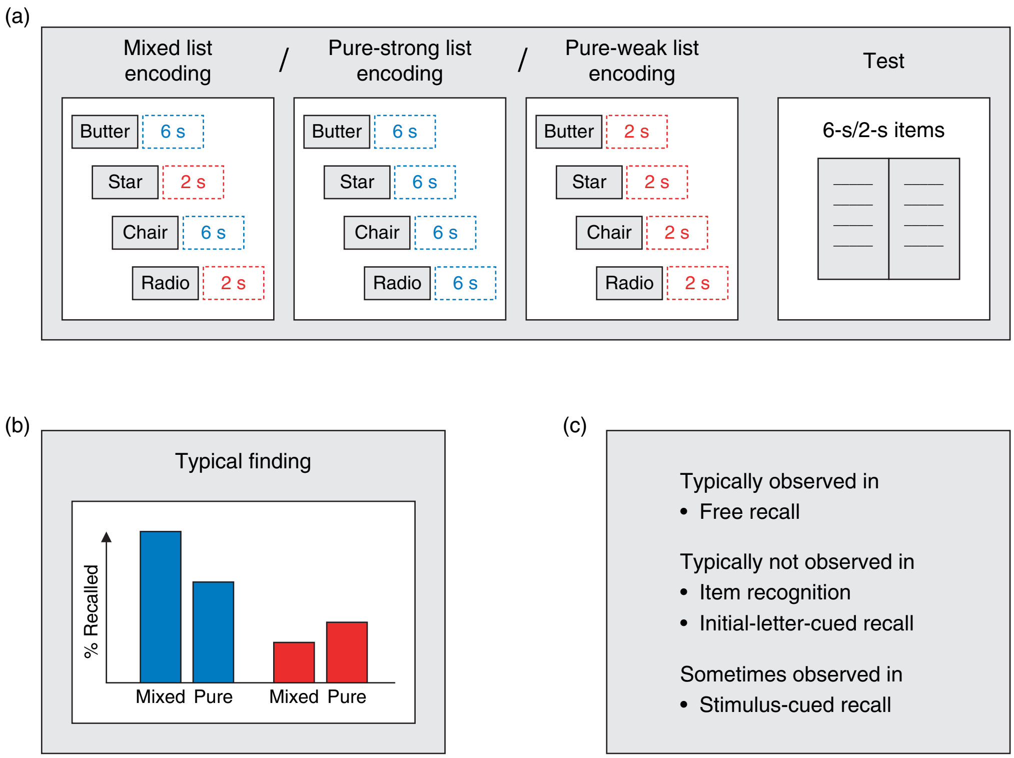

**Figure 2** The list-strength effect. (a) The experimental paradigm. Participants study a mixed list consisting of strong and weak items. Memory for the two types of items on a later test is compared to two baseline conditions: a pure-strong list condition containing strong items only and a pure-weak list condition containing weak items only. Strengthening is accomplished by varying either the exposure time or the number of repetitions of the items to be strengthened. (b) The typical finding. Relatively more strong items are recalled from the mixed list than from the pure-strong list, and relatively fewer weak items are recalled from the mixed list than from the pure-weak list. (c) Memory tests. Examples of memory tests in which the list-strength effect typically arises and in which it typically does not arise.

found to be poorer in mixed lists than in pure lists (Tulving and Hastie, 1972; Ratcliff et al., 1990; see also Malmberg and Shiffrin, 2005). In contrast, such list-strength effects have typically been found to be absent in recognition tasks. Although recognition of strong items was found to be higher than recognition of weak items, performance for the two types of items did not vary with list composition (Ratcliff et al., 1990; Murnane and Shiffrin, 1991; Ratcliff et al., 1992).

A few studies reported reliable recognition effects in the mixed-list paradigm (see Norman, 2002, for item recognition, and Verde and Rotello, 2004, for associative recognition), which were used to draw inferences on whether the effects were caused by changes in recollection or changes in the familiarity of the items. Tulving (1985) distinguished between two bases for judging an item as 'old' on a recognition test: The participant specifically remembers the temporal and/or spatial context in which the item was studied (recollection), or the participant finds the item just familiar (familiarity; for a review, see Yonelinas, 2002). From the studies reporting reliable list-strength effects in recognition, evidence has arisen that the list-strength effect reflects mainly a modulation in recollection but does not affect familiarity.

A number of studies examined list-strength effects in cued recall. In paired-associate learning with stimulus-cued recall tests, a mixed picture arose with reliable effects in some experiments and nonreliable ones in others (Ratcliff et al., 1990). List-strength effects were also examined when categorized lists were studied. In this case, each category studied was a mixed category, with half of the items being strong (high-frequency) exemplars and half of the items weak (low-frequency) exemplars of the category, or a pure category, with all items being strong exemplars or all items weak exemplars. The items' category name and their unique initial letters were provided as retrieval cues at test. Performance of strong and weak items was compared between mixed categories and pure categories when the items were tested first within their categories, thus controlling for possible effects of output order. For both strong and weak items, no effect of category composition arose (Bäuml, 1997).

As a whole, these findings are largely consistent with the proposal that strengthening, as employed in the mixed-list paradigm, leads to blocking at test, which improves access to the relevant information at the expense of the access to the irrelevant material. Accordingly, the list-strength effect is typically present in free-recall tasks and is absent in recognition tasks. If output order is controlled, the effect is also absent in cued-recall tasks, which is consistent with the view that the inhibitory mechanism does not affect the items' retrieval routes or their memory representation.

#### *2.13.2.1.2 Relearning and interference paradigms*

Findings consistent with those from the mixed-list paradigm have been reported in two further strengthening paradigms, relearning and interference. In the relearning paradigm, strengthening effects are examined by presenting the relevant and irrelevant material together within one list and subsequently presenting the relevant material again for an additional study trial. This relearning condition is then compared with a condition in which there is no such reexposure of the relevant material.

Again, the idea of blocking suggests that, at least in free-recall tasks, retrieval competition may become biased because of the strengthening of a subset of the material and thus may increase recall of the relearned material at the expense of the material presented only once. Such effects, however, should not arise in recognition tests or tests using item-specific probes. A number of studies examined this latter prediction in cued-recall tests, in which the items' unique initial letters were provided as additional retrieval cues and output order was controlled by testing the target items first. In all these studies, relearning improved recall of the strengthened material but did not affect recall of the nonstrengthened material (Ciranni and Shimamura, 1999; Anderson et al., 2000a; Bäuml and Aslan, 2004). This finding is consistent with the assumption that strength-induced forgetting is mediated by blocking rather than by deactivation of retrieval routes or by deactivation of the item representation.

Both in retroactive and proactive interference, older studies had shown that strengthening of prior or subsequently encoded material can increase interference and thus increase forgetting of target material (for a review, see Crowder, 1976). Varying the degree of interpolated learning in a list-learning paradigm, Bäuml (1996) replicated this result and found that a higher degree of interpolated learning induced greater retroactive interference. In this experiment, output order was not controlled, and participants were free to recall the strengthened interpolated material prior to the (weaker) target material. In a second experiment, which was largely identical to the first experiment, output order was controlled, and participants were asked to recall the (weaker) target material first. No effect of degree of interpolated learning was observed (for a related result regarding proactive interference, see DaPolito, 1966; for further investigation, see Delprado, 2005). Again, these findings point to the action of a blocking mechanism, which is activated in memory tests that permit recall of items in any order.

#### *2.13.2.1.3 Summary*

Results from paradigms investigating strength-induced forgetting indicate that the strengthening of relevant material at encoding can trigger inhibitory processes to improve memory for the strengthened material at the expense of that for the not strengthened or irrelevant material. Strength-induced forgetting is present in free-recall tests and absent in recognition tests or cued-recall tests, in which output order is controlled. These results are consistent with the proposal that the enhanced accessibility of strengthened material and the reduced accessibility of nonstrengthened material result from blocking at test, in which early recall of stronger items prevents subsequent recall of the weaker ones. The results do not support the idea that the memory effects in these paradigms are caused by direct inhibitory effects on the irrelevant material's representation or its retrieval routes.

### 2.13.2.2 Retrieval-Induced Forgetting

The strengthening of relevant material at encoding can trigger inhibitory processes on the nonstrengthened irrelevant material. Strengthening of relevant material, however, does not only occur at encoding but may happen through retrieval as well. In fact, while relearning is an often employed method to emphasize memory for relevant material, retrieval of previously studied material can serve the same goal. One may even expect to find strengthening through retrieval to induce the same inhibitory processes as strengthening at encoding.

Experimental studies have shown that retrieval typically enhances later recall of the practiced material (Hogan and Kintsch, 1971) and can even be more powerful in its effect than relearning is (Carrier and Pashler, 1992; Roediger and Karpicke, 2006). The question arises of whether strengthening through retrieval also induces inhibitory processes and, if it does, whether such inhibition is mediated by the same competition bias as the inhibition underlying strengthening through relearning. On the basis of many computational models of memory, this might be expected, given that retrieval has often been assumed to reflect some form of relearning (e.g., Rundus, 1973; Raaijmakers and Shiffrin, 1981).

#### *2.13.2.2.1 Retrieval-practice paradigm*

In the retrieval-practice paradigm, a subset of learned material is repeatedly retrieved, and the effect of this manipulation on later memory for the practiced and unpracticed material is examined (Anderson et al., 1994; **Figure 3**). Memory is typically assessed by means of free recall, cued recall, and recognition tests. In addition, so-called independent probe tests are conducted, in which memory is assessed using cues at test that were not employed in earlier parts of the experiment. On the basis of retrieval competition and blocking, it might be assumed that retrieval simply strengthens the practiced material and thus causes blocking for the unpracticed material. Such blocking would increase recall for the practiced material and decrease recall for the unpracticed material, relative to control items in a no-practice condition. If true, then the effect of retrieval would mimic the effect of relearning.

A large number of free- and cued-recall experiments have addressed this issue in recent years. In these experiments, participants often learned categorized item lists and then practiced half of the items from half of the categories. At test, the category names were then provided as retrieval cues and the task was to recall the previously studied items that belonged to the category name. Relative to the control items from the unpracticed categories, retrieval practice typically improved recall of the practiced items and impaired that of the unpracticed items from the practiced categories (Anderson et al., 1994; Anderson and Spellman, 1995; Macrae and MacLeod, 1999; MacLeod and Macrae, 2001; Bäuml and Hartinger, 2002). This pattern of results first of all mirrors the beneficial and detrimental effects of strengthening at encoding, suggesting that the effect may be a result of blocking.

If the effects of retrieval were equivalent to those of relearning and only reflected biased competition and blocking, the detrimental effects of retrieval practice should be eliminated once item-specific probes were employed at test and output order was controlled. The issue was examined in experiments in which the detrimental effects of relearning and retrieval were compared directly. Participants learned categorized lists. At test, the category names

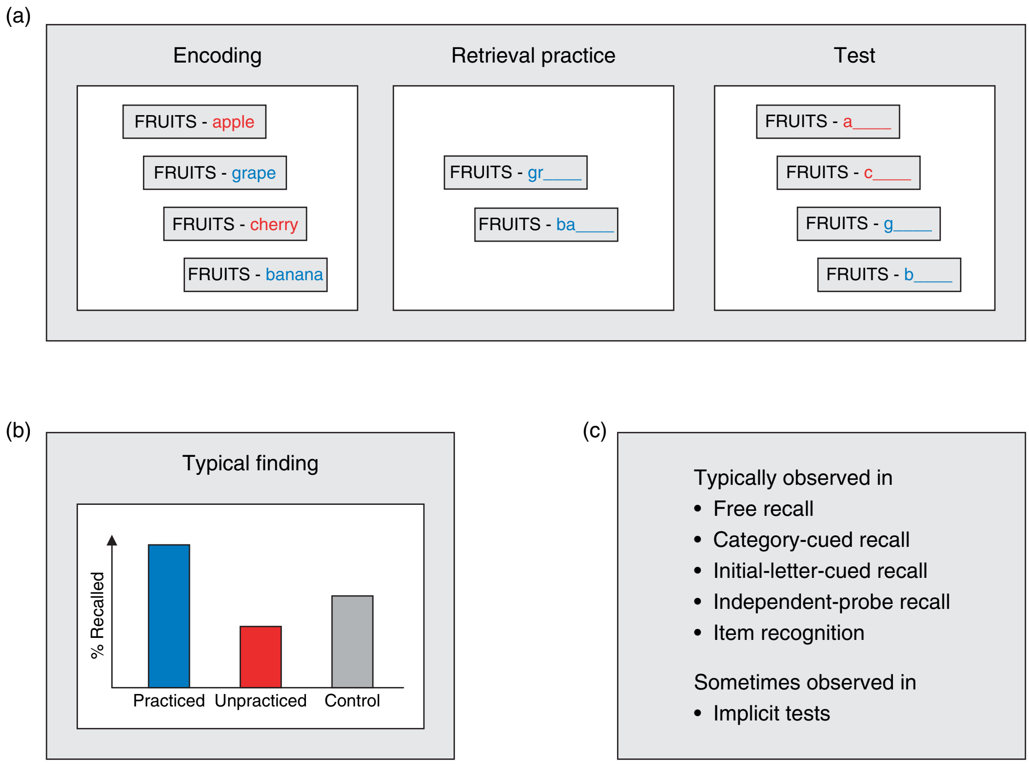

**Figure 3** Retrieval-induced forgetting. (a) The experimental paradigm. Participants study a categorized item list. In a subsequent retrieval-practice phase, half of the items from half of the studied categories are repeatedly retrieved. On the final test, participants are asked to recall all previously studied items. (b) The typical finding. Practiced items show higher recall rates, and unpracticed items show lower recall rates relative to the control items from the unpracticed categories. (c) Memory tests. Examples of memory tests in which retrieval-induced forgetting typically arises.

and the targets' initial letters were provided as retrieval cues. To control for output order, the targets were always tested first within their categories. Consistent with the results from the strengthening paradigms, no detrimental effect of relearning arose. In contrast, reliable forgetting arose in the retrieval practice condition (Anderson et al., 2000a), indicating that retrieval-induced forgetting reflects a recall-specific effect and is not caused by blocking (for related results, see Ciranni and Shimamura, 1999; Bäuml, 2002).

Further studies support the proposal that retrieval-induced forgetting does not reflect blocking by showing that the effect is not only present in free and category-cued recall but occurs in other types of tests as well. Using the so-called independent probe procedure, for instance, retrieval-induced forgetting has been reported to be cue independent, that is, to generalize to cues other than those used at study or retrieval practice (Anderson and Spellman, 1995; Anderson et al., 2000b; Saunders and MacLeod, 2006; Aslan et al., 2007b). Accordingly, retrieval practice of 'fruit-apple' was found to induce forgetting of 'banana' not only when banana was tested with the same cue as was used at study and retrieval practice ('fruit') but also when it was probed with a new, independent cue (e.g., 'monkey'). This property of cue independence is taken as strong support for the view that retrieval-induced forgetting is caused by inhibition (Anderson, 2003; for failures to find cue independence, see Williams and Zacks, 2001; Perfect et al., 2004).

Retrieval-induced forgetting has also been found in recognition tests (Hicks and Starns, 2004; Verde, 2004; Gómez-Ariza et al., 2005; Spitzer and Bäuml, in press). As outlined in section 2.13.1.2, recognition can be based on recollective processes and/or familiarity processes (Tulving, 1985; Jacoby, 1991). In retrieval-induced forgetting, the recognition tests provided evidence that retrieval practice affects both recollective and familiarity processes of the unpracticed material. Studies in which associative recognition was employed reported a reduction in recollective processes (Verde, 2004); studies in which item recognition was employed reported additional reductions in familiarity processes (Spitzer and Bäuml, in press). Regarding implicit memory tests, a mixed picture arises. Whereas some studies found reliable impairment in implicit tests (Veling and van Knippenberg, 2004), others failed to find an effect (Racsmany and Conway, 2006). Still others found effects in some tests but no effects in others (Perfect et al., 2002; see also Camp et al., 2005).

The results from all these studies are largely consistent with the assumption of an inhibitory mechanism that directly affects the representation of the unpracticed items itself. Because of such an impairment in item representation, all retrieval routes to the inhibited item should be less effective than without retrieval practice, and forgetting should be observed across a wide range of memory tests. The results from the studies employing recognition tests and tests using independent probes as cues support this view and are inconsistent with the hypothesis that the inhibition is the result of blocking or an effect on the retrieval routes between the inhibited item and its studied cue. Blocking assumes an inhibitory mechanism that operates at test. Here the proposal is that the inhibitory mechanism operates before the test in the retrieval practice phase of the experiment. In this phase, the not-to-be-practiced material is supposed to interfere and to be inhibited to reduce the interference and make retrieval of the target information easier (Anderson and Spellman, 1995; see also Anderson, 2003).

Two further lines of research support this view of retrieval-induced forgetting. First, response latency analysis sheds light on the dynamics of recall, allowing conclusions on the size of the underlying search set and the memory strength of the set's items (for a review, see Wixted and Rohrer, 1994). Applying such response latency analysis, Bäuml et al. (2005) found that retrieval practice reduces unpracticed items' recall probability but does not affect their response latency. This result mirrors typical effects of item strength manipulations as they occur as a result of variations in study time or study trials (Rohrer, 1996; Wixted et al., 1997), indicating that retrieval practice affects the memory strength of unpracticed items but does not prevent the items from being sampled. Second, a recent electrophysiological study reported retrieval-specific brain activities during the retrieval-practice phase, which were reflected in sustained prefrontal event-related potentials and correlated with the amount of forgetting in the later memory test (Johansson et al., 2007). The reported retrieval-specific effect indicates that retrieval-induced forgetting is the result of processes operating during retrieval practice and is not the result of blocking at test.

The inhibitory view of retrieval-induced forgetting presupposes some degree of retrieval competition and relational processing between single items. Consistently, Smith and Hunt (2000) reported reliable retrieval-induced forgetting if individuals encoded items in a relational way but not when they encoded them in an item-specific way, that is, by their features and distinctive qualities (regarding relational and item-specific processing, see Hunt and McDaniel, 1993). It is often assumed that positive moods encourage relational processing and negative moods encourage item-specific processing (e.g., Storbeck and Clore, 2005), thus raising the expectation that mood affects retrieval-induced forgetting. Bäuml and Kuhbandner (2007) examined the effect of positive and negative mood induction immediately before retrieval practice on retrieval-induced forgetting. Indeed, negative mood induction, but not positive mood induction, eliminated the forgetting.

Once material is processed in a relational way so that retrieval competition arises, the forgetting may be affected by the degree of interitem associations between the practiced and unpracticed material. Indeed, both instructions to interrelate to-be-practiced and not-to-be-practiced items in a meaningful way (Anderson et al., 2000b) and the use of strong pre-experimental associations between the two types of items (Bäuml and Hartinger, 2002; Bäuml and Kuhbandner, 2003) have been shown to eliminate retrieval-induced forgetting. Under conditions that simulate educational situations, Chan et al. (2006) even demonstrated that retrieval practice can benefit memory for the unpracticed material. These findings are consistent with a variant of item suppression in which items are represented as sets of features, and features that the unpracticed item shares with the practiced items are strengthened rather than inhibited. Because of this strengthening of some of the item's features, forgetting is reduced or eliminated and may even be reversed to show recall facilitation (for details, see Anderson, 2003).

At the core of the retrieval-practice paradigm is the action of an inhibitory mechanism that directly affects the representation of the irrelevant material. This effect is observable across a wide range of memory tests because the items' representation itself is affected. Note, however, that because item suppression induces a difference in relative strength between practiced and unpracticed items, the inhibitory process should also create a competition bias at test, favoring early recall of practiced items at the expense of unpracticed items. Moreover, because there is not only suppression of unpracticed material but also strengthening of the practiced material, this bias should be particularly strong, triggering additional blocking in free-recall tasks. Results from several studies are consistent with this prediction (e.g., Anderson et al., 1994).

#### *2.13.2.2.2 Output interference*

If retrieval of material can cause forgetting of nonretrieved material, then retrieval-induced forgetting should also occur in the course of a recall test. In principle, recall of a first item should cause inhibition of the still-to-be-remembered items, as should recall of the second item, the third item, and so on. As a result, recall performance at test should decline as a function of testing position. This pattern is exactly what has been known as output interference for more than 30 years. Output interference has been demonstrated in a number of studies (Smith, 1971; Roediger, 1974; Roediger and Schmidt, 1980) and, among other factors, was taken as evidence that recall is a self-limiting process (Roediger, 1978).

Originally, output interference was explained in terms of retrieval competition, assuming that recall of a first item strengthens the item and thus, because of biased retrieval competition, makes retrieval of the remaining items harder. This blocking account obviously disagrees with the explanation of retrieval-induced forgetting as it occurs in the retrieval-practice paradigm (see section 2.13.2.2.1). Arguably, however, retrieval-induced forgetting as studied in the retrieval-practice paradigm and retrieval-induced forgetting as studied in the output-interference paradigm should be mediated by similar mechanisms and might even be equivalent.

A blocking account of output interference predicts that the forgetting should disappear once item-specific probes are presented at test. Thus, recall should not decline with testing position if, for instance, the items' unique initial letters were provided as cues (see section 2.13.2.1.1). In contrast, if output interference was mediated by the same mechanism as the forgetting in the retrieval-practice paradigm, recall should decline with testing position regardless of whether item-specific cues were provided or not (see section 2.13.2.2.1). As it turned out, output interference effects are maintained in the presence of item-specific probes (Anderson et al., 1994; Anderson and Spellman, 1995; Bäuml, 1997), which supports the suggested equivalence of effects in the two paradigms.

The relation between the two paradigms was further examined in two studies in which the role of item strength and item similarity in output interference were examined (Bäuml, 1998; Bäuml and Hartinger, 2002). The two studies found effects of item strength and item similarity in output interference that mirrored those known from the retrieval-practice paradigm, which is consistent with the view that the same inhibitory mechanisms operate in the two paradigms. Given the evidence for item suppression in studies using the retrieval-practice paradigm (see section 2.13.2.2.1), these results suggest a role of item suppression in output interference as well.

#### *2.13.2.2.3 Summary*

Like relearning of relevant material, retrieval of relevant material can impair memory for irrelevant material. Results from the retrieval-practice paradigm suggest that retrieval triggers two processes: one process strengthening the practiced material and a second process inducing inhibition of the unpracticed material. These two processes create some difference in relative strength between practiced and unpracticed items and thus leave room for blocking. Going beyond blocking, however, retrieval affects the unpracticed material's representation itself. Such item suppression is at the core of retrieval-induced forgetting and implies that the inaccessibility of the irrelevant material is not restricted to free-recall tasks but generalizes to a wide range of memory tests. The results also indicate that the detrimental effects of retrieval and relearning are mediated by different mechanisms.

### 2.13.2.3 Directed Forgetting

Relearning and retrieval practice may be regarded as forms of memory updating, in which part of previously studied material is reexposed or retrieved, suggesting that it is more relevant than the remaining material (Anderson and Schooler, 1991). Inhibitory processes then act on the seemingly less relevant material, either by blocking its access during recall or by directly affecting the material's representation itself. A different form of updating may arise in situations in which new information, such as the new computer password, has to displace old information, for example, the expired password. In this case, memory for the new relevant information would benefit if memory for the irrelevant out-of-date information was reduced. Whether such updating is part of our memory and is mediated by inhibitory processes has been studied in list-method directed forgetting.

#### 2.13.2.3.1 List-method directed forgetting

In list-method directed forgetting, participants learn two lists of items. After learning List 1, they receive a cue to either forget or continue remembering this list before studying List 2. After learning List 2, a recall or recognition test is conducted in which participants are asked to remember the previously studied items, including those the participants were originally cued to forget. Memory for List 1 and List 2 items is then compared between the two conditions (Bjork, 1970, 1989; **Figure 4**).

The results from numerous recall experiments show two effects of the forget cue: reduced recall of List 1 items, referred to as forgetting and improved recall of List 2 items, referred to as enhancement (for a review, see MacLeod, 1998). These effects provide the first evidence for memory updating in this paradigm, demonstrating reduced accessibility for the out-of-date information and enhanced accessibility for the new information. Arguably, the forgetting of List 1 items might be a result of demand characteristics, because participants may not try as hard to recover the to-be-forgotten List 1 items as they do for the to-be-remembered List 2 items. The effect of the forget cue, however, does not disappear if money is offered for recalled List 1 items (MacLeod, 1999), indicating that the effect probably is not a result of demand characteristics (for a recent variant of list-method directed forgetting, see Szpunar et al., in press).

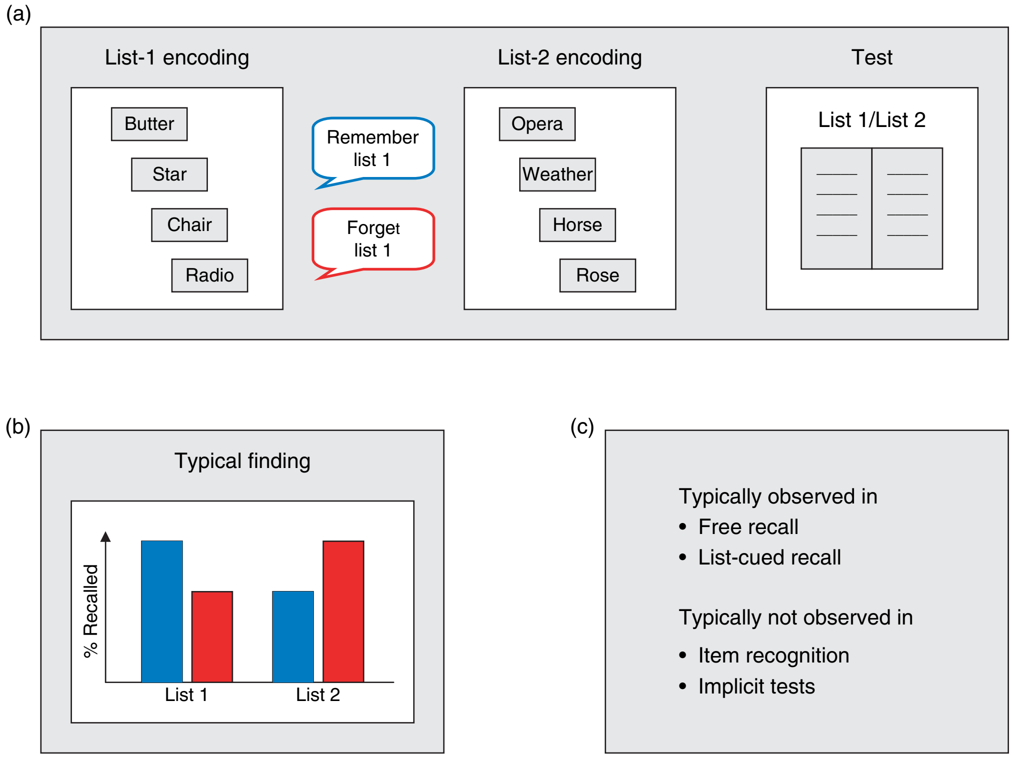

**Figure 4** List-method directed forgetting. (a) The experimental paradigm. Participants study two lists of items and, after the presentation of List 1, receive a cue to either forget or continue remembering this list before studying List 2. After study of List 2, a recall test is conducted in which participants are asked to recall all of the previously presented items, including those the participants were originally cued to forget. (b) The typical finding. Compared with remember-cued participants, forget-cued participants typically show impaired recall of List 1 items and improved recall of List 2 items, referred to as the forgetting and the enhancement induced by the forget cue. (c) Memory tests. Examples of memory tests in which list-method directed forgetting typically arises and in which it typically does not arise.

In free-recall tests, participants in the forget condition show a tendency to recall List 2 items before List 1 items (Geiselman et al., 1983). As a result, the effect of the forget cue on List 1 items could be a result of blocking and output interference, in which early recall of List 2 items impairs subsequent recall of List 1 items. The two effects of the forget cue, however, have been found regardless of whether the two lists were recalled simultaneously in any order the participants wished (i.e., with a tendency to recall List 2 items before List 1 items) or whether they were recalled successively with List 1 items recalled prior to List 2 items (Geiselman et al., 1983; Zellner and Bäuml, 2006). This result indicates that list-method directed forgetting does not reflect effects of blocking and output interference.

List-method directed forgetting has also been assessed by means of recognition tests. In most of these studies, no effect of the forget cue emerged for either List 1 items or List 2 items (Geiselman et al., 1983; Basden et al., 1993; Sego et al., 2006; for an exception, see Benjamin, 2006). Impairments on List 1 recognition, however, were found when participants were required to make source memory judgments (Geiselman et al., 1983). On the basis of the recollection/familiarity distinction, this finding suggests that the forgetting in this paradigm reflects primarily a deficit in recollection and not in familiarity. No effects of the forget cue arose in implicit memory tasks (Basden et al. 1993; Basden and Basden, 1996).

Two particularly prominent accounts of list-method directed forgetting are selective rehearsal and inhibition. The selective rehearsal account assumes that during List 2 encoding participants in the remember condition rehearse both List 2 and List 1 items, whereas in the forget condition, the forget cue leads to selective rehearsal activities on List 2 items, thus improving later recall of List 2 at the expense of List 1 (Bjork, 1972). The inhibition account assumes that, by inhibiting List 1 items, the forget cue deactivates retrieval routes to List 1 items and, because of the resulting decrease in the items' interference potential, simultaneously improves access to List 2 items (Geiselman et al., 1983). Because the selective rehearsal hypothesis attributes directed forgetting to differences in encoding, it predicts effects on recall and recognition tests. The inhibition account attributes directed forgetting to effects on the List 1 items' retrieval routes, and thus the forgetting should be present in recall but should be absent in recognition. The above-mentioned failure to find directed forgetting on recognition tests supports the inhibition account.

Further evidence for the inhibition view arises from an experiment by Geiselman et al. (1983). They used a variant of the standard paradigm, in which participants alternately learned items intentionally and incidentally. Indeed, all participants were told to learn one item and judge the pleasantness of the next one. For both learn and judge items, the standard pattern of directed forgetting arose with reduced recall of List 1 items and improved recall of List 2 items. This result challenges the selective rehearsal hypothesis, because participants in the remember condition should not have tried to rehearse the incidental List 1 items and, rather, should have focused their rehearsal on the learn items. Incidental List 1 items thus should have shown the same performance in the remember as in the forget condition, which was not the case.

For most of the paradigms discussed in this chapter, there is broad consensus that inhibition operates on an item level. In contrast, in list-method directed forgetting it has been suggested that the inhibition operates on a list-level basis. According to this view, List 1 items form a unit, and the presence of the forget cue induces inhibition of the whole unit. Evidence in favor of this view comes from the Geiselman et al. (1983) observation that incidentally learned List 1 items share the same fate as intentionally learned List 1 items. Further support for the view arises from part-list reexposure studies. In these studies, after learning of the two lists, a subset of the List 1 items was reexposed as part of a recognition test before all previously studied items were to be recalled on a final recall test. The results provided evidence that part-list reexposure eliminates the forgetting of the remaining items (Bjork et al. 1973; Goernert and Larson, 1994; Bjork and Bjork, 1996), which is consistent with the view that the inhibition operates on a list-level basis. More recently, however, the findings were challenged by results suggesting that part-list reexposure reinstates mainly reexposed items and not the entire List 1 episode (Basden et al., 2003).

A priori, one might like to assume that the presence of the forget cue in the list-method directed forgetting procedure is sufficient to create the forgetting of List 1 items. As the results from two lines of research show, however, this is not the case. First, it has been found that the presentation of the forget cue creates forgetting only if it is presented before List 2 encoding, but not if it is presented after the encoding (Bjork, 1970). Second, the effect of the forget cue arises only if there is additional List 2 encoding. That is, the forgetting of List 1 items disappeared if the forget cue was provided, but no additional List 2 learning took place (Gelfand and Bjork, 1985; Pastötler and Bäuml, in press). This finding indicates that the presence of the forget cue per se is not sufficient to create list-method directed forgetting. In particular, the result suggests that the inhibitory mechanism in this paradigm operates during List 2 encoding.

Accounts of directed forgetting are typically one-mechanism accounts according to which the same mechanism underlies the two effects of forgetting and enhancement. Although enhancement and forgetting in directed forgetting often go hand in hand, recently some exceptions to this rule have been observed, and forgetting has been found without enhancement (Conway et al., 2000; Sahakyan and Delaney, 2003, 2005; Zellner and Bäuml, 2006), and enhancement obtained without forgetting (Macrae et al., 1997; Benjamin, 2006). These dissociations suggest the action of two separate mechanisms, one mediating the forgetting and the other mediating the enhancement. Consequently, a two-mechanism account was suggested, according to which the forgetting is caused by some form of inhibition, whereas the enhancement results from a change in people's List 2 encoding with more elaborate encoding in the forget than in the remember condition (Sahakyan and Delaney, 2003).

At the core of list-method directed forgetting is the action of an inhibitory mechanism that induces effects on the irrelevant material by affecting the items' retrieval routes to their cue. Such inhibition should also trigger blocking. The difference in retrieval strength between inhibited List 1 items and noninhibited List 2 items should create biased retrieval competition, with relevant items being recalled prior to irrelevant items. Although there is evidence for the predicted recall order (Geiselman et al., 1983), to date such blocking effects have not been uncovered (Geiselman et al., 1983; Zellner and Bäuml, 2006).

#### *2.13.2.3.2 Item-method directed forgetting*

In list-method directed forgetting, relevant new material is encoded after irrelevant old information, initiating updating processes on the out-of-date information. However, relevant and irrelevant material may also be presented interspersed. In this case, different processing of the two types of information might be achieved by triggering inhibitory processes on each single irrelevant item. Whether such processes can affect later accessibility of the irrelevant information has been studied in item-method directed forgetting.

In item-method directed forgetting, participants study a list of items in which a cue to remember or forget the item follows presentation of each single item. Later, a memory test is conducted in which both to-be-remembered (TBR) and to-be-forgotten (TBF) items have to be recalled or recognized (Woodward and Bjork, 1971; see **Figure 2(a)** for a formally related paradigm). Performance for the relevant and irrelevant material is directly compared without reference to any additional baseline conditions (for a review, see MacLeod, 1998). Results from free-recall experiments typically reveal a difference in performance between TBR and TBF items, with better recall for TBR than TBF items, thus showing that the cuing is effective (Davis and Okada, 1971; Woodward and Bjork, 1971; Basden et al., 1993). Moreover, as is true in list-method directed forgetting, the effect is probably not a result of demand characteristics, because it does not disappear if money is offered for recall of the TBF items (MacLeod, 1999).

List-method directed forgetting is present in recall but is absent on recognition tests. In contrast, the difference between TBR and TBF items in item-method directed forgetting has been observed in both recall and recognition tests (Davis and Okada, 1971; MacLeod, 1989; Basden et al., 1993). Regarding the contribution of recollection and familiarity on recognition performance, the effect of the forget cue seems to reflect a difference in recollective processes rather than in familiarity. This is indicated because the difference in performance has been found to be present in remember judgments but not in know judgments (Gardiner et al., 1994; Basden and Basden, 1996). A different performance for TBR and TBF items was also found in implicit memory tasks (MacLeod, 1989; Basden and Basden, 1996), although the effect does not seem to be present in all types of tasks (MacLeod and Daniels, 2000).

The simplest view of these findings is a strengthening view according to which TBF and TBR items only differ in the degree to which the single items are rehearsed and strengthened in response to the respective cue (Bjork, 1972; Basden et al., 1993; see also MacLeod, 1998). Such an interpretation is consistent with the finding of differences between TBR and TBF items in most types of memory tests, including recognition and some implicit memory tasks. Following this view, the forget cue would not inhibit retrieval routes or the memory representation of the TBF items. Because of the induced difference in relative strength between the two types of items, the forget cue, however, might create some blocking at test, with early recall of (stronger) TBR items blocking access to the (weaker) TBF items. If true, item-method directed forgetting would be similar in character to what occurs in the list-strength effect (see section 2.13.2.1.1). Moreover, item-method directed forgetting would reflect an instructional variant of the list-strength effect.

Our knowledge of the role of inhibitory processes in the list-strength effect is largely based on comparisons between performance in the mixed-list condition and performance in two pure-list conditions that are used as baseline conditions (see section 2.13.2.1.1). Item-method directed forgetting may also create a form of mixed list, consisting partly of the stronger TBR items and partly of the weaker TBF items. In this case, however, performance is typically not compared with pure-list baseline conditions. Such comparisons would strongly improve the database to derive a more clearcut indication of the role of inhibitory processes in item-method directed forgetting. Until then, it seems that inhibition may play a role in item-method directed forgetting experiments, but that this effect is restricted to blocking and is not caused by direct effects on the items' retrieval routes or the items' memory representation.

#### *2.13.2.3.3 Summary*

The presence of a forget cue can induce forgetting of irrelevant material. Depending on whether the relevant material is presented subsequent to the irrelevant material (the list method) or relevant and irrelevant material are presented interspersed (the item method), different effects arise. In list-method directed forgetting, the effect of the forget cue is found in free-, and list-cued recall tests but not in recognition or implicit memory tasks. The effect is likely to be the result of some deactivation of the retrieval route between the TBF items and their cue. The representation of the TBF items itself, however, does not seem to be affected. In item-method directed forgetting, the effect of the forget cue can be found across a wide range of memory tests, including free recall and recognition tasks. The results are largely consistent with a strengthening view, according to which the two cues lead to items of different memory strength because of selective rehearsal. While this difference in relative strength may create blocking in recall tests, no clearcut evidence for other forms of inhibitory processes, such as direct effects on retrieval routes or item representations, has yet been identified. It thus seems that quite different mechanisms are at work in list-method and item-method directed forgetting.

### 2.13.2.4 Think/No-Think Impairment

In item-method directed forgetting, a forget cue is provided after presentation of an item to inform participants that the item is irrelevant and will not be tested later. As summarized in the previous section, the results from a number of studies have shown that, in response to such a cue, rehearsal of an item can be stopped, thus demonstrating that forget cues at encoding can be effective. The question arises of whether a forget cue can not only stop rehearsal but may stop retrieval as well (Weiner and Reed, 1969). Evidence for this type of proposal arises from studies using the think/no-think paradigm.

The think/no-think paradigm is a memory adaptation of the go/no-go task, which is typically used to study control of prepotent motor responses. In the think/no-think paradigm, participants study weakly related word pairs (e.g., butter-opera) and are trained to answer with the appropriate associate (target) upon presentation of its counterpart (cue). After the training, participants engage in a think/no-think task. In each trial of the task, the cue word (butter) is provided and participants are required either to remember (think) or to actively suppress any thought (no-think) about its corresponding target (opera) and not let it enter consciousness. A large number of such trials is typically conducted. In a final cued-recall test, participants are then asked to recall the targets in response to the original stimulus cue, regardless of whether in the intermediate phase they were instructed to think about the item or to suppress it. As a variant of this testing procedure, a semantically related word (music) may be presented as cue rather than the original stimulus cue, thus permitting a test of cue-independent forgetting in this paradigm (Anderson and Green, 2001; **Figure 5**).

Results from several studies showed improved recall of think items and impaired recall of no-think items relative to baseline items, which were neither remembered nor suppressed in the intermediate think/no-think phase (Anderson and Green, 2001;

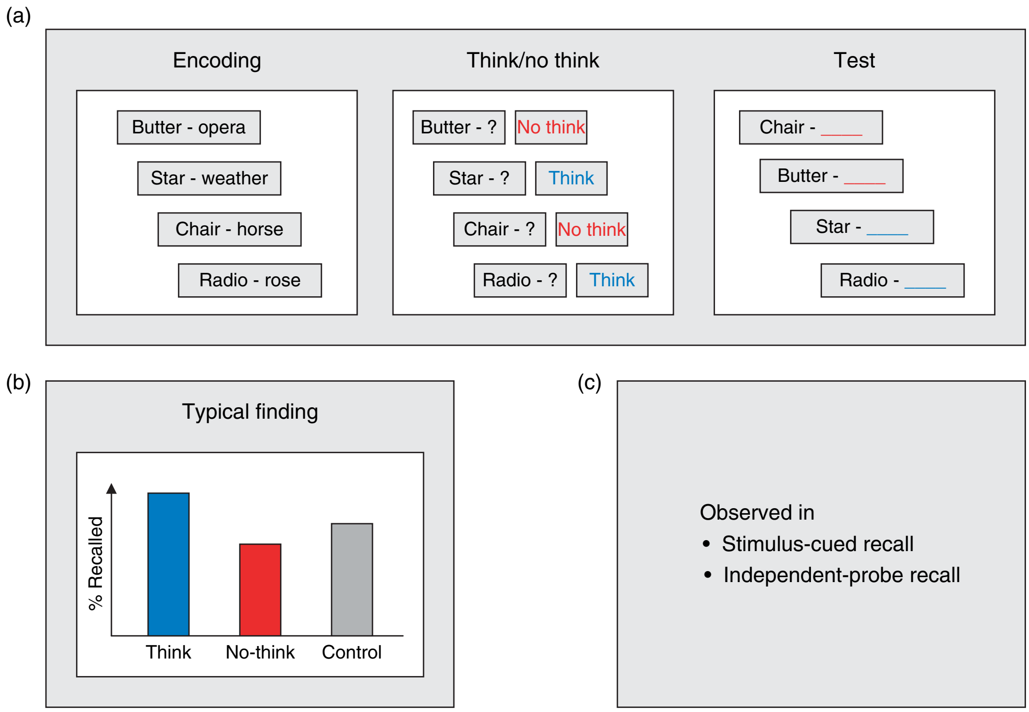

**Figure 5** Think/no-think impairment. (a) The experimental paradigm. Participants study weakly related cue–target pairs and are trained to answer with the target upon presentation of its cue. After the training, participants engage in the think/no-think task. In each trial of the task, they are provided with a cue word and are required to either remember (think) or actively suppress any thought (no-think) about its corresponding target. On a later test, all targets are tested given their associate as the retrieval cue. (b) The typical finding. Think items are recalled better and no-think items are recalled worse than control items, which were neither remembered nor suppressed in the intermediate think/no-think task. (c) Memory tests: Examples of memory tests in which think/no-think impairment has been observed.

Anderson et al., 2004; Hertel and Calcaterra, 2005; Depue et al., 2006). In particular, the effect did not only arise if at test the original stimulus cue was presented, but was also present if a semantically related independent probe was provided (Anderson and Green, 2001; Anderson et al., 2004). Again, the effect does not seem to be a result of demand characteristics, as the forgetting has been found to be still present if money was offered as a reward for each recalled no-think item (Anderson and Green, 2001).

The few studies that to date reported successful forgetting in the think/no-think paradigm indicate that the forgetting in this paradigm arises if the number of no-think trials is high (16 trials) but is not present if the number of such trials is relatively low (one or four trials). Moreover, even with a high number of no-think trials, the effects are typically small, although the forgetting can increase somewhat if emotional material rather than neutral material is employed in the experiment (Depue et al., 2006). Researchers also failed to replicate the finding, despite several careful attempts to do so (Bulevich et al., in press), which suggests that the forgetting in this paradigm may not be very reliable.

Anderson and Green (2001) argued that the forgetting in the think/no-think paradigm is caused by inhibition. According to this account, during no-think trials, the memory representation of the targets is reduced so that accessibility is lowered regardless of which cue is provided and which retrieval route is used. In consequence, the forgetting should be observed across a wide range of memory tests, including independent-probe tasks, recognition tasks, or implicit memory tasks. Although there is evidence for cue independence in this paradigm (Anderson and Green, 2001; Anderson et al., 2004; but see Bulevich et al., in press, for failures to get the effect), no studies have yet been reported examining think/no-think impairment in recognition or implicit memory tests. Using imaging techniques, Anderson et al. (2004) examined neural correlates of the forgetting during no-think trials. They identified an interaction between prefrontal cortex and hippocampus, which was related to the forgetting of no-think items on the final recall test and was interpreted as evidence for inhibition. However, because there was also increased activity in other brain regions during no-think trials, it was argued that the forgetting might also be a result of subjects' attempts to think about something else rather than to inhibition (Hayne et al., 2006).

Indeed, rather than reflecting item suppression, the forgetting in this paradigm might also be caused by some form of inaccessibility created through associative interference. This might occur if, for instance, participants adopt a strategy of thinking about other, distracting words during no-think trials, thereby building new associations to the cue and increasing (retroactive) interference (Hertel and Calcaterra, 2005; Bulevich et al., in press). Because interference effects are typically restricted to situations in which the original cue is provided at test, such noninhibitory accounts of the phenomenon would not predict forgetting when independent probes are provided. The reported failure to find forgetting when independent probes are provided as cues (Bulevich et al., in press) thus supports the associative interference account of the phenomenon. In contrast, Anderson and colleagues' reports of cue independence (Anderson and Green, 2001; Anderson et al., 2004) challenge the interference account and support the suppression account. Obviously, further research is warranted.

The results from the think/no-think paradigm suggest that cues to stop retrieval of an item can cause later forgetting of the item. Item-method directed forgetting shows that cues to stop rehearsal of an item can also be effective. While these lines of evidence converge on the view that cues to stop the processing of items, be it at encoding or retrieval, can be successful, there is evidence that the two forms of stopping are nonetheless different. First, stopping rehearsal seems to be relatively easy for participants, typically inducing strong performance differences between TBR and TBF items. In contrast, stopping retrieval seems to be hard, and participants may even fail to show forgetting in this task. Second, the stopping of rehearsal does not seem to be inhibitory in the sense that a TBF item is inhibited in its representation or its retrieval routes. In contrast, the stopping of retrieval has been argued to induce deactivation of the item representation, so that the item becomes unavailable. If true, stopping rehearsal and stopping retrieval may be quite different things in memory.

### 2.13.2.5 Part-List Cuing Impairment

What is common to the paradigms described earlier (in the subsections in 2.13.2 to this point) is that inhibitory mechanisms operate to emphasize accessibility of relevant material at the expense of that for irrelevant information. Inhibition thus seems to serve an adaptive goal and to support memory to function efficiently. On the other hand, there is evidence that inhibition is not always adaptive and goal directed. This is indicated by an example from the memory literature in which inhibitory processes emphasize accessibility of irrelevant material at the expense of that for relevant information. The example is part-list cuing impairment.

#### *2.13.2.5.1 Beneficial and detrimental effects of cuing*

There is broad agreement in the literature that the presence of adequate retrieval cues is crucial for successful episodic memory (e.g., Tulving, 1974). Consistently, cuing has been found to facilitate recall in many situations. For instance, if a categorized list with several items from each category is presented to participants and, at test, the category names or one item from each category are provided as retrieval cues, then such cuing typically enhances recall compared to unaided free recall (Tulving and Pearlstone, 1966; Tulving and Psotka, 1971).

Cuing, however, is not always facilitatory and can even be detrimental. If participants learn a categorized list and, at test, receive several items from each category as retrieval cues, then such part-list cuing often reduces recall performance for the remaining items, compared with the condition in which just one category exemplar is provided as a retrieval cue (Slamecka, 1968; Roediger, 1973; for reviews, see Nickerson, 1984, or Roediger and Neely, 1982). In general, if more part-list cues are provided than necessary to remind participants of the various categories, or subjective units, cuing can be detrimental (Basden and Basden, 1995).

Prior work assumed that part-list cuing impairment is caused by blocking (Roediger, 1973; Rundus, 1973). The idea was that reexposure of items as cues strengthens these items' representation. During attempts to recall the noncue items at test, this strengthening of the cue items then should lead participants to covertly retrieve cue items before noncue items and thus block recall of the noncues. Part-list cuing, therefore, should mimic the effects of relearning, in which reexposure has been shown to block recall of the target material (see section 2.13.2.1.2).

Prior work demonstrated that the detrimental effects of relearning disappear once item-specific probes, such as the targets' unique initial letters, are provided to aid recall of the items. Thus, if part-list cuing impairment, like the detrimental effects of relearning, was caused by blocking, then part-list cuing impairment should also be absent if item-specific probes were provided. The issue was directly addressed in an experiment by Bäuml and Aslan (2004). Participants learned category exemplars consisting of target and nontarget items. In a subsequent phase, the nontarget items were reexposed, either for relearning (i.e., for a second study trial) or for use as retrieval cues at test. This reexposure occurred immediately before test, mimicking the typical part-list cuing procedure, or separated from test by a distractor task, mimicking typical part-list relearning. At test, the category-plus-first-letter cues of the target items were presented, and participants were instructed to recall the target items.

As expected from the relearning literature, part-list relearning had no detrimental effect on the target material. In contrast, part-list cuing had a detrimental effect. This held true both when the reexposure occurred immediately before test and when reexposure was separated from test by a distractor task. This finding indicates that part-list cuing differs from relearning and that its detrimental effects are not caused by blocking. In particular, it shows that part-list cuing impairment reflects an instructional effect. Reexposure induces forgetting when participants are oriented to use the reexposed items as retrieval cues (part-list cuing) but does not induce forgetting when the reexposed items are presented for an additional study trial (part-list relearning).

Results from recognition studies support the view that part-list cuing differs from relearning and other strengthening effects. Indeed, while strength-induced forgetting is typically absent in recognition tests, reliable part-list cuing impairment was found when memory for the noncues was assessed by means of a recognition task (Todres and Watkins, 1981). Part-list cuing impairment also arose in speeded recognition (Neely et al., 1983; Oswald et al., 2006). Because recognition performance is assumed to rely more on familiarity than recollection when participants are required to make recognition decisions very quickly (e.g., Yonelinas, 2002), this finding suggests that part-list cuing does not only affect recollective processes but affects the familiarity of the noncue items as well.

There is evidence that part-list cuing impairment is also present in recall tasks that employ independent probes (see section 2.13.2.6.1). Aslan et al. (2007a) reported a repeated-testing experiment in which, in the first test, participants were provided with part-list cues and were asked to recall half of the target items when cued by the items' unique initial letters. After a delay, a second test was conducted in which no part-list cues were provided and participants were asked to recall the remaining targets by means of independent probes, that is, probes that were not used in a previous phase of the experiment. Part-list cuing impairment was present in both tests, indicating that independent probes do not eliminate the forgetting.

The results from all these studies are consistent with an inhibitory view of part-list cuing impairment according to which part-list cuing triggers inhibitory processes that directly affect the item representation of the noncues. In this sense, the effect may mimic the effect of retrieval practice in retrieval-induced forgetting (see section 2.13.2.2). Indeed, several studies compared the detrimental effects of retrieval practice and part-list cuing directly within a single experiment (Bäuml and Kuhbandner, 2003; Bäuml and Aslan, 2004; Zellner and Bäuml, 2005). In all these cases, the same qualitative and quantitative effects arose. These findings agree with the view that part-list cuing leads to instructed covert retrieval of cue items and causes inhibition of noncue items very similar to how overt retrieval in retrieval-induced forgetting inhibits nonretrieved items (Bäuml and Aslan, 2004).

Retrieval-induced forgetting has been shown to be lasting and to still be present when item-specific probes are provided (see section 2.13.2.6.1). Consistent with the inhibitory view of part-list cuing impairment, part-list cuing impairment can also persist, even with item-specific probes (Bäuml et al., 2002; Bäuml and Aslan, 2004, 2006). On the other hand, there are demonstrations that, under certain conditions, the cuing effect can disappear with a delay (Basden and Basden, 1995; Bäuml and Aslan, 2006) and can be absent in the presence of item-specific probes (Aslan and Bäuml, in press). Bäuml and Aslan (2006) identified associative relations at encoding as a crucial factor in part-list cuing impairment. Data suggest that the detrimental effect of part-list cues is mediated by inhibition in situations with a relatively low level of interitem associations and is mediated by noninhibitory mechanisms in situations with a relatively high level of interitem associations. Thus, apparently more than one mechanism is involved in this form of forgetting.

#### *2.13.2.5.2 Summary*

Providing a subset of studied material as retrieval cues for recall of the remainder often does not enhance but rather reduces accessibility of relevant targets. Such part-list cuing impairment reflects an instructional effect, with reexposure of items being detrimental only if participants are oriented to use the items as retrieval cues. Part-list cuing differs from part-list relearning and, in many situations, is the result of the action of an inhibitory mechanism that affects the noncue items' representation directly. Part-list cuing impairment thus mirrors retrieval-induced forgetting, in which retrieval practice affects the representation of the nonretrieved items. In contrast to retrieval-induced forgetting, however, part-list cuing is not adaptive or goal directed but, rather, provides an example in which inhibitory processes can impair access to relevant information rather than enhance it.

### 2.13.2.6 Developmental Trajectory of Inhibitory Processes

The role of inhibition in cognition is of central importance in the literature on cognitive development. This stems in part from findings reporting poor performance of young children and older adults in a number of inhibition tasks (Simpson and Foster, 1986; Tipper et al., 1989; Hartman and Hasher, 1991; Hasher et al., 1997). In particular, it is attributable to the hypothesis that young children and older adults suffer from a general deficit in inhibitory function (Hasher and Zacks, 1988; Bjorklund and Harnishfeger, 1990). Such a general deficit in inhibitory function might also apply to memory and be at the heart of the reduced memory performance of young children and older adults. It thus is important to examine the performance of young children and older adults in the inhibitory paradigms addressed earlier (in the subsections in 2.13.2 to this point).

The hypothesis of a general inhibitory deficit in young children and older adults indicates that the two age groups show problems across the whole range of inhibitory paradigms reviewed above. This holds while the results reported in the subsections in 2.13.2 to this point suggest the action of quite different inhibitory mechanisms in the different paradigms. Knowledge on the developmental trajectory in the single paradigms would improve our understanding of memory development and would also improve our understanding of the development of cognitive inhibition in general. In recent years, a number of results emerged regarding young children's and older adults' retrieval-induced forgetting, directed forgetting, and part-list cuing impairment. These results are reviewed in the next sections.

#### *2.13.2.6.1 Retrieval-induced forgetting*

In children, retrieval-induced forgetting has been studied using both cued recall and recognition tasks at test. Zellner and Bäuml (2005) reported two experiments using verbal categorized lists and category-cued recall tasks at test. First graders, second graders, fourth graders, and young adults were tested. All four groups of participants showed the standard pattern of retrieval-induced forgetting with improved recall of practiced items and impaired recall of unpracticed items. In particular, there were no differences in the amount of forgetting across participant groups, suggesting that the inhibition was effective in young children (**Figure 6(a)**).

Using pictorial material, Ford et al. (2004) examined retrieval-induced forgetting in 7-year-olds by means of a yes/no recognition task in the practice phase and a category-cued recall test and a recognition test in the final test phase. In both cases, robust retrieval-induced forgetting was found. Furthermore, the magnitude of the effect did not differ between children and young adults. Analogous results were reported by Lechuga et al. (2006), who examined retrieval-induced forgetting in 8- and 12-year-old children. Related results were obtained in studies using the selective postevent review (questioning) procedure with 5- and 9-year-olds (Conroy and Salmon, 2005) and 5- to 6-year-olds (Williams et al., 2002). Review of some events impaired memory for nonreviewed events with comparable impairment in all age groups.

Only very few studies exist to date in which retrieval-induced forgetting was studied in older adults. In a nondevelopmental study, Moulin et al. (2002) found retrieval-induced forgetting in Alzheimer disease patients and healthy age-matched older adults in both a standard category-cued recall and a category generation task. While this study demonstrated reliable forgetting in older adults, it left open the question of whether the effect differs quantitatively from that in younger adults. Aslan et al. (2007b) examined retrieval-induced forgetting in younger and older adults and found equivalent amounts of

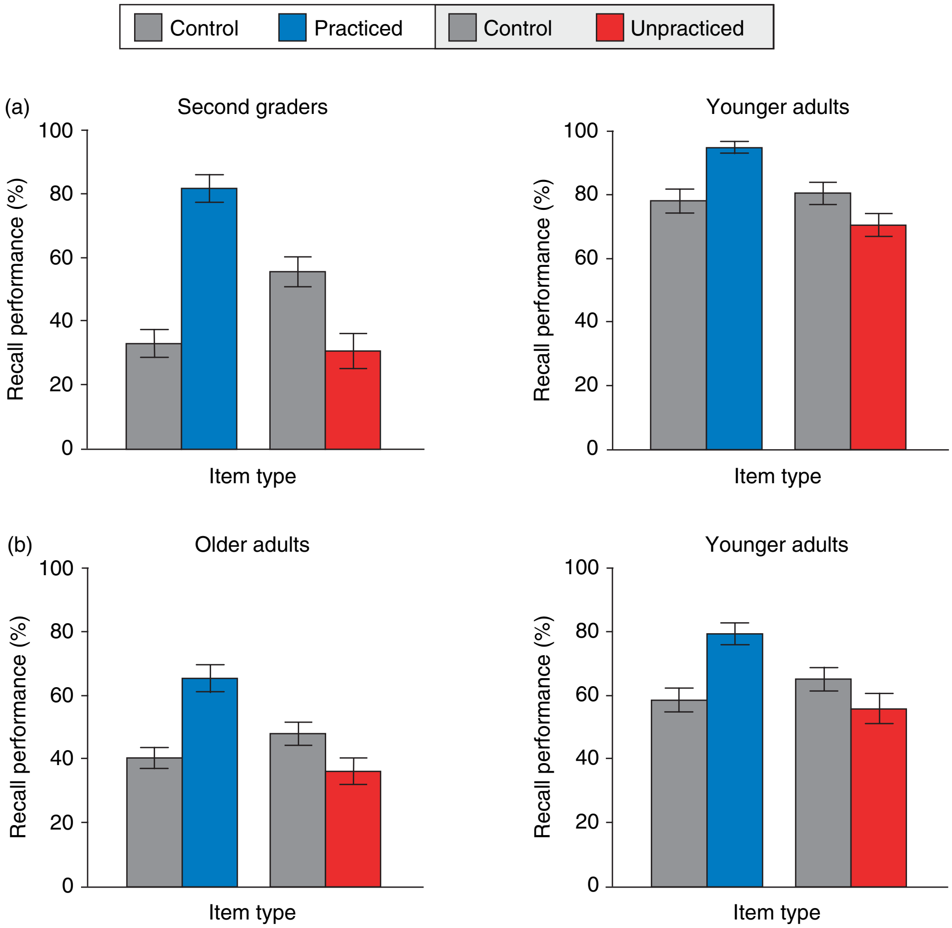

**Figure 6** Retrieval-induced forgetting in young children and older adults. (a) Recall percentage (and standard error) of retrieval-practiced and not-retrieval-practiced items and of their (separate) control items in second graders and younger adults. For both participant groups, the data show beneficial effects of retrieval practice on practiced items and detrimental effects of retrieval practice on unpracticed items. From Zellner M and Bäuml K-H (2005) Intact retrieval inhibition in children's episodic recall. *Mem. Cogn.* 33: 396–404. Psychonomic Society, Inc., Experiment 1. Adapted with permission. (b) Recall percentage (and standard error) of retrieval-practiced and not-retrieval-practiced items and of their (separate) control items in younger and older adults. For both participant groups, the data show beneficial effects of retrieval practice on practiced items and detrimental effects of retrieval practice on unpracticed items. From Aslan A, Bäuml K-H, and Pastötter B (2007) No inhibitory deficit in older adults' episodic memory. *Psychol. Sci.* 18: 111–115. Blackwell Publishing, Experiment 1. Adapted with permission.

forgetting in the two age groups. This result held both when category names and when independent probes were provided as retrieval cues, suggesting that, in both age groups, the inhibition affects the items' memory representation itself (**Figure 6(b)**). Related results were again obtained when using the selective postevent review procedure (Koutstaal et al., 1999).

Thus, retrieval-induced forgetting seems to be present over most of the lifespan and to differ hardly, if at all, between young children, younger adults, and older adults. In particular, the results suggest that, in all these age groups, the effect is caused by the same inhibitory mechanism, which affects the nonretrieved items' representation itself. Thus, no evidence for an inhibitory deficit in young children or older adults arises in this type of task.

### *2.13.2.6.2 Directed forgetting*

1. List-method directed forgetting

A number of studies examined list-method directed forgetting in young children (e.g., Bray et al., 1983; Harnishfeger and Pope, 1996). The results from these studies suggest that young children show problems in this type of task. In the study by Harnishfeger and Pope (1996), for instance, first, third, and fifth graders and young adults were compared. First and third graders failed to show directed forgetting and showed hardly any effect of the forget cue at all. Normal directed-forgetting performance, however, was present from fifth grade on. The inhibition mechanism apparently develops over the elementary school years (Figure 7(a)).

There are three published studies to date that have examined list-method directed forgetting in older adults. In the first study, Zacks et al. (1996) used a variant of the task in which several short lists had to be studied and recall performance was measured cumulatively after presentation of all lists. A greater amount of forgetting was found for younger than for older adults. The results, however, were affected by floor effects. In a second study, Sego et al. (2006) followed previous work by Geiselman et al. (1983) and let younger and older adults alternately learn items intentionally and incidentally. For both types of items, largely identical forgetting was found in the two age groups. Zellner and Bäuml (2006) compared younger and older adults' directed forgetting in three experiments, in which the forget cue was varied within and between participants, the two lists were unrelated or related to each other, and recall of the lists was required simultaneously or successively. No age-related difference in directed forgetting performance emerged in any of the three experiments (Figure 7(b)).

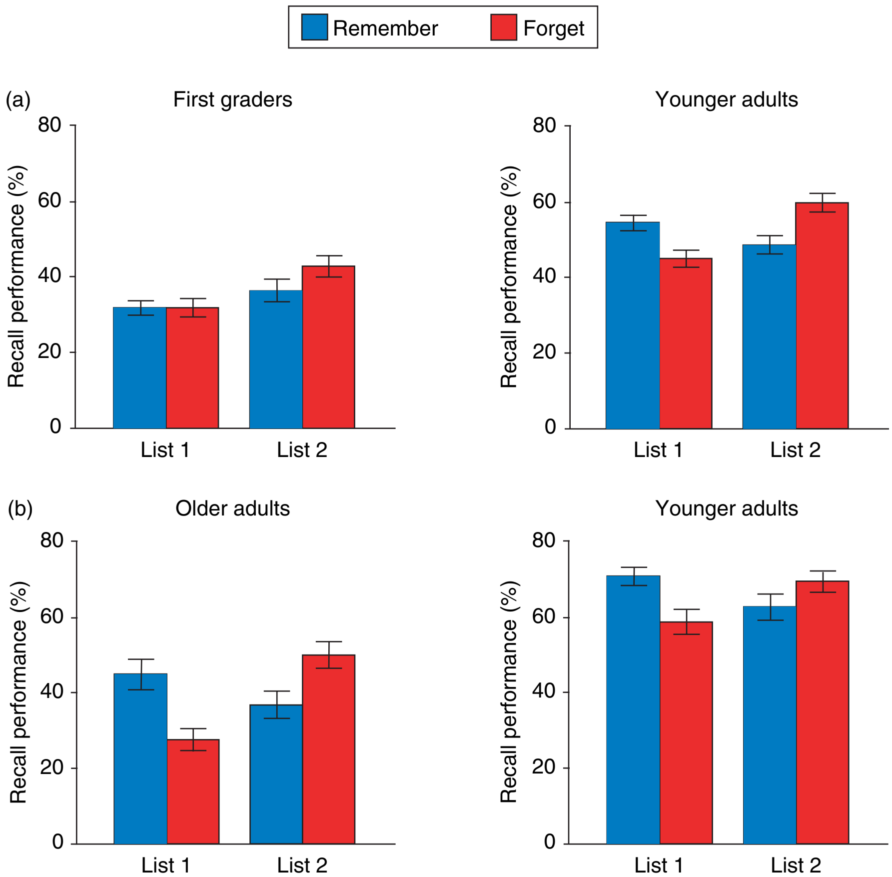

**Figure 7** List-method directed forgetting in young children and older adults. (a) Recall percentage (and standard error) of List 1 and List 2 items as a function of whether a remember or forget cue was provided between learning of the two lists. While younger adults show the standard pattern of directed forgetting, for young children no reliable effect of the forget cue arises. This holds for both List 1 and List 2 items (K.-H. Bäuml, M. Zellner, and A. Aslan, unpublished data). (b) Recall percentage (and standard error) of List 1 and List 2 items as a function of whether a remember or forget cue was provided between learning of the two lists. Both younger adults and older adults show the standard pattern of List-method directed forgetting. From Zellner M and Bäuml K-H (2006) Inhibitory deficits in older adults – List-method directed forgetting revisited, *J. Exp. Psychol. Learn. Mem. Cogn.* 32: 290–300, American Psychological Association, Experiment 3. Adapted with permission.

Thus, while young children fail to show list-method directed forgetting, older adults seem to show intact forgetting. This result suggests that the underlying inhibitory mechanism develops in later childhood. Once developed, however, it remains intact with increasing age. The inhibitory mechanism underlying list-method directed forgetting thus differs in its developmental trajectory from that underlying retrieval-induced forgetting.

2. Item-method directed forgetting

Few studies have examined item-method directed forgetting in young children. Posnansky (1976) found better recall of TBR items than TBF items in both third and seventh graders, with no difference in the effect of the forget cue between the two age groups. Foster and Gavelek (1983) reported that even first graders recalled more TBR than TBF items, although the effect of the forget cue was smaller for first than for fifth graders. Regarding older adults' directed forgetting, several studies found a reliable difference between TBR and TBF items with increasing age. The difference, however, was smaller in older adults than in younger adults (Zacks et al., 1996; Earles and Kersten, 2002; Dulaney et al., 2004), which indicates that older adults show deficient directed forgetting in this type of task.

Together the results suggest that both young children and older adults show deficits in item-method directed forgetting. Following the strengthening view of item-method directed forgetting, these findings, however, do not imply inhibitory deficits in young children and older adults but, rather, may indicate differences in the degree to which the two age groups are able to strengthen relevant material.

#### 2.13.2.6.3 Part-list cuing impairment

There seems to be only one study in the literature that examined part-list cuing impairment in young children. Zellner and Bäuml (2005) examined the detrimental effect of part-list cues in first graders, fourth graders, and young adults. All three groups showed reliable part-list cuing impairment with no difference in amount of forgetting across the three age groups. Moreover, in this experiment, part-list cuing impairment was directly compared with retrieval-induced forgetting. None of the three age groups showed any reliable difference between the detrimental effect of retrieval practice and the detrimental effect of part-list cuing.

In older adults, Marsh et al. (2004) found robust part-list cuing impairment in both younger and older adults across three experiments. If anything, the older adults showed stronger detrimental effects than the young adults and were disproportionately slow in the presence of part-list cues. This result suggests that part-list cuing impairment is not reduced in older adults. Part-list cuing impairment, like retrieval-induced forgetting, thus may be intact across most of the lifespan.

#### 2.13.2.6.4 Summary

To date, relatively few studies have addressed the development of inhibition in human memory. From these studies a fair amount of knowledge has been gained regarding the development of inhibitory mechanisms as they occur in retrieval-induced forgetting, directed forgetting, and part-list cuing impairment. Unfortunately, there are no published studies to date in which the development of inhibitory processes involved in strength-induced forgetting and think/no-think impairment has been addressed, so that the current picture on the development of inhibition in memory is only fragmentary.

Still, current results clearly challenge the hypothesis of a general inhibitory deficit in young children and older adults by showing that both age groups show intact inhibition in some memory tasks. It thus seems that the picture of a general inhibitory deficit needs to be updated in favor of the picture of task-dependent inhibitory function. Specifying the exact nature of the inhibitory mechanisms that are intact in young children and older adults and of those that are deficient is a high priority for future research on the development of inhibitory function.

## 2.13.3 Conclusions

In the introduction, three inhibitory mechanisms were suggested to reduce accessibility of irrelevant memories: blocking, route deactivation, and item suppression (**Figure 1**). These mechanisms differ in whether they affect memories indirectly (blocking) or directly (route deactivation, item suppression), and whether they affect memories' retrieval routes (route deactivation) or their representation itself (item suppression). As a result, the three mechanisms also differ in the range of memory tests in which the effects of inhibition can be observed. While effects of blocking manifest themselves mainly in free-recall tests and effects of route deactivation in free- and cued-recall tests, effects of item suppression are present over a wide range of memory tasks, including recognition and independent-probe tests.

The results on the experimental paradigms reviewed in section 2.13.2 suggest that each of the three mechanisms plays a role in reducing irrelevant memories' accessibility. However, the results also suggest that none of the three mechanisms is responsible for the effects in all the paradigms. Rather, it seems that a multiplicity of mechanisms are at work to induce inaccessibility of irrelevant material across a wide range of situations. In strength-induced forgetting, for instance, inhibition seems to be realized by means of blocking, in which early recall of strengthened (relevant) material hinders subsequent recall of nonstrengthened (irrelevant) material. Consistently, forgetting is present mainly in free recall tasks and is absent in recognition tasks. Strength-induced forgetting thus is mediated by a relatively weak form of inhibition that affects the irrelevant material only indirectly. The same mechanism is likely to be involved in item-method directed forgetting, at least when following the strengthening view of this form of directed forgetting.

In list-method directed forgetting, a stronger form of inhibition is at work in which the retrieval routes between the irrelevant material and its cue(s) are affected directly. Accordingly, forgetting in this paradigm can be observed in free and cued recall tasks while no effects arise in recognition tests, which rely mainly on the items' representation itself. In strength-induced forgetting, the effects on the relevant and irrelevant material's accessibility are mediated by the same mechanism. In list-method directed forgetting, there is evidence for two separate processes, one process reducing accessibility of the irrelevant material and the other process enhancing accessibility of the relevant information. When operating in concert, these two processes can create very effective memory updating.

In retrieval-induced forgetting, inhibition is realized by suppressing the representation of the inhibited items themselves, thus making retrieval less effective regardless of which retrieval cue is employed. Consistent with this strong form of inhibition, the forgetting in this paradigm can be found across a wide range of memory tests, including recognition and independent probe tests. As in list-method directed forgetting, there is evidence for the action of two processes, a forgetting mechanism directed on the irrelevant material and an enhancement mechanism directed on the relevant information. Together, they induce a strong difference in accessibility between relevant and irrelevant material and thus induce effective memory updating. There is also evidence that the same inhibitory mechanism underlies the forgetting in the think/no-think paradigm and in part-list cuing, because in both cases the forgetting has been found not only to arise in free- and cued-recall tasks but to generalize to other tasks as well.

The evidence that different mechanisms mediate inhibition in the single paradigms motivates a taxonomy of the paradigms, in which the paradigms are partitioned into three subsets, one in which the forgetting is caused by blocking (strength-induced forgetting, possibly item-method directed forgetting), one in which the forgetting is caused by route deactivation (list-method directed forgetting), and one in which the forgetting is caused by item suppression (retrieval-induced forgetting, think/no-think impairment, and part-list cuing impairment; **Figure 8**). Although currently there is only restricted knowledge regarding the developmental aspects of inhibition in the single paradigms, the suggested taxonomy is at least consistent with current knowledge. Current knowledge suggests comparable developmental trajectories for retrieval-induced forgetting and part-list cuing impairment and a different trajectory for list-method directed forgetting. Item suppression and route deactivation thus may follow different developmental paths.

Besides the differences in underlying mechanism, the single paradigms also differ regarding the stage at which the inhibition takes place. In list-method directed forgetting, inhibition operates before the test during the encoding of the new relevant material. In retrieval-induced forgetting and think/no-think impairment, inhibition also operates before the test, either while selectively retrieving relevant information (retrieval-induced forgetting) or while trying to stop retrieval of irrelevant information (think/no-think impairment). In strength-induced forgetting, item-method directed forgetting, and part-list cuing impairment, the inhibition operates at test, either by blocking recall of irrelevant material (strength-induced forgetting, item-method directed forgetting) or by suppressing relevant material through covert retrieval of cue items (part-list cuing impairment).

It is the general goal of inhibition in memory to enhance accessibility of relevant material at the expense of the accessibility of the irrelevant material. This goal is realized very differently in different situations. The differences are reflected in the

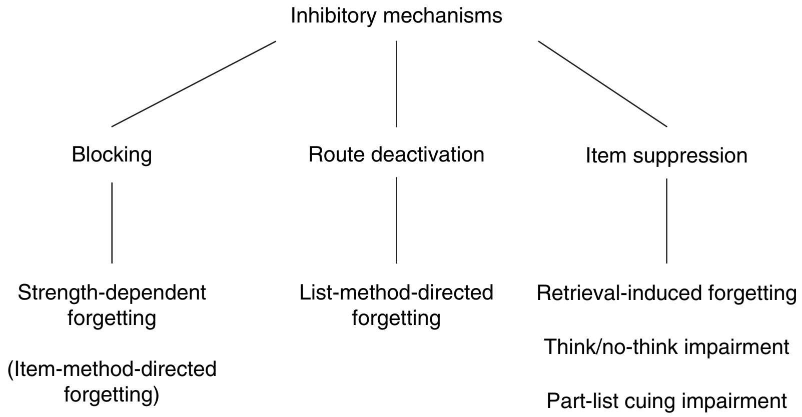

**Figure 8** Taxonomy of inhibition paradigms. The taxonomy lists experimental paradigms in which some form of inhibitory mechanism is assumed to be crucially involved. The paradigms are partitioned according to which of the three mechanisms – blocking, route deactivation, and item suppression (**Figure 1**) – is supposed to mediate the inhibition.

diversity of mechanisms that mediate the effect in the single situations, and they are reflected in the varying stages at which the inhibition takes place. Together, the picture of a very flexible and goal-directed updating system arises, in which a multiplicity of inhibitory mechanisms operate at very different processing stages to overcome the problem of retrieval competition and interference and thus help memory function effectively. At the end of the nineteenth century, Ribot wrote that "Forgetfulness . . . is not a disease of memory, but a condition of its health and life" (Ribot, 1882: 61). The results reviewed in this chapter provide a vivid and detailed demonstration of the adequacy of this early view.

## Acknowledgments

This work was supported by a grant from the German Research Foundation (FOR 448). I thank A. Aslan, C. Kuhbander, B. Pastötter, B. Spitzer, and M. Wimber for their help in preparing the chapter.

# 2.14 False Memories

**E. J. Marsh, A. N. Eslick, and L. K. Fazio**, Duke University, Durham, NC, USA

Memory is impressive. People can recognize hundreds of pictures seen only once (Shepard, 1967) and recall hundreds of words in response to cues (Mäntylä, 1986). Memory's feats are not limited to short delays or to remembering simple materials in laboratory settings. People remember their high school classmates 15 years after graduation (Bahrick et al., 1975) and recall details about the German invasion of Denmark 50 years after they experienced it (Berntsen and Thomsen, 2005). This short list could easily be expanded.

And yet memory's failures can be equally impressive. For example, people's recognition memory for a penny is actually quite poor, even though they have likely handled hundreds (if not thousands) over the years (Nickerson and Adams, 1979). Similarly, the majority of people fail when asked to draw the layout of the number keys on a calculator, even though they could easily use such a device (Rinck, 1999). Memory failures are not limited to mundane objects, of course. Consider just a few examples: Parents misremember the way they raised their children (Robbins, 1963), eyewitness misidentifications occur (Wells et al., 2006), and people falsely remember being abducted by aliens (Clancy, 2005).

To understand human memory, we must understand memory's failures as well as its successes. What is more interesting than the fact that memory is fallible is that the errors are systematic. By systematic, we simply mean that the errors are not random. We understand something about the conditions under which errors are more or less likely; for example, delay is a manipulation that often increases memory errors. This systematicity occurs because errors are often byproducts of mechanisms that normally aid memory, meaning that memory errors can provide a window into the mechanisms of memory.

One of the classics in this tradition is Bartlett's 1932 study in which participants read and retold a Native American story entitled 'The War of the Ghosts.' When participants retold the story, they made systematic errors. They changed the unfamiliar Native American tale so that it made more sense to them and so that it fit better with their English culture. For example, in the retellings 'canoe' became 'boat' and the more supernatural parts of the story either disappeared or changed to be more consistent with a typical English story.

Bartlett concluded that our memories are reconstructive. We do not recall exactly what happened; rather, we reconstruct events using our knowledge, culture, and prior beliefs about what must have occurred. In other words, we use schemas to help reconstruct our memories. A schema is a knowledge structure that organizes what one knows and expects about some aspect of the world. Schemas are useful heuristics that allow us to fill in the gaps and to make predictions. Bartlett's participants possessed a schema about what happens in a typical story and they used this schema to reconstruct the atypical story that they had read.

Bartlett's ideas about reconstructive memory and the influence of one's prior knowledge have been modified only slightly through the years and are still thought to be the backbone of how our memory functions. Schemas have been repeatedly shown to have large effects on later memory. For example, consider a classic study in which participants read short passages, including one about an unruly child.

When told that the story was about Helen Keller, participants later falsely recognized sentences such as 'She was deaf, dumb, and blind.' When the protagonist was labeled as Carol Harris, however, participants rarely falsely recognized the same sentences (Dooling and Christiaansen, 1977). The familiar label presumably activated participants' prior knowledge of Helen Keller, which participants used to make sense of the passage and to fill in gaps in the story. One's schema of Helen Keller, for example, might include information about her childhood in Alabama and her disabilities, as well as how she blossomed into a successful speaker and writer with the help of her teacher Anne Sullivan. While this background knowledge is likely to aid comprehension of the passage, it also sets up the need to later discriminate between what was read in the passage versus what was inferred.

Schemas provide one example of a memory mechanism that can both help and hurt memory. Most of the time, schemas support accurate memory; however, in some instances (such as the Helen Keller example), they can lead us astray. In this chapter, we will consider several different memory mechanisms that, like schemas, can sometimes lead our memories astray. We will focus on memory errors that meet Roediger's (1996) definition of memory illusions. Specifically, the focus will be on "cases in which a rememberer's report of a past event seriously deviates from the event's actual occurrence" (Roediger, 1996: 76). We will place a particular emphasis on memory errors that are made with high confidence, are labeled as remembered, or otherwise appear phenomenologically real. To preview a few of the vivid memory errors we will discuss: they include high-confidence errors in eyewitness testimony, never-presented words 'remembered' as spoken by a specific person, and ease of processing mistaken for fame. In each case, we will describe a prototypical experiment and the results and discuss possible underlying mechanisms.

## 2.14.1 False Memory for Words: The Deese-Roediger-McDermott Paradigm

As already described, Bartlett emphasized the use of meaningful materials when examining reconstructive memory, to avoid studying memory that was "primarily or literally reduplicative, or reproductive ... I discarded nonsense material because, among other difficulties, its use almost always weights the evidence in favor of mere rote recapitulation, and for the most part I used exactly the type of material that we have to deal with in daily life" (Bartlett, 1932: 204). Consistent with Bartlett's ideas, most of the studies we will describe in this chapter involve remembering videos, stories, slide shows, or personal memories. While words and nonsense syllables were frequently used in verbal learning experiments, Bartlett did not believe they would be useful in studying reconstructive memory since they did not encourage elaboration nor the use of schemas.

However, words have many properties that make them handy tools for the experimental psychologist. Tulving (1983) has made this argument eloquently: "words to the memory researcher are what fruit flies are to the geneticist: a convenient medium through which the phenomena and processes of interest can be explored and elucidated... words are of no more intrinsic interest to the student of memory than *Drosophila* are to a scientist probing the mechanisms of heredity" (Tulving, 1983: 146). Tulving goes on to point out that words have well-defined boundaries and are easily perceived, and that memories for words can easily be checked for accuracy. The point is that using word stimuli to study false memories would be very useful, if word stimuli could be selected that would encourage elaboration and the use of schemas. The argument is that the Deese-Roediger-McDermott (DRM) stimuli fit these requirements, and allow a simple and robust paradigm for studying false memories.

In a typical DRM experiment, participants learn lists of words, each related to a central nonpresented word, the critical lure. For example, participants hear or see 'nurse, sick, lawyer, medicine, health, hospital, dentist, physician, ill, patient, office, stethoscope, surgeon, clinic, cure.' Even though the critical lure 'doctor' was never presented, subjects are likely to include it when recalling the list items. They are also likely to incorrectly call it 'old' on a recognition memory test. The DRM paradigm appeals to experimenters because of the incredibly high rates of false memories observed in both free recall and on recognition measures. For example, in one of Roediger and McDermott's (1995) experiments, participants recalled the critical lures 55% of the time, a rate similar to recall of studied items presented in the middle of the list! False recognition was also very robust; Roediger and McDermott observed a false alarm rate of 76.5% for critical lures as compared to a hit rate of 72% for studied items. Similarly high levels of false memories have been observed in dozens, likely hundreds, of experiments using this methodology.

Not only are DRM errors frequent, they are also phenomenologically compelling to the rememberer. Roediger and McDermott asked participants to label each word called 'old' as either 'remembered' or 'known.' 'Remembering' was defined as vividly recollecting details associated with a word's presentation (e.g., where it occurred on the list, what it sounded like, what one was thinking during its presentation), whereas 'knowing' meant simply knowing a word had been presented even though one could not recall the details of its presentation. As shown in **Figure 1**, the proportion of remember and know responses was very similar for the studied words and for the critical lures (Roediger and McDermott, 1995). That is, people were just as likely to claim they remembered the critical nonpresented lures as the studied words. People will also describe their false memories in some detail, attributing them to locations in the study list (Read, 1996) and to a particular speaker (Payne et al., 1996). They are also willing to estimate how frequently they rehearsed each false memory (Brown et al., 2000). In general, the false memory effect is very robust, persisting even when participants have been forewarned about the nature of the illusion (McDermott and Roediger, 1998).

Given the strength of the illusion, it is intriguing that not all lists of related words yield false memories (Deese, 1959; Gallo and Roediger, 2002). Listening to 'sour, candy, sugar, bitter, good, taste, tooth, nice, honey, soda, chocolate, heart, cake, tart, pie' is likely to yield a false memory for 'sweet,' whereas listening

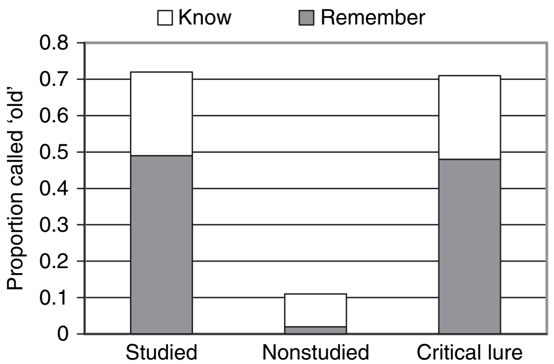

**Figure 1** Recognition results for studied items and critical lures. Data from Roediger HL III and McDermott KB (1995) Creating false memories: Remembering words not presented in lists. *J. Exp. Psychol. Learn. Mem. Cogn.* 21: 803–814, Experiment 2.

to 'sweet, sour, taste, chocolate, rice, cold, lemon, angry, hard, mad, acid, almonds, herbs, grape, fruit' is very unlikely to yield a false memory for the critical lure 'bitter.' Both lists were constructed from the same free-association norms, but only one yields high levels of false memories. A key difference between the lists involves backward associative strength (BAS); this is a measure of how likely the list items are to elicit the critical item in a free association task. In other words, BAS measures how likely participants are to report the critical lure as the first word that comes to mind in response to list items. Participants are likely to respond 'sweet' but not 'bitter' in response to words like 'sugar, sour, taste,' meaning that BAS is very high for 'sweet' but very low for 'bitter.' This difference is crucial; BAS is a major predictor of false recall ($r = 0.73$, Roediger et al., 2001b).

In the activation monitoring framework's explanation of the DRM illusion, activation at encoding spreads through a preexisting semantic network of words, and the source of this activation is monitored at test. Hearing 'sour, candy, sugar' in the study list activates those nodes in the network. This activation spreads through the network (Collins and Loftus, 1975), activating related nodes. Because the critical lure is associated with so many study items (as indicated by its BAS value), it is activated from many different directions, leading to its heightened activation. If the participant fails to correctly monitor the source of that activation, a false memory will result.

According to the activation monitoring framework, manipulations that increase the amount of activation spreading to the critical lure should result in higher rates of false memories. Consistent with this, false memories increase as the study list increases in length, as longer lists mean that activation from a greater number of words spreads to the critical lure (Robinson and Roediger, 1997). Similarly, activation can spread from phonological associates. Listening to a list of words like 'bite, fight, rut, sprite, slight, rye' yields false memories for phonologically related nonpresented words such as 'right' (Sommers and Lewis, 1999). Intriguingly, lists that combine phonological and semantic associates (e.g., 'bed, rest, awake, tired, dream, scrub, weep, wane, keep') led to even higher rates of false memories than did purely semantic or purely phonological lists (Watson et al., 2003).

Activation alone cannot, however, explain all of the data. An interesting experiment on the effects of presentation rate highlights the need for both activation and monitoring components. McDermott and Watson (2001) presented DRM lists at five different presentation rates: 20, 250, 1000, 3000, and 5000 ms per word. As expected, veridical recall of list items increased with longer presentation rates. More interesting were the false recall data. When the presentation rate increased from 20 to 250 ms, false recall increased from 0.14 to 0.31. However, when the presentation rate was further increased, the rate of false memories decreased, from 0.22 at 1000 ms to 0.14 at 3000 or 5000 ms. The argument is that semantic activation is increasing as the presentation rate increases, hence the jump in false memories observed at 250 ms. However, with the longer presentation rates, participants encode more information about studied words, allowing them to invoke monitoring strategies during retrieval that help them to judge the source of the activation.

Monitoring is necessary to explain other DRM data, such as the finding that on average older adults remember fewer studied words but falsely remember just as many critical lures (or even more) as do college students (e.g., Balota et al., 1999). That is, because older adults have relatively preserved semantic memory, there should not be age differences in the activation of the critical lure. Rather, what is affected is the ability to monitor the source of activation, as older adults typically have difficulty on source-monitoring tasks (Hashtroudi et al., 1989). More direct support for the monitoring explanation comes from a study linking the age effect to problems with frontal functioning (Butler et al., 2004). In this study, older adults were classified as high versus low functioning on tasks known to require frontal functioning (e.g., the Wisconsin card sort task). Importantly, older adults who scored high on frontal tasks performed similarly to young adults in a typical DRM paradigm. Only older adults who scored poorly on frontal tasks showed reduced true recall and increased false recall. Because frontal areas are often implicated in monitoring tasks (e.g., Raz, 2000), these data suggest it is monitoring ability, not age, that is critical for avoiding false memories.

Even young adults can be placed in situations that make monitoring difficult, forcing them to rely on activation. Consider Benjamin's (2001) study in which he repeatedly presented the DRM lists. Young adults were less likely to incorrectly endorse critical lures from lists presented three times, presumably because they were able to monitor the source of that activation. However, when participants were required to respond quickly at test, they falsely recognized more critical lures from the lists presented three times. Repeating the list presumably increased the activation of the critical lures. When time was plentiful during the recognition test, participants used monitoring processes to correctly attribute the source of the activation (and thus reduce, but not eliminate, the illusion). When retrieval time was short, monitoring was not possible, and the increased activation resulted in high false alarm rates (see also Marsh and Dolan, 2007).

The distinctiveness heuristic is one monitoring strategy that has been investigated in detail. Schacter and colleagues defined the distinctiveness heuristic as "a mode of responding based on participants' metamemorial awareness that true recognition of studied items should include recollection of distinctive details" (Schacter et al., 1999: 3). Anything that makes DRM stimuli more distinctive should increase participants' standards for what they consider to be old. Thus, picture lists yield lower rates of false memories than do word lists (Israel and Schacter, 1997), and pronouncing and hearing the words at study lowers the false alarm rate as compared to only hearing the words (Dodson and Schacter, 2001).

Activation monitoring is the preferred explanation of many researchers, but certainly not all. Other explanations share in common a mechanism for the lures being encoded, and then a monitoring function at test. For example, fuzzy trace theory (Brainerd and Reyna, 2002) proposes that both verbatim and gist traces are encoded for events. Verbatim traces reflect memories of individual events, while gist traces reflect the extraction of meaning across experienced events. During the presentation of a DRM list, verbatim traces would be encoded for the individual words, while at the same time the meaning of the entire list would be extracted and encoded into a gist memory. Later, retrieval of the gist trace could drive false memory effects.

We turn now from false memories of never-presented words to errors when remembering events such as crimes or traffic accidents. More important than the switch in what is being remembered, though, is that different memory mechanisms likely underlie the two types of errors.

## 2.14.2 Eyewitness Suggestibility: The Misinformation Paradigm

Psychologists have long been interested in the reliability of witnesses. Early in the twentieth century, researchers such as Hugo Münsterberg and William Stern were publishing on the unreliability of testimony. The major methodological breakthrough in this area, though, did not appear until the 1970s when Elizabeth Loftus published her seminal work. She developed the misinformation paradigm (also known as the post-event information paradigm) that involves a twist on the basic retroactive interference paradigms that were popular during the verbal learning era (McGeoch, 1932). In retroactive interference studies, researchers examine the effect of a second, interfering event on memory for an original event (as compared to a control group that was not exposed to the interference). The typical design is shown in the top part of **Table 1**. In verbal learning terms, all participants study paired associates A – B in the first phase of the experiment (e.g., Table – Radio). Next, participants in the experimental group learn A – D associations (e.g., Table – Pencil), whereas participants in the control group rest or learn C – D (e.g., Purse – Pencil). Finally, all participants are tested on A – B (e.g., Table – ?), and memory is poorer in the group that learned two different associations in response to A. What does this have to do with eyewitness memory? The bottom portion of **Table 1** shows the connection between the standard retroactive interference design and eyewitness memory. The witness views an event (A – B), such as a traffic accident (A) occurring near a stop sign (B). After the event, the police will repeatedly interview the witness, the newspaper will publish accounts of the crime, and the witness will talk about the event with other people. All these have the potential to provide interfering information. For example, the police might erroneously suggest that the accident (A) occurred near a yield sign (D) when really it occurred near a stop sign (B). Later, when the witness tries to remember the details of the original event (A – ?), he or she may recall the interfering misinformation instead of what was actually witnessed. In contrast, misinformation production would be low for subjects in a control condition who heard a neutral reference to a traffic sign.

One of the most classic laboratory demonstrations comes from Loftus et al. (1978; see also Loftus and Palmer, 1974). All participants viewed a slide show depicting a traffic accident; in the critical slide, a red Datsun was approaching an intersection with a traffic sign. One-half of participants saw a stop sign; the other participants saw exactly the same slide except that the intersection was marked with a yield sign. After seeing the slides, all participants answered a series of questions about the accident. Embedded in one of the questions was a reference to the traffic sign; half of participants were asked 'Did another car pass the red Datsun while it was stopped at the stop sign?' whereas the others answered 'Did another car pass the red Datsun while it was stopped at the yield sign?' Twenty minutes later, participants examined pairs of slides and determined which one had been presented in the original slide show. The critical pair required participants to pick between the Datsun at a stop sign versus a yield sign. When participants had answered the question containing misinformation, they selected the correct slide 41% of the time (below chance), as compared to 75% when the question had referred to the correct sign.

Numerous studies have since replicated the basic finding: Information presented after an event can change what the eyewitness remembers. The original event may take the form of a film, slide show, staged event, written story, or a real event. The misinformation may be delivered in the form of presuppositions in questions, suggestive statements, photographs (e.g., mugshots), or narrative summaries. It can come from the experimenter, a confederate, or the witness herself. The misinformation effect qualifies as a false

**Table 1** Experimental designs for studying retroactive interference (RI) and eyewitness suggestibility

| | *Condition* | *Study target (A – B)* | *Interference (A – D) or (C – D)* | *Test target (A – B)* |
|---|---|---|---|---|
| RI | | | | |
| | Experimental | Table – Radio | Table – Pencil | Table – ? |
| | Control | Table – Radio | Purse – Pencil | Table – ? |
| Eyewitness | | | | |
| | Misled | Accident – Stop sign | Accident – Yield sign | Accident – ? |
| | Control | Accident – Stop sign | Accident – Traffic sign | Accident – ? |

memory since participants generally endorse the misinformation quickly and with high confidence (Loftus et al., 1989). When participants described their erroneous memories, undergraduate judges were at chance at differentiating between real and suggested memories (Schooler et al., 1986).

One prerequisite for suggestibility is that participants fail to notice any problem with the misinformation when it is presented. This is called the discrepancy detection principle (Loftus, 1992). Participants are more likely to accept and reproduce misinformation about peripheral details than central characters or details (e.g., Christianson, 1992). In contrast, blatant misinformation not only is rejected, it also increases resistance to other peripheral misinformation (Loftus, 1979). Blatant misinformation may serve as a warning that the source is not to be trusted. This would be consistent with findings that warnings given before encoding of misinformation successfully reduce suggestibility, probably because warned participants read more slowly as they search for errors (Greene et al., 1982). In general, slow readers are more likely to notice (and resist) misinformation (Tousignant et al., 1986).

Given that participants do not detect the misinformation, manipulations that are generally known to enhance remembering lead to increased suggestibility, presumably because they increase memory for the misinformation. For example, suggestibility is greater if participants generate the misinformation (Roediger et al., 1996) and if the misinformation is repeated (Mitchell and Zaragoza, 1996; Zaragoza and Mitchell, 1996). Participants may also be more likely to rely on the misinformation if they have poor memory for the original events. For example, dividing attention during study (but not during the post-event information phase) increases suggestibility (Lane, 2006).

One important question is what happens to the original memory. It is easy to imagine the practical implications: If the original and post-event misinformation coexist in memory, it suggests the usefulness of developing strategies to help witnesses retrieve the original event. However, if the misinformation overwrites the original memory, it suggests that no retrieval strategy will allow access to the original event. Originally, there was much debate over this issue, but several lines of evidence suggest that the two memories may coexist. For example, consider what happens when misled participants are allowed to make a second guess after producing misinformation. If the original memories were completely unavailable, second-chance responses should be at chance (as what would they be based on?). Instead, second-chance guesses of misled participants are above chance (Wright et al., 1996), suggesting that some information about the original event is still available.

Compelling data for the coexistence hypothesis comes from experiments using source monitoring tests rather than recognition tests. Typically, in the 1970s and 1980s participants were required to make ‘old/new’ judgments about items. However, an ‘old’ judgment does not necessarily imply that participants remember seeing the misinformation in the original event. For example, participants may remember reading the misinformation in a post-event narrative and assume that remembering it from the narrative means it must have been in the video as well. To test these ideas, Lindsay and Johnson (1989) compared two groups of participants, all of whom studied the same photograph of an office. Afterward, half of participants read a narrative that mentioned eight office-related objects that were not actually in the original picture. Control participants read an accurate narrative description of the scene. The novel manipulation was at test; half of participants took a standard ‘yes/no’ recognition test, and half took a source monitoring test. For each item on the recognition test, participants indicated ‘yes’ if the object had been in the photograph and ‘no’ if it had not. On the source test, participants indicated whether each test object had been only in the picture, only in the text, in both the picture and the text, or in neither the picture nor the text. The results were dramatic: The misinformation effect was eliminated in the source condition! In later experiments, the advantage of the source test was replicated, although suggestibility was reduced rather than completely eliminated (Zaragoza and Lane, 1994).

Recent research on the misinformation effect has moved from the debate about the fate of the original memory trace to other interesting questions. One current trend is the examination of the effects of social context on suggestibility. This includes both the social context in which participants are exposed to misinformation, as well as the social context in which participants first intrude errors. For example, researchers are examining the effects of receiving misinformation from other people as opposed to reading it in narratives or embedded in questions (e.g., Roediger et al., 2001a; Gabbert et al., 2004; Wright et al., 2005). A related question involves the response the witness receives from other people after she (the witness) makes a mistake. The question of how feedback affects a witness’ memory is an important one, as incorrectly telling the witness 'Good, you identified the suspect' can have many negative consequences (see Douglass and Steblay, 2006, for a review; *See* Chapter 2.44).

## 2.14.3 Verbal Overshadowing

Rehearsal (especially elaborative rehearsal) can be a useful mnemonic for remembering word lists and prose. But what happens when a rehearsal fails to adequately capture the original experience? For example, words rarely capture the richness of our perceptions. What are the memorial consequences of a description (a rehearsal of sorts) that is inadequate or even inaccurate?

Questions about the effects of language and memory are not new ones. Many undergraduates are familiar with a classic study in which labels influenced memory for pictures. A picture of two circles joined by a line was labeled as either 'glasses' or 'barbell,' and participants later redrew the pictures to be similar to the label (Carmichael et al., 1932). In the 1970s, there was much interest in how participants integrated verbal and visual information in memory (e.g., Pezdek, 1977; Gentner and Loftus, 1979). Depending on the study, opposite conclusions were reached. Sometimes labeling pictures and objects led to enhanced memory (e.g., Santa and Ranken, 1972), but other times labeling was associated with difficulty on later memory tests (e.g., Gentner and Loftus, 1979).

More recently, Schooler and Engstler-Schooler (1990) sparked interest in the question by contextualizing it within the eyewitness memory domain. After watching a 30-s video of a bank robbery, participants in their Face Verbalization condition wrote a description of the thief's face (participants in the control condition did an unrelated task during that time). At test, all participants saw eight similar faces (including the thief) and were asked to select the perpetrator from the video or to indicate if he was absent from the line-up. The intriguing finding was that 64% of control participants selected the target, as compared to 37% in the face verbalization condition. Schooler and Engstler-Schooler labeled their finding verbal overshadowing.

Verbal overshadowing is not limited to faces; it extends to other types of perceptual information. Describing a voice reduces the ability to later identify that voice from among six options (Perfect et al., 2002). The typical wine drinker shows verbal overshadowing for wines, as they are unable to verbalize the nuances of wine in the vocabulary of experts (Melcher and Schooler, 1996). After memorizing a map of a small town, participants who wrote about it later performed worse on distance estimation tasks than did control participants (Fiore and Schooler, 2002). That is, having described one's spatial mental model of the town led to confusion about the distances between the landmarks.

Several different explanations have been proposed. One possibility involves recoding (*See* Chapter 2.07). Specifically, when participants describe a visual stimulus from memory, they are effectively recoding it from a visual representation to a verbal one, and the more recent recoded memory then interferes with the original visual memory. Consistent with an interference account, inserting a delay between the description and the final test reduces verbal overshadowing (Finger and Pezdek, 1999), in the same way that a delayed test can reduce retrieval blocking in other interference situations (e.g., Choi and Smith, 2005).

The recoding account would predict that the quality of the new verbal representation (as measured by the description) should predict the effects of verbalization on later memory tasks. Although Schooler and Engstler-Schooler (1990) did not find a relationship between the quality of the descriptions and the ability to recognize the perpetrator, this may be because of the way the descriptions were scored. Descriptions were considered better if they described more features of the target; however, this dependent measure is not ideal, as face recognition depends on configural information rather than on recognition of individual features (e.g., Diamond and Carey, 1986). That is, while people may only be able to verbalize individual facial features (e.g., she has big eyes and she has freckles on her nose), face recognition depends upon hard-to-verbalize configural information about the relationship of features to one another (e.g., the relationship between the eyes and the nose).

Support for the recoding hypothesis comes from a meta-analysis of the literature about the type of instructions given to witnesses. Meissner and Brigham (2001) coded each study's instructions to participants as either standard or elaborative. Instructions were considered elaborative if "the authors explicitly encouraged their participants to go beyond their normal criterion of free recall and to provide more elaborative descriptions" (Meissner and Brigham, 2001: 607). Presumably, elaborative descriptions led to less accurate recodings; consistent with this, elaborative descriptions were more likely to lead to verbal overshadowing than were descriptions resulting from standard free recall instructions (Meissner and Brigham, 2001). One study published since the meta-analysis deserves mention here. MacLin (2002) compared the effects of several different types of instructions on the verbal overshadowing effect. When participants were told to describe facial features, the standard effect occurred: On a later test, participants were less likely to identify the target than were control participants who did not describe the target. However, when participants were told to write a description comparing the target to a famous person such as Julia Roberts (the exemplar condition), verbal overshadowing was reduced. The effect disappeared in a prototype condition in which participants described "what type of person you think he most looks like" (MacLin, 2002: 932) in terms of occupation and personality. Thus, verbal overshadowing was most likely in the condition in which recoding emphasized facial features rather than more holistic information about the target face.

A second explanation of verbal overshadowing also hinges on the fact that descriptions often emphasize individual facial features rather than configural information. However, rather than proposing that a feature-based description interferes with retrieval of the original memory, the argument is that verbalization induces a processing shift at test (Dodson et al., 1997; Schooler, 2002). That is, because descriptions of faces emphasize individual features (as it is hard to verbalize relations between features), the participant carries over this type of processing to test. This is considered a processing shift, as face identification is normally based on configural information rather than features; carrying over a featural orientation would constitute inappropriate processing. One interesting finding is shown in **Figure 2**. Dodson and colleagues had participants view a target face and then do one of three tasks: Describe the target face, describe a parent's face, or list U.S. states and capitals (a control condition). As shown in the figure, describing any face (e.g., a relative's) reduced participants' ability to identify the target (Dodson et al., 1997). This is hard to reconcile with the idea that a recoded representation (of the target) is interfering with access to the original memory. Rather, it suggests that anything that emphasizes featural processing will encourage that same type of processing at test.

Similar conclusions were reached by Finger (2002), who added a second factor to the typical verbal overshadowing experiment. She crossed description (describe vs. control) with a post-description task (verbal vs. mazes). When solving mazes followed the face description, verbal overshadowing disappeared. In a second experiment, Finger replicated the effect with a second nonverbal task, namely listening to music. Engaging in holistic processing can change the processing set from one that emphasizes individual features to one that does not, with consequences for face identification.

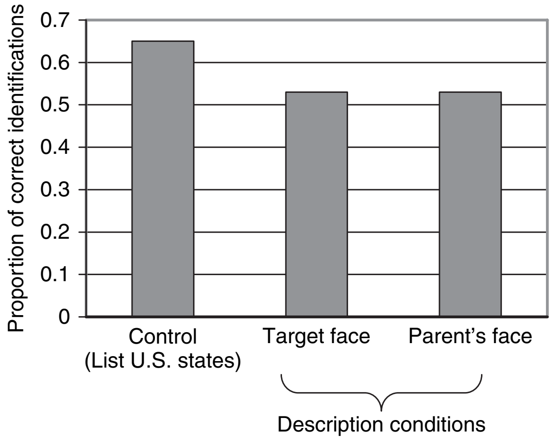

**Figure 2** Recognition of target face after describing target face, parent's face, or listing U.S. states and capitals. Data from Dodson CS, Johnson MK, and Schooler JW (1997) The verbal overshadowing effect: Why descriptions impair face recognition. *Mem. Cogn.* 25: 129–139, Experiment 2.

Recent research suggests a number of relatively simple solutions to minimize the effects of verbal overshadowing of faces, such as inserting a delay between description and test (Finger and Pezdek, 1999) and preceding the test with a task that encourages configural processing (Finger, 2002). It remains to be tested whether these solutions are equally effective at reducing verbal overshadowing of other types of perceptual stimuli such as voices, wines, and maps.

## 2.14.4 Misattributions of Familiarity

Thus far, we have discussed misremembering laboratory events – be it misremembering a word that was never presented in a study list (in the DRM paradigm), incorrectly recalling a detail of a slide show (in the misinformation paradigm), or misidentifying a person from a video (in verbal overshadowing experiments). In contrast, in the next paradigm we will review, the memory error involves misattributing something learned in the laboratory to pre-experimental experience. More specifically, the paradigm is a recipe for fame; Larry Jacoby used straightforward experimental manipulations to make ordinary names appear famous.

The names Brad Pitt, Mark McGwire, and Sandra Day O'Connor are likely recognizable to you. In addition to agreeing that you have heard of these people before, you can probably justify your response by telling us Brad Pitt is an actor, Mark McGwire is an athlete, and Sandra Day O'Connor is a retired Supreme Court justice. You can also tell me whether or not other names are the names of famous people, even if you cannot say exactly why each person is famous. For example, try to identify the three famous people in the following list of six names: Zoe Flores, Minnie Pearl, Jessica Lynch, Joanna Emmons, Summer Foster, Hattie Caraway. Hopefully, at least one or two of the names will seem familiar to you, even if you do not know what accomplishments to associate with each name. Quite simply, the false fame paradigm increases the familiarity of nonfamous names (like Zoe Flores, Joanna Emmons, and Summer Foster) and places the respondent in a situation where familiarity is interpreted as fame.

In the typical paradigm, participants read a list of names explicitly labeled as nonfamous. In a second phase, participants judge the fame of each of a series of names; the test list includes moderately famous names like Minnie Pearl, new nonfamous names, and old nonfamous names that were read in the first part of the experiment. Critically, half of the participants are required to do a secondary task (e.g., monitoring an auditory stream of numbers for a series of three odd numbers in a row) at the same time as the fame judgment task. In the full-attention (control) condition, old nonfamous names are less likely to be judged famous than are new nonfamous names; in this condition, if participants can remember a name is old, then they can assume it is not famous. In contrast, in the divided-attention condition, participants are more likely to call old nonfamous names famous ($M = 0.28$) than new nonfamous names ($M = 0.14$) (Jacoby et al., 1989b). The logic is that under divided attention, participants are forced to base their judgments on the familiarity of a name, and that the cognitive load interferes with their ability to recollect whether names were presented in the first part of the experiment.

The false fame effect requires conditions that force participants to rely on familiarity rather than recollecting information about the names. For example, the false fame effect also occurs when attention is divided during encoding, as presumably that prevents encoding of item-specific information (Jacoby et al., 1989a). Similarly, under conditions of full attention, the illusion requires a delay between study of the nonfamous names and the fame judgments. Consistent with the idea that the false fame effect is familiarity driven, the effect is stronger in populations that are more likely to rely on familiarity, such as older adults (Bartlett et al., 1991; Multhaup, 1995).

This illusion is related to a more general framework on how people interpret feelings of familiarity. Vague feelings of familiarity are not specific to names; there are many situations in which familiarity is experienced and the perceiver must attribute that familiarity to something. In an impressive series of studies, Jacoby has shown that how that familiarity is interpreted depends on the experimental context. Familiarity can be interpreted as fame, but it can also lead to illusions of duration and noise level, for example. At test, previously studied words are judged to be presented longer than are new words (Witherspoon and Allan, 1985) and background noise is judged to be quieter for old sentences than for new sentences (Jacoby et al., 1988). The familiarity of the items causes them to be processed fluently, and in the context of perceptual judgments, this fluent processing is interpreted as perceptual conditions that aid identification of the items.

Familiarity may also play a role in the déjà vu experience (Brown, 2003, 2004). In the prior examples in this section, familiarity was successfully attributed to a source, albeit incorrectly: Familiarity was misinterpreted as fame and longer presentation durations, among other things. In contrast, déjà vu occurs when something feels familiar but the familiarity cannot be attributed to any prior experience. It is this unexplained familiarity with a situation that yields the puzzling déjà vu reaction. One hypothesis is that the individual previously experienced all or part of the present situation or setting, but cannot explicitly remember it. Thus implicit memory yields a familiarity response that is puzzling given the lack of episodic memory. Because déjà vu is a relatively infrequent phenomenon (Brown, 2003, 2004), it is difficult to capture in the laboratory. Some support for the implicit memory hypothesis, however, has been found in a laboratory paradigm (Brown and Marsh, in press). In this study, students from Duke University and Southern Methodist University viewed photos of the away campus in an initial exposure phase (none of these students reported having visited the other campus in real life). During the initial session, participants made a simple perceptual judgment about each of 216 photos, which included the target away-campus photos as well as many filler photos. One week later, participants made judgments about whether or not they had visited each of a series of test photos. Critically, in addition to familiar places from their home campus, participants judged photos from the prior session. Prior exposure to away-campus scenes boosted participants' beliefs that they had visited the places in real life. Intriguingly, almost half of participants reported experiencing something like déjà vu in the study. In this case, familiarity with a scene influenced belief that the place had been visited in real life, and sometimes this familiarity was puzzling enough to be labeled as déjà vu (*See* Chapter 2.21).

In this section, we described how familiarity could be interpreted as fame as well as perceptual attributes such as the volume of noise. In the next section, we will consider whether familiarity with an event can increase people's beliefs that an event happened in their pasts.

## 2.14.5 Imagination Inflation

The relationship between imagery and perception has a long intellectual history, reaching back to philosophers such as Hume and Mills. In the 1970s, the key question involved the nature of the representation underlying images. In this context, Johnson and colleagues asked how we separate memories for images from memories based on perception. More generally, reality monitoring involves deciding whether a memory originated from an internal or external source, with internal sources being cognitive processes such as imagery, thought, and dreams. Johnson argued that internally generated and externally presented memories tend to differ in prototypical ways, and that these differences in qualitative characteristics were the basis for attributing memories to thought versus perception (e.g., Johnson and Raye, 1981). Compared to memories based on perception, memories of images were postulated to be less vivid and to be associated with the cognitive operations involved in their generation. Reality monitoring errors occur when memories contain characteristics atypical of their class. For example, easily generated images are more likely to be misattributed to perception than are difficult-to-imagine objects. Easily generated images are likely atypically vivid; in addition, their easy generation means they are not associated with a record of cognitive operations (Finke et al., 1988).

Misattributions of imagined events to perception have been documented with many different kinds of stimuli, including imagined voices (Johnson et al., 1988), imagined rotations of alphanumeric characters (Kahan and Johnson, 1990), and imagined pictures (Johnson et al., 1982). But can imagery cause confusions beyond these types of simple laboratory stimuli? That is, if you imagine an event, will you later come to believe that it really happened?

Garry and colleagues (1996) created a three-stage procedure to answer this question. In the first part of the experiment, participants rated the likelihood that they had experienced each of a series of life experiences (the Life Events Inventory; LEI), including winning a stuffed animal at a fair and breaking a window with one's hand. Two weeks after reading descriptions of the target events, participants imagined both the setting and the action of events in response to specific prompts. For example, in the broken window event, participants spent 20–60 s imagining the following setting: "It is after school and you are playing in the house. You hear a strange noise outside, so you run to the window to see what made the noise. As you are running, your feet catch on something and you trip and fall" (Garry et al., 1996: 210). After the imagination phase was finished, the experimenter pretended to have lost the original LEI and asked participants to fill out the questionnaire for a second time.

There were eight critical events judged unlikely to have occurred for a majority of the participants, and each participant imagined four of those during phase 2. Of interest was whether participants were more likely to change their beliefs about events they had imagined in phase 2, as compared to the control events not imagined. Garry et al. examined the percentage of critical items that were rated as more likely to have happened at time 2 (after the imagery phase) than at time 1. Increases in likelihood ratings were more common for imagined events than for control events. For example, consider the effect of imagining on people's beliefs that as a child they broke a window with their bare hand. The likelihood ratings increased from time 1 to time 2 for 24% of participants in the imagery condition, as compared to only 12% of control participants.

It is possible, of course, that participants had actually experienced these unusual events and that imagining them helped to cue the previously forgotten memories. One solution to this criticism is to control the original events in the laboratory, to allow certainty about what actually occurred. Because this is not possible with childhood memories, Goff and Roediger (1998) brought the encoding phase into the laboratory. The experiment had three sessions; during the first session, participants enacted, heard, or imagined simple events. For example, when the experimenter read aloud the sentence 'bounce the ball,' one participant would simply listen; another would imagine bouncing the ball, and a third would actually bounce the ball. Twenty-four hours later, participants returned for a second session in which half of participants imagined events and half did math problems. In the imagery condition, participants were guided to imagine each event zero, one, three, or five times; the events included ones from the first session as well as completely new events. Participants in this condition rated the vividness of each image. Finally, 2 weeks after the initial session, participants were given recognition and source monitoring tests. Participants were explicitly told that their memory was being tested for the first day only. They were first asked if they remembered hearing certain events. If they answered no, they gave a confidence rating in their answer. If they answered yes, they specified the format of the remembered event (heard and enacted, heard and imagined, or heard only) and rated their confidence in that judgment. Of interest was whether imagining new events in session 2 would increase beliefs that the events had been performed in session 1. Replicating findings from studies using LEI measures, Goff and Roediger found that events that were only imagined during the second session were later misremembered as having been performed during the first session. Imagining a bouncing ball in the second session increased participants' beliefs that they had actually bounced a ball in the first session. Furthermore, as the number of imaginings in session 2 increased, participants were more likely to incorrectly label a never-performed action as having been performed in the first session, as shown in **Figure 3**.

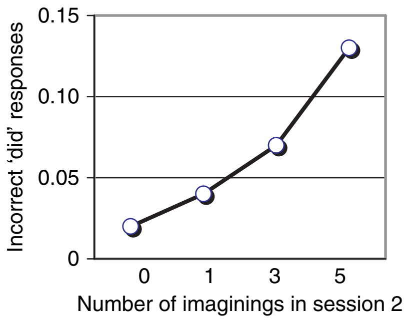

**Figure 3** False 'did' judgments for never-performed actions as a function of number of imaginings in session 2. Data from Goff LM and Roediger HL III (1998) Imagination inflation for action events: Repeated imaginings lead to illusory recollections. *Mem. Cogn.* 26: 20–33.

The finding of imagination inflation for laboratory events supports the idea that imagination can yield false memories and that the effects observed with the LEI cannot be attributed solely to recovery of previously forgotten events. Why do these effects occur? In their original demonstration of imagination inflation, Garry and colleagues favored a reality monitoring explanation, whereby an imagined memory was misattributed to perception. Specifically, Garry et al. argued that imagination increased the perceptual information associated with the events, thus increasing the similarity of these imagined memories to performed events. This account predicts that imagination inflation should be greater when images are detailed, as they will be more readily confused with perception. Consistent with this hypothesis, Thomas and colleagues (2003) found that elaborative imagery instructions increased the imagination inflation effect, as compared to standard imagery instructions. Like Goff and Roediger, Thomas' participants completed an initial encoding phase and returned a day later for the imagination phase. Instructions in the simple imagery condition paralleled Goff and Roediger; for example, participants were asked to 'imagine getting up and opening the door.' Participants in the elaborative imagery condition were to imagine two additional statements, which included two sensory modalities; for example, 'Imagine getting up and opening the door. Imagine how the door handle feels in your hand. Imagine how the door sounds as you open it.' If the event was not imagined in the middle session, participants were very good at identifying new events. However, imagining events in the middle session led to imagination inflation, and this effect was bigger (12%) following elaborative imagery than simple imagery (7%).

To recap, imagining events may increase their vividness, a key characteristic of perceived memories. This is not the only explanation for the imagination inflation effect, however. Imagining events may also increase their familiarity, which can also lead to memory misattributions (as described in the previous section of this chapter). The imagination scripts used to guide the imagery also usually contain a lot of suggestive information over and above the vivid images generated by the participant. In short, does imagination underlie the effect, or is the effect at least partly driven by familiarity (as discussed in the section on false fame), as opposed to imagination?

Several data points suggest that imagining vivid details is not necessary to increase beliefs that events occurred in childhood. For example, similar effects are observed when participants paraphrase the script normally used to guide imagery (Sharman et al., 2004). The data also look similar when participants explain how the events might have happened in one's childhood (Sharman et al., 2005). Of course, in both of these cases, it is possible that participants might spontaneously generate images even though they were not explicitly directed to do so. However, Bernstein and colleagues observed inflation in a study in which spontaneous generation of images was quite unlikely. Their study extended the revelation effect to autobiographical memory (Bernstein et al., 2002). The revelation effect is the finding that requiring participants to unscramble a stimulus (to reveal it) increases the likelihood that it will be judged 'old' (Westerman and Greene, 1996). Bernstein et al. found that participants were more likely to believe childhood events had in fact occurred if they had to unscramble the events before judging them (e.g., 'broke a dwniwo playing ball'). Unscrambling presumably does not encourage imagery, and thus it suggests that LEI ratings can be based on factors other than image vividness, such as familiarity.

It should be clear that the just-described results do not negate the role of imagination in false memory creation. Finding that explaining, paraphrasing, and unscrambling events can all inflate confidence in remembered events does not preclude imagination also playing a role. Rather, such results emphasize the importance of isolating the contribution of imagination, as imagination is often combined with other factors that yield false memories.

### 2.14.6 Implanted Autobiographical Memories

It is possible to make a person remember a word that was never presented, to misjudge the fame of a name, or to misremember a detail from a witnessed event. But do people ever falsely remember entire events? The answer is yes. Consider the case of Shauna Fletcher, who came to believe her horrible memories of childhood sexual abuse were false memories (Pendergrast, 1996). How could this happen? Shauna traced her memories to several different sources, blaming her therapist for suggesting that the events occurred, and books and movies for providing the images she remembered. Shauna's experiences parallel the findings from laboratory studies: Implanting memories is possible, but not simple. A single misleading statement does not yield the kind of false memories experienced by Shauna. Correspondingly, the laboratory procedures for implanting entire memories tend to be much more complicated than those described earlier in the chapter, oftentimes combining multiple suggestive techniques.

Loftus and Pickrell (1995) demonstrated that false autobiographical memories can be implanted using laboratory techniques. The critical false memory involved being lost in a shopping mall as a child. To camouflage the purpose of the experiment, participants were also interviewed about childhood events that had actually occurred; a close relative of the participant provided the true memories. The relative also provided plausible details to aid in constructing the false memory (e.g., stores the family shopped, other family members likely to have been present, etc.) and verified that the participant had not been lost in a shopping mall around the critical time period (age 5).

Participants reviewed four events: three that were true and the critical false event. Each event was described in a booklet, and participants were instructed to remember the events and to write about the specific details of each. If participants did not remember the event, they were to indicate that on the form. Approximately 1–2 weeks later, participants were interviewed about the events. In addition to recalling details of the events, participants rated each memory for clarity (1 = not clear; 10 = extremely clear) and confidence that additional details could be remembered later (1 = not confident; 5 = extremely confident). A second interview, conducted 1–2 weeks later, was similar to the first interview.

Did participants come to remember being lost in the shopping mall at age 5? Critically, seven out of 24 participants claimed to remember the false memory (fully or partially) while writing about it in the initial booklet. Although their descriptions of the false events were shorter than those of true memories, the clarity ratings given to these false memories increased across interviews. At the end of the experiment, five participants were unable to pick out the false event and instead guessed that one of the true events had never happened.

The reader may be wondering why we consider the Loftus and Pickrell (1995) study to be an example of successful memory implantation. After all, most participants never believed the lost-in-the-mall memory and were able to identify it as the false event. What is crucial is that the implantation rate was above zero. That is, to argue that implanting false memories is possible, one only needs to show one successful implantation.

False memories are not limited to erroneous memories of being lost in the mall as a child. Experimenters have been successful at implanting many different types of events in participants. Participants have come to falsely remember participating in a religious ceremony (Pezdek et al., 1997), riding in a hot air balloon (Wade et al., 2002), putting the gooey toy Slime in an elementary school teacher's desk (Lindsay et al., 2004), and being admitted to the hospital (Hyman et al., 1995). Different approaches have been taken to ensure a false memory was in fact implanted, as opposed to a true memory being recovered. One is to confirm events with parents, as Loftus and Pickrell (1995) did. Another is to choose events that are very implausible, or even impossible. Braun and colleagues (2002) used the latter approach, implanting false memories for meeting a Warner Brothers character, Bugs Bunny, at Disneyland.

The procedures for implanting false memories are often elaborate, far beyond the simple suggestions typical of eyewitness misinformation studies. Successful studies typically follow three rules of thumb (Mazzoni et al., 2001; Lindsay et al., 2004). First, the target event must be deemed plausible. For example, it is easier to implant a false memory for being lost in the mall than it is to implant a false memory of an enema (Pezdek et al., 1997; see also Hart and Schooler, 2006). Second, the target event must be elaborated upon. For example, suggestibility was greater for participants who were required to imagine and describe the target events, probably because the guided imagery task led to more detailed memories (Hyman and Pentland, 1996). Third, the products of this elaboration must be attributed to memory, as opposed to other sources.

Although this framework is generally useful for thinking about memory implantation, one difficulty is that many manipulations likely affect more than one process. Consider, for example, Pezdek and colleagues' difficulty in implanting a false memory involving a Catholic ceremony (the Eucharist) in Jewish participants. Were the Jewish participants able to reject the event because it was implausible to them or because they were not familiar enough with the event to elaborate upon the suggestion? Similarly, consider what happens when a participant sees a doctored photograph depicting her engaged in the target false event. In this type of study, after a relative verifies that the participant has never ridden in a hot air balloon, Photoshop is used to insert a real childhood photo into a photograph depicting a hot air balloon ride (Wade et al., 2002). Such a procedure yields false memories in about half of participants (a high rate) – but is unclear at a cognitive level how the photograph has its effect on memory. The very existence of a photograph of the event increases the plausibility of the event, as well as providing vivid details about the supposed event.

The aforementioned examples illustrate the challenge of doing research in this area, namely the difficulty of linking manipulations to specific cognitive processes. We do not, however, intend to be pessimistic. The demonstrations of memory implantation were critical first steps, and they are being followed by systematic manipulations aimed at better elucidating the underlying cognitive processes. Rather than trying to equate different events with different levels of an independent variable, one approach is to try to implant the same event while experimentally manipulating a variable that affects only one possible factor, such as plausibility. Mazzoni and colleagues took this approach when examining memories for demonic possession (Mazzoni et al., 2001). Keeping the target event constant, they showed that reading articles about possession dramatically increased later beliefs that one had witnessed a demonic possession (as compared to the control group).

One of the major puzzles in this research area is why vivid false memories can be successfully implanted in some participants but not others. For example, across eight well-cited studies, Lindsay et al. (2004) observed that the implantation rate ranged from 0% to 56% of participants! We know of no study in which the false memory was successfully implanted into 100% of participants. Thus we predict one fruitful avenue for future research will be investigating individual differences in suggestibility. In the best study to date, Hyman and Billings (1998) looked for relationships between rates of false memory implantation and scores on four cognitive/personality scales. Two interesting results emerged. First, false memory scores were higher for participants who scored higher on the Creative Imagination Scale (CIS), a scale that measures imagery ability as well as suggestibility. In other words, participants who were better able to elaborate upon the suggestion were more likely to come to remember the false event. Second, false memory scores were higher for participants who scored higher on the Dissociative Experiences Scale (DES), a scale that measures both normal experiences such as distraction as well as less normal experiences such as hearing voices. Scoring higher on the DES may be related to difficulties with source monitoring.

In short, implanting detailed false memories is a complex process. It combines many of the techniques described earlier in the chapter in the context of other false memory paradigms, including imagery instructions, misleading suggestions, and a test situation that does not encourage participants to evaluate the source(s) of their memories. In this context, we turn to a discussion of how the various memory errors relate to one another.

## 2.14.7 Connections Across False Memory Paradigms

We have described six different paradigms that yield memory errors: The DRM paradigm, the eyewitness misinformation paradigm, verbal overshadowing studies, misattributions of familiarity, imagination inflation, and implanted autobiographical memories. What is the relationship between these very different paradigms?

We linked each memory error to possible mechanisms: Spreading activation (and monitoring of that activation) in the DRM paradigm, interference and failure to monitor source in the misinformation paradigm, an inappropriate shift in processing at test in the verbal overshadowing paradigm, a misattribution of familiarity in the false fame effect, increased familiarity and vividness (and possibly reality monitoring failures) in imagination inflation, and elaboration and source misattribution in the implanted memory studies. Sometimes, the same mechanism is implicated across illusions; for example, source monitoring failures are implicated in the misinformation effect and in implanting false autobiographical memories. Imagination inflation likely involves reality-monitoring errors, a specific type of source error. Misattributions of activation (in the DRM paradigm) and familiarity (as observed in the false fame paradigm) can also be interpreted as source errors. In other cases, the mechanisms appear qualitatively different, as in the case of the transfer inappropriate processing shift in verbal overshadowing studies. Of course, one issue is that likely more than one mechanism is involved in each illusion (and the convergence of mechanisms is probably why the errors are so robust). For example, imagination inflation likely depends on both vivid encoding (which may also increase familiarity) and some kind of monitoring failure at test. One other point worth noting is that even if the same mechanism is implicated in two different illusions, the instantiations of that mechanism may be quite different. For example, even though source errors are implicated in both the DRM illusion and the misinformation effect, giving participants a source test has very different effects in the two cases. As already mentioned, a source test can reduce susceptibility to post-event information (e.g., Lindsay and Johnson, 1989; Zaragoza and Lane, 1994). However, source tests yield more puzzling results when used in the DRM paradigm; depending on the features of the source test, the rate of false memories may be higher (Hicks and Marsh, 2001), lower (Multhaup and Conner, 2002), or similar (Hicks and Marsh, 1999) to that observed on item memory tests.

More generally, comparing the effects of standard manipulations on the different measures of suggestibility is a useful way of examining similarities and differences across false memory paradigms. For example, many researchers are interested in differences in suggestibility between children and college students. This comparison has been made in at least three of the six paradigms we described – DRM, eyewitness misinformation, and implanted memories – and the conclusion about age is not the same across paradigms. For example, younger children are normally more suggestible in eyewitness misinformation paradigms than are older children (Bruck and Ceci, 1999), but older children are more suggestible than younger children in the DRM paradigm (e.g., Brainerd and Reyna, 2007). That is, even though there are clear age differences in source monitoring abilities (e.g., Lindsay et al., 1991), with older children doing better than younger, older children are more suggestible in the DRM paradigm. Why is this, given that we already alluded to the role of source monitoring in the DRM paradigm? The paradox can be resolved by attributing the key age difference to encoding, rather than to retrieval-based processes such as source monitoring. Specifically, because younger children have difficulty noting semantic relations between items (Brainerd and Reyna, 2007), they may be less likely to encode the critical lure. In the terms of activation-monitoring theory, activation will be less likely to spread to the critical lure from related studied items; in the terms of fuzzy trace theory, younger children will be less likely to extract the gist of the list. By either account, the result is the same: It does not matter if younger children are poor at source monitoring if there is no trace for them to attribute to a source! Again, this example highlights the inadequacy of simply attributing DRM and eyewitness errors to difficulties with source; the full picture is more complicated.

There are at least two other approaches for connecting false memory paradigms. One is to test the same participants in multiple paradigms, and another is to link false memory in different paradigms to the same standardized measures of individual differences. The logic is that if comparable mechanisms underlie the errors, then the same individuals (or the same types of people) should perform similarly across paradigms. For example, Clancy and colleagues (2002) examined suggestibility in the DRM paradigm in control participants and in people who believed aliens had abducted them. Memories of alien abduction are of interest since the scientific community views alien abductions as impossible occurrences, leading these memories to be classified as false memories (although not implanted in the laboratory, of course). Interestingly, false recognition of nonpresented words was higher for people with alien abduction memories ($M = 0.67$) than for control participants ($M = 0.42$). In this same study, correlations between false memory and scores on individual difference scales were also observed. The rate of false memories was greater for individuals who scored highly on scales measuring absorption and dissociative experiences (DES) and reported more symptoms of post-traumatic stress disorder. The reader will recall that the DES is a scale that measures both normal experiences such as distraction as well as less normal experiences such as hearing voices, and that higher scores on the DES may be related to difficulties with source monitoring. Higher DES scores predicted implantation of a false childhood memory for spilling punch on the mother of the bride, although absorption did not (Hyman and Billings, 1998). Scores on the DES have also been related to imagination inflation (Paddock et al., 1999), and pathological scores on this scale have been linked to suggestibility in the eyewitness misinformation paradigm (Eisen et al., 2001). However, DES scores are not related to susceptibility to the false fame illusion (Peters et al., 2007). Understanding such individual differences will likely be an important part of future research on memory errors and suggestibility.

We end with a note on another approach we believe will help elucidate the relationships between different false memory paradigms: neuroimaging. Consider a study by Cabeza and colleagues (2001), in which participants watched two very different sources (a Caucasian male and an Asian female) read DRM-like lists, followed by a recognition memory test. At test, studied words and critical lures yielded similar activation in anterior medial temporal lobe (MTL) areas, but activation in posterior MTL differentiated true and false memories. Cabeza et al. associated anterior MTL with retrieval of semantic information and posterior MTL with perceptual information. What would the pattern be like for familiarity-driven illusions, such as false fame? To the extent that the same mechanisms underlie different memory errors, similar patterns of activation should occur.

## 2.14.8 Conclusions

In this chapter, we reviewed just six of the many published paradigms for creating false memories. Together, the data highlight the constructive nature of memory, as proposed by Bartlett (1932). We have also tried to stress that not all memory errors are equal. Not surprisingly, given the complexity of memory, there are many different ways that error can enter the system, from encoding to retrieval.

While we have focused on errors, we would be remiss not to point out that reconstructive memory is often very useful. For example, familiarity often is an excellent cue that something has been experienced before, and it is only in certain situations that this heuristic leads to error. More generally, errors are often the by-product of processes that support veridical memory. Memory errors are more than intriguing illusions. A thorough understanding of memory's errors will provide insight into the processes that normally aid memory.

# 2.15 Memory in and about Affect

**E. Eich**, University of British Columbia, Vancouver, BC, Canada

**E. Geraerts**, Harvard University, Cambridge, MA, USA

**J. W. Schooler**, University of British Columbia, Vancouver, BC, Canada

**J. P. Forgas**, University of New South Wales, Sydney, Australia

Philosophers, politicians, and playwrights alike have recognized for centuries the capacity of moods to color the way people remember the past, experience the present, and forecast the future. Psychologists, however, were relatively late to acknowledge this reality, despite a number of promising early leads (e.g., Rapaport, 1942/1961; Razran, 1940). Indeed, it is only within the past 30 years that empirical investigations of the interplay between affect and cognition have been published with regularity in mainstream psychology journals (see LeDoux, 1996).

Psychology's late start in exploring the affect–cognition interface reflects the fact that neither behaviorism nor cognitivism – the two paradigms that dominated the discipline throughout the twentieth century – ascribed much importance to affective phenomena, whether in the form of specific, short-lived emotional reactions or more nebulous, long-lasting mood states (for detailed discussion of affect-related concepts, see Russell and Feldman Barrett, 1999; Russell and Lemay, 2000).

From the perspective of the radical behaviorist, all unobservable mental events, including those affective in nature, were by definition deemed beyond the bounds of scientific psychology. Though early behaviorist research examined the environmental conditioning of emotional responses, later studies focused mainly on the behavioral consequences of readily manipulated drive states, such as thirst or fear. In such studies, emotion was instilled in animals through crude if effective means, such as electric shock, and emotionality was operationalized by counting the number of fecal boluses deposited by small, scared animals. As a result, behaviorist research and theory added little to our understanding of the interrelations between affect and cognition.

Until recently, the alternative cognitive paradigm also had little interest in affective phenomena. To the extent that the cognitive revolutionaries of the early 1960s considered affects at all, they typically envisaged them as disruptive influences on 'proper' – read 'emotionless' or 'cold' – thought processes. Thus, the transition from behaviorism to cognitivism allowed psychology to reclaim its head, but did nothing to recapture its heart.

Things are different today. Affect is now known to play a key role in how information about the world is processed and represented. Moreover, affect underlies the cognitive representation of social experience (Bower and Forgas, 2000), and emotional responses can serve as an organizing principle in cognitive categorization (Niedenthal and Halberstadt, 2000). Thus, the experience of affect – how we feel about people, places, and events – is central to people's cognitive representations of themselves and the world around them.

When it comes to memory, a major theme of this book, two overarching questions are of interest. One of these concerns memory 'in' affect: How do affective states or moods influence the acquisition and retention of information? The other question involves memory 'about' affect: What determines the accuracy and other attributes of memory for emotionally charged events? Over the past 30 years, both questions have been pursued with a wide array of subject species (humans, mice, mollusks, etc.), scientific approaches (experiential, physiological, neuroimaging), and memory methods (different materials, tasks, and measures). In addition, each of these highly general questions subsumes a host of more specific issues, including such varied topics as the consistency of flashbulb recollections (Talarico and Rubin, 2003), cognitive and clinical investigations of mood-dependent memory (Eich and Macaulay, 2006), dissociable influences of affective valence and arousal on memory vividness (Kensinger and Corkin, 2004; Kensinger and Schacter, 2006), and neural systems underlying the encoding and retrieval of emotional events in animals and humans (LaBar and Cabeza, 2006; Phelps, 2006).

This chapter surveys only a small segment of the vast affect/memory literature and its scope is limited to human cognitive and social research. Whereas the first part of the chapter covers mood-congruent cognition, a concept that is central to understanding how affective states influence memory, the second part focuses on memory for trauma, a controversial topic with important implications both for cognitive theory and for clinical practice. Given that mood congruence has had little overlap, conceptually or methodologically, with research on memory for traumatic events, our approach will be to treat memory in and about affect as distinct topics. Nevertheless, consideration of these topics together invites exploration of the possible empirical and theoretical issues that might unite them. To this end, we close with a discussion of potential ways in which the principles and findings of mood congruence might apply to understanding the processes leading to reports of recovered memories of trauma.

## 2.15.1 Memory in Affect

People often acquire, remember, and interpret information about themselves, and the world around them, in a manner that matches their current state of affect or mood. However, these mood-congruent effects are not universal, but depend for their expression on a variety of task-, person-, and situation-specific variables (Bower and Forgas, 2000). Since the early 1980s, a great deal of effort has gone into explaining why mood-congruent effects are robust and reliable under certain circumstances, but weak or nonexistent under others. The fruits of this effort are the focus of discussion in this part of the chapter.

We begin by introducing the concepts of affect priming and affect-as-information, both of which are central in understanding the impact of moods on the substance of cognition, or what people think. Attention then turns to the processing consequences of affect, that is, the impact of moods on cognitive style, or how people think. These opening remarks on cognitive substance versus style will set the stage for discussion of an integrative theory – Forgas's (1995, 2002) affect infusion model (AIM) – that seeks to specify the ways in which affect influences cognition in general and social cognition in particular. Next we consider the critical part that different information processing strategies play in the occurrence of mood congruence, and we conclude this section by summarizing some of the strengths and shortcomings of the AIM.

#### 2.15.1.1 Affect Priming and Affect-as-Information

Several theorists maintain that moods influence the content of cognition because they influence the memory structures people rely on when processing information. For example, Wyer and Srull (1989) suggested that recently activated concepts are more accessible because such concepts are returned to the top of mental storage bins, which in turn means that subsequent sequential searches are more likely to access the same concepts again. As affective states facilitate the use of positively or negatively valenced mental concepts, this could account for the greater use of mood-congruent constructs in subsequent tasks.

A more comprehensive explanation of this effect was provided by Bower's (1981) associative network model. On this view, the observed links between affect and cognition are neither motivationally based (cf. the psychoanalytic theory of Feshback and Singer, 1957), nor are they the result of merely incidental, spatiotemporal associations (cf. the conditioning theory of Byrne and Clore, 1970). Instead, Bower (1981) argued that affect is integrally linked to an associative network of mental representations. Accordingly, the activation of an affective state should selectively and automatically prime associated thoughts and representations previously linked to that affect, and these concepts should be more likely to be used in subsequent constructive cognitive tasks.

Consistent with the network model, early studies provided strong support for the concept of affective priming, indicating mood congruence across a wide range of cognitive tasks. For example, people induced to feel good or bad tend to selectively remember more mood-congruent details from their childhood and more of the real-life events they had recorded in a daily diary for a week (Bower, 1981). Mood congruence was also observed in subjects' interpretations of social behaviors and in their impressions of other people (Bower and Forgas, 2000).

However, subsequent research showed that mood congruence is subject to several boundary conditions (see Blaney, 1986; Bower, 1987; Singer and Salovey, 1988). Difficulties in demonstrating reliable mood-congruent effects were ascribed to such varied causes as the lack of sufficiently strong or intense moods (Bower and Mayer, 1985), the subjects' inability to perceive a meaningful, causal connection between their current mood and the cognitive task they are asked to perform (Bower, 1991), and the use of tasks that prevent subjects from processing the target material in a self-referential manner (Blaney, 1986). Interestingly, mood-congruent effects tend to be more reliably obtained when complex and realistic materials are used in conjunction with tasks (e.g., association generation, impression formation, or inference making) that require a high degree of open, constructive processing (e.g., Bower and Forgas, 2000; Mayer et al., 1992). Such tasks provide people with a rich set of encoding and retrieval cues and thus allow affect to more readily function as a differentiating context (Bower, 1992). A similar point was made by Fiedler (1991), who suggested that mood congruence may obtain only in constructive cognitive tasks – those that involve an open-ended search for information (as in recall tasks) and the active elaboration and transformation of stimulus details using existing knowledge structures (as in judgmental and inferential tasks).

It appears, then, that affect priming occurs when an existing affective state preferentially activates and facilitates the use of affect-consistent information from memory in a constructive cognitive task. The consequence of affect priming is affect infusion: The tendency for judgments, memories, thoughts, and behaviors to become more mood congruent (Forgas, 1995, 2002). But in order for such infusion effects to emerge, it is important that subjects adopt an open, elaborate information processing strategy that facilitates the incidental use of affectively primed memories and information. Thus, the nature and extent of affective influences on memory and cognition should largely depend on what kind of information processing strategy people employ in a particular situation. Later we will review the empirical evidence for this prediction and describe an integrative theory that emphasizes the role of information-processing strategies in moderating mood congruence.

Alternatively, the affect-as-information (AAI) model of Schwarz and Clore (1983, 1988) suggests that "rather than computing a judgment on the basis of recalled features of a target, individuals may . . . ask themselves: 'How do I feel about it? [and] in doing so, they may mistake feelings due to a pre-existing state as a reaction to the target" (Schwarz, 1990: 529). Thus, the model implies that mood congruence in judgments is due to an inferential error, as people misattribute a preexisting affective state to a judgmental target.

The AAI model incorporates ideas from three past research traditions. First, the predictions of the model are often indistinguishable from earlier conditioning research by Clore and Byrne (1974). Whereas the conditioning account claimed that spatiotemporal contiguity is chiefly responsible for linking affect to judgments, the AAI model posits an internal inferential process as producing the same effects (see Berkowitz et al., 2000). A second tradition that informs the AAI model comes from research on misattribution, according to which judgments are often inferred on the basis of salient but irrelevant heuristic cues – in this case, affective state. Thus, the AAI model also predicts that only previously unattributed affect can produce mood congruence. Finally, the model also shows some affinity with research on judgmental heuristics, insofar as affective states are thought to function as heuristic cues in informing people's judgments.

People typically rely on affect as a heuristic cue when they lack either or both the motivation and the cognitive resources to process information more extensively. This happens when "the task is of little personal relevance, when little other information is available, when problems are too complex to be solved systematically, and when time or attentional resources are limited" (Fiedler, 2001: 175). For example, some of the earliest and still most compelling evidence for the AAI model came from an experiment (Schwarz and Clore, 1983) that involved telephoning respondents and asking them unexpected and unfamiliar questions. In this situation, subjects have little personal interest or involvement in responding to a stranger, and they have neither the motivation, the time, nor the cognitive resources to engage in extensive processing. Relying on prevailing affect to infer a response seems a reasonable strategy under such circumstances. In a conceptually similar example, Forgas and Moylan (1987) asked people to complete an attitude survey on the sidewalk outside a cinema in which they had just watched either a happy or a sad movie. The results showed strong mood congruence: Happy theatergoers gave much more positive responses than did their sad counterparts. In this situation, as in the study by Schwarz and Clore (1983), respondents presumably had insufficient time, motivation, or capacity to engage in elaborate processing, and hence they may well have relied on their temporary affect as a heuristic cue to infer a reaction. Thus, depending on the task, situation, and resources at hand, either affect priming or AAI can take the lead in coloring or infusing cognition with current affect.

#### 2.15.1.2 Processing Consequences of Affect

Affective states or moods shape not only the substance of cognition but also its style. It has been proposed that positive affect recruits less effortful and more superficial processing strategies; in contrast, negative affect seems to trigger a more analytic and vigilant processing style (Clark and Isen, 1982; Schwarz, 1990; Mackie and Worth, 1991). However, more recent studies have shown that positive affect can also produce distinct processing advantages: Happy people often adopt more creative and inclusive thinking styles and display greater mental flexibility than do sad subjects (Bless, 2000; Fiedler, 2000; Isen, 2004).

Several theories have sought to explain affective influences on processing strategies. One suggestion is that the experience of a negative mood, or any affective state, gives rise to intrusive, irrelevant thoughts that deplete attentional resources, which in turn leads to poor performance in a variety of cognitive tasks (Ellis and Ashbrook, 1988; Ellis and Moore, 1999). An alternative hypothesis points to the motivational consequences of positive and negative affect: Whereas people experiencing positive affect may try to maintain a pleasant state by refraining from any effortful activity, negative affect may motivate people to engage in vigilant, effortful processing (Isen, 1984). In a variation of this idea, Schwarz (1990) has suggested that affective states have a signaling or tuning function, informing the person that relaxed, effort-minimizing processing is appropriate in the case of positive affect, whereas vigilant, effortful processing is best suited for negative affect.

These various accounts all assume that positive and negative affect decrease or increase the effort, vigilance, and elaborateness of information processing, albeit for different reasons. Recently, Bless and Fiedler (2006) have conjectured that the evolutionary significance of positive and negative affect is not simply to influence processing effort, but to trigger two fundamentally different processing styles. They suggest that positive affect promotes a more schema-based, top-down, assimilative processing style, whereas negative affect produces a more bottom-up, externally focused, accommodative processing strategy.

These strategies can be equally vigilant and effortful, yet produce markedly different cognitive outcomes by directing attention to internal or external sources of information.

These affect-induced processing differences may well have evolutionary origins, consistent with the idea that the basic function of affective states is to rapidly trigger cognitive strategies most likely to produce adaptive responses to a situation (Frijda, 1986). In other words, affect may operate like domain-specific adaptation that meets the requirements for special design (Haselton and Ketelaar, 2006; also see Forgas et al., 2007).

#### 2.15.1.3 Cognitive Benefits of Mild Dysphoria for Eyewitness Memory

Another perspective on the processing consequences of affect is provided by recent research showing that affect-induced differences in processing style have major implications for memory and memory-based social cognitive tasks, including some surprising cognitive advantages associated with mild dysphoria.

For example, a recent series of studies revealed a beneficial effect of negative affect on eyewitness memory (Forgas et al., 2005). Affect can impact eyewitness memory at any or all of three distinct stages: (1) when the event is first witnessed (encoding stage), (2) when misleading information is encountered later on (post-event stage), and (3) when the information is retrieved (retrieval stage). Several experiments examined mood effects at Stage 2 and found that positive affect promoted, and negative affect inhibited, the incorporation of false details into eyewitness memories (Forgas et al., 2005), consistent with the more attentive, accommodative processing style associated with negative affect that may have helped witnesses to identify misleading details when exposed to them (Bless and Fiedler, 2006).

In one study (Forgas et al., 2005, Experiment 1), participants viewed pictures showing a car crash scene (negative event) and a wedding party scene (positive event). One hour later, following the induction of a happy, sad, or neutral mood, participants completed a questionnaire about the scenes that either contained or did not contain misleading information. In this particular study, moods were induced by asking participants to reflect upon, write about, and emotionally relive either a positive, neutral, or negative experience from their personal past. In addition to this life-events technique, many other methods of mood modification (involving videos, music, guided

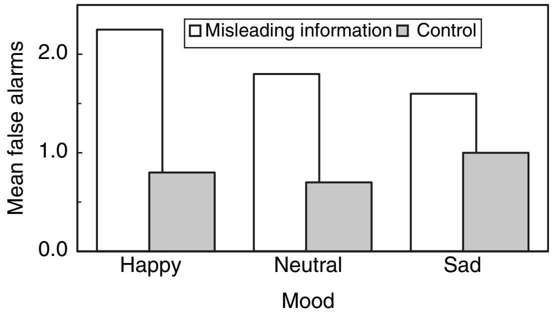

**Figure 1** Mean false alarms to misleading postevent information as a function of participants' mood (happy, neutral, or sad) and condition (misleading information previously presented versus control). From Forgas JP, Vargas P, and Laham S (2005) Mood effects on eyewitness memory: Affective influences on susceptibility to misinformation. *J. Exp. Soc. Psychol.* 41: 574–588; Experiment 1; used with permission from Elsevier.

imagery, etc.) are available to investigators in the affect/cognition area (see Coan and Allen, 2007). After an additional interval filled with other tasks, the accuracy of their eyewitness memory for the scenes was tested. As predicted, and as indicated in **Figure 1**, exposure to misleading information significantly reduced eyewitness accuracy, an effect that, remarkably, was increased by positive mood and decreased by negative mood. In fact, negative mood almost completely eliminated the familiar misinformation effect.

In a second study (Forgas et al., 2005, Experiment 2), students in a lecture hall witnessed a staged aggressive encounter between a lecturer and a female intruder. One week later, eyewitnesses to this episode were induced into a positive or negative mood and then completed a questionnaire about the episode that either did or did not contain planted, misleading information. When the accuracy of their eyewitness memory for the episode was subsequently tested, negative affect again seemed to have all but eliminated this source of error in eyewitness memory. Signal detection analyses confirmed that negative affect actually improved eyewitnesses' ability to discriminate between correct and misleading details.

Can people suppress the impact of their moods on their thinking when instructed to do so? In a third study (Forgas et al., 2005, Experiment 3), participants watched a videotape of a complex event (a wedding or a convenience-store robbery). After viewing a happy or sad videotape, they completed a short questionnaire that either did or did not contain misleading information. Some participants were also instructed to disregard and control their current affective state. Exposure to misleading information again reduced eyewitness accuracy, and did so most when people were in a happy rather than a sad mood. Instructions to control affect did not reduce this mood effect, but rather, produced an overall conservative response bias.

These experiments offer convergent evidence that negative moods can have significant adaptive effects on memory and cognitive performance, by promoting a more focused, accommodative processing style that reduced people's susceptibility to misleading information and thus improved eyewitness memory. These results are consistent with theories that predict that good and bad moods should have an asymmetric effect on processing strategies and outcomes (Forgas, 1995, Bless, 2000; Forgas, 2002).

### 2.15.1.4 Mood Congruence and the Affect Infusion Model

We have seen that affective states have clear if complex effects on both the substance of cognition (i.e., the contents of one's thoughts) and its style (e.g., whether information is processed systematically or superficially). It is also clear, however, that affective influences on cognition are context-specific. A comprehensive explanation of these effects needs to specify the circumstances that promote or impede mood congruence, and should also define the conditions likely to trigger either affect priming or affect-as-information mechanisms.

The AIM (Forgas, 1995) seeks to accomplish these goals by expanding on Fiedler's (1991) idea that mood congruence is most likely to occur when circumstances call for an open, constructive style of information processing. Such a style involves the active elaboration of the available stimulus details and the use of memory-based information in this process. The AIM thus predicts that (1) the extent and nature of affect infusion should be dependent on the kind of processing strategy that is used, and (2) all things being equal, people should use the least effortful and simplest processing strategy capable of producing a response. As this model has been described in detail elsewhere (Forgas, 1995, 2002), only a brief overview will be provided here.

The AIM identifies four processing strategies that vary according to both the degree of openness or constructiveness of the information-search strategy and the amount of effort exerted in seeking a solution. The direct access strategy involves the retrieval of preexisting responses and is most likely when the task is highly familiar and when no strong situational or motivational cues call for more elaborate processing. For example, if you were asked to make an evaluative judgment about a well-known political leader, a previously computed and stored response would come quickly and effortlessly to mind, assuming that you had thought about this topic extensively in the past. People possess a rich store of such preformed attitudes and judgments. Given that such standard responses require no constructive processing, affect infusion should not occur.

The motivated processing strategy involves highly selective and targeted thinking that is dominated by a particular motivational objective. This strategy should be impervious to affect infusion (Clark and Isen, 1982) and may produce mood-incongruent outcomes when the motivation is to control or reverse affect congruence (Forgas and Ciarrochi, 2002). For instance, if in a job interview you are asked about your attitude toward the company you want to join, the response will be dominated by the motivation to produce an acceptable response. Open, constructive processing is inhibited and affect infusion is unlikely to occur. The consequences of motivated processing should depend on the particular processing goal and may also produce a reversal of mood-congruent effects (Berkowitz et al., 2000).

The remaining two processing strategies require more constructive and open-ended information search strategies, and thus facilitate affect infusion. Heuristic processing is the kind of superficial, quick processing style people are likely to adopt when they lack motivation or resources to process more extensively (Schwarz and Clore, 1983; Forgas and Moylan, 1987). Heuristic processing can lead to affect infusion as long as people rely on affect as a simple inferential cue and depend on the 'how do I feel about it' heuristic to produce a response (Schwarz and Clore, 1988; Clore et al., 2001).

When simpler strategies such as direct access, motivated processing, or heuristic processing prove inadequate, people need to engage in substantive processing to satisfy the demands of the task at hand. According to the AIM, substantive processing should be adopted when (1) the task is in some ways demanding, atypical, complex, novel, or personally relevant, (2) there are no direct-access responses available, (3) there are no clear motivational goals to guide processing, and (4) adequate time and other processing resources are available. Substantive processing is an inherently open and constructive strategy, and affective states may selectively prime or enhance the accessibility of related thoughts, memories, and interpretations. The model makes the interesting and counterintuitive prediction that affect infusion – and hence mood congruence – should be increased when extensive and elaborate processing is required to deal with a more complex, demanding, or novel task. This prediction has been borne out by several studies that will be summarized shortly.

The AIM also specifies a range of contextual variables related to the task, the person, and the situation that jointly influence processing choices. For example, greater task familiarity, complexity, and typicality should recruit more substantive processing. Personal characteristics that influence processing style include motivation, cognitive capacity, and personality traits such as self-esteem (Smith and Petty, 1995; Rusting, 2001). Situational factors that influence processing style include social norms, public scrutiny, and social influence by others (Forgas, 1995).

An important feature of the AIM is that it recognizes that affect itself can also influence processing choices. As noted earlier, Bless and Fiedler (2006) have proposed that positive affect typically generates a more assimilative, top-down, schema-driven processing style whereby new information is assimilated into what is already known. In contrast, negative affect often promotes a more accommodative, piecemeal, bottom-up processing strategy in which attention to external events dominates over existing stored knowledge.

The key prediction of the AIM is the absence of affect infusion when direct access or motivated processing is used and the presence of affect infusion during heuristic and substantive processing. The implications of this model have been investigated in many studies involving several substantive areas in which mood congruence has been demonstrated, including affective influences on attention, learning, memory, and social cognition. The following subsections present a snapshot of some of these studies and areas.

#### 2.15.1.4.1 Mood congruence in attention and learning

Many everyday cognitive tasks are performed under conditions of considerable information overload, when people need to select a small sample of information for further processing. Affect may have a significant influence on what people will pay attention to and learn (Niedenthal and Setterlund, 1994). Due to the selective activation of an affect-related associative base, mood-congruent information may receive greater attention and be processed more extensively than affectively neutral or incongruent information (Bower, 1981; Bower and Cohen, 1982). Several studies have shown that people spend longer reading mood-congruent material, linking it into a richer network of primed associations; as a result, they are better able to remember such information (Bower and Forgas, 2000).

These effects occur because "concepts, words, themes, and rules of inference that are associated with that emotion will become primed and highly available for use . . . [in] . . . top-down or expectation-driven processing . . . [acting] . . . as interpretive filters of reality" (Bower, 1983: 395). Thus, there is a tendency for people to process mood-congruent material more deeply, with greater associative elaboration, and thus learn it better. Consistent with this notion, depressed psychiatric patients tend to learn and remember depressive words particularly well, a cognitive bias that disappears once the depressive episode is over (Bradley and Mathews, 1983; Watkins et al., 1992). However, mood-congruent learning is seldom seen in patients suffering from anxiety (Watts and Dalgleish, 1991; Burke and Mathews, 1992), perhaps because anxious people tend to use particularly vigilant, motivated processing strategies to defend against anxiety-arousing information (Mathews and MacLeod, 1994; Ciarrochi and Forgas, 1999). Thus, as predicted by the AIM, different processing strategies appear to play a critical role in mediating mood congruence in learning and attention.

#### 2.15.1.4.2 Mood congruence in memory

Several studies have shown that people are better able to consciously or explicitly recollect autobiographical memories that match their prevailing mood (Bower, 1981). Depressed patients display a similar pattern, preferentially remembering aversive childhood experiences, another kind of cognitive bias that disappears once depression is brought under control (Lewinsohn and Rosenbaum, 1987). In line with the AIM, these mood-congruent effects also emerge when people try to recall complex social stimuli (Fiedler, 1991; Forgas, 1993).

Research using implicit tests of memory, which do not require conscious recollection of past experience, also provides evidence of mood congruence. For example, depressed people tend to complete more word stems (e.g., ‘can’) with negative than with positive words they have studied earlier (e.g., ‘cancer’ vs. ‘candy’; Ruiz-Caballero and Gonzalez, 1994). Similar results have been obtained in other studies involving experimentally induced states of happiness or sadness (Tobias et al., 1992).

#### 2.15.1.4.3 Mood congruence in associations and interpretations

Cognitive tasks often require people to go beyond the information given, forcing them to rely on associations, inferences, and interpretations to construct a judgment or a decision, particularly when dealing with complex and ambiguous social information (Heider, 1958). Affect can prime the kind of associations used in the interpretation and evaluation of a stimulus (Clark and Waddell, 1983).

The greater availability of mood-congruent associations can have a marked influence on the top-down, constructive processing of complex or ambiguous details (Bower and Forgas, 2000). For example, when asked to freely associate to the cue ‘life,’ happy subjects generate more positive than negative associations (e.g., ‘love, freedom’ vs. ‘struggle, death’), whereas sad subjects do the opposite (Bower, 1981). In a related vein, mood-congruent associations emerge when emotional subjects daydream or concoct stories about fictional characters depicted in the Thematic Apperception Test (Bower, 1981). Mood-primed associations also play an important role in clinical states: Anxious people tend to interpret spoken homophones such as pane/pain or dye/die in the more anxious, negative direction (Eysenck et al., 1987), consistent with the greater activation these mood-congruent concepts receive.

Such mood-congruent effects can have a marked impact on many types of social judgments, including perceptions of human faces (Schiffenbauer, 1974), impressions of people (Bower and Forgas, 2000), and self-perceptions (Sedikides, 1995). However, several studies have shown that this associative effect is diminished as the targets to be judged become more clear-cut and thus require less constructive processing (Forgas, 1995). Such a diminution in the associative consequences of mood with increasing stimulus clarity again suggests that open, constructive processing is crucial for mood congruence to occur. This same mechanism also leads to mood congruence in more complex and elaborate social judgments, such as judgments about the self and others, as the results sketched in the following section suggest.

#### 2.15.1.4.4 Mood congruence in self-judgments

Affective states have a strong assimilative influence on memory-based judgments about the self: Positive affect improves and negative affect impairs the valence of self-conceptions. In one study (Forgas et al., 1990), happy or sad students who had scored well or poorly on a recent exam were asked to rate the extent to which their test performance was attributable to factors that were internal in origin and stable over time. Compared to their negative mood counterparts, students in a positive mood were more likely to claim credit for success, making more internal and stable attributions for high test scores, but less willing to assume personal responsibility for failure, making more external and unstable attributions for low test scores.

Of related interest is a study by Sedikides (1995), who asked subjects to evaluate a series of self-descriptions related to their behaviors or personality traits while they were in a happy, sad, or neutral mood. Based on the AIM, Sedikides predicted that highly rehearsed core conceptions of the self should be processed quickly using the direct-access strategy and hence should show no mood-congruent bias; in contrast, less salient, peripheral self-conceptions should require more time-consuming substantive processing and accordingly be influenced by an affect-priming effect. The results supported these predictions, making Sedikides’ (1995) research the first to demonstrate differential mood-congruent effects for central versus peripheral conceptions of the self.

Affect also appears to have a greater congruent influence on self-related memories and judgments made by people with low versus high self-esteem, which may reflect a parallel difference in the stability of their respective self-concepts (Brown and Mankowski, 1993). For instance, Smith and Petty (1995) observed stronger mood congruence in the self-related memories reported by low rather than high self-esteem individuals. As predicted by the AIM, these findings suggest that low self-esteem people need to engage in more open and elaborate processing when thinking about themselves, increasing the tendency for their current mood to influence the outcome.

Affect intensity may be another moderator of mood congruence. One study showed that mood congruence is greater among people who score high on measures assessing openness-to-feelings as a personality trait (Ciarrochi and Forgas, 2000). However, other studies suggest that mood congruence in self-related memories and judgments can be spontaneously reversed as a result of motivated processing strategies. Sedikides (1994) observed that after mood induction, people initially generated self-statements in a mood-congruent manner. However, with the passage of time, negative self-judgments spontaneously reversed, suggesting the operation of an automatic process of mood management. Research by Forgas and Ciarrochi (2002) replicated these results and indicated further that the spontaneous reversal of negative self-judgments is particularly rapid and pronounced in people with high self-esteem.

In summary, moods have been shown to exert a strong congruent influence on self-related memories and judgments, but only when some degree of open and constructive processing is required and when there are no motivational forces to override mood congruence. Research to date also indicates that the infusion of affect into self-judgments is especially likely when these judgments (a) relate to peripheral in contrast to central aspects of the self, (b) require extensive, time-consuming processing, and (c) reflect the self-conceptions of individuals with low rather than high self-esteem.

#### 2.15.1.4.5 Mood congruence in person perception

The AIM predicts that the more people need to think in order to compute a response, the greater the likelihood that affectively primed ideas will influence the outcome. To test this prediction, several researchers have manipulated the complexity of the subjects' task in order to create more or less demand for elaborate processing.

In one set of studies (Forgas, 1992), happy and sad participants were asked to read and form impressions about fictional characters who were described as being highly typical or highly atypical and having an odd combination of attributes (e.g., an avid surfer whose favorite music is Italian opera). The expectation was that when people have to form an impression about a complex, ambiguous, or atypical individual, they will need to engage in more constructive processing and affectively primed associations should thus have a greater chance to infuse the judgmental outcome.

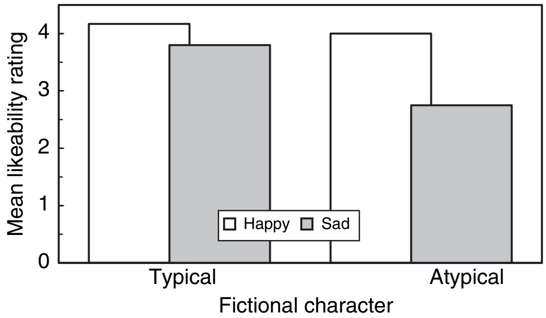

**Figure 2** Impact of participants' mood on their ratings of the likeability of typical or atypical fictional characters. From Forgas JP (1992) On bad mood and peculiar people: Affect and person typicality in impression formation. *J. Pers. Soc. Psychol.* 62: 863–875; Experiment 3; used with permission from the American Psychological Association.

Consistent with this reasoning, participants took longer to read about unusual as opposed to conventional characters. Moreover, mood-congruent effects were more pronounced when happy and sad participants judged the likeability of atypical in contrast to typical fictional characters, a finding depicted in **Figure 2**. Similar results were found in a follow-up study in which the to-be-judged targets were odd versus ordinary couples rather than individuals (Forgas, 1993).

Research investigating the impact of mood on judgments and inferences about real-life interpersonal issues paints a similar picture. For example, partners in long-term, intimate relationships showed clear evidence of mood congruence in their memories and attributions for actual conflicts, and paradoxically, these effects were greater when thinking about more serious conflicts that required more extensive processing (Forgas, 1995). These results provide direct evidence for the process dependence of affect infusion into social judgments and inferences. Even judgments about highly familiar people are more prone to affect infusion when a more substantive processing strategy is used.

Some individual-difference or personality characteristics, such as trait anxiety, can also influence processing styles and thereby significantly moderate the influence of negative mood on intergroup judgments (Ciarrochi and Forgas, 1999). Low trait-anxious whites in the United States reacted more negatively to a threatening black out-group when experiencing negative affect. Surprisingly, high trait-anxious individuals showed the opposite pattern: They went out of their way to control their negative tendencies when feeling bad and produced more positive judgments. Thus it appeared that low trait-anxious people allowed affect to influence their judgments, while high trait-anxiety combined with aversive mood triggered a more controlled, motivated processing strategy designed to eliminate socially undesirable intergroup judgments.

### 2.15.1.5 Strengths and Shortcomings of the Affect Infusion Model

To recap, the AIM attempts to account for mood-congruent effects in social cognition (Forgas, 1995). It provides a means of integrating two explanations of mood effects, namely AAI (Schwarz and Clore, 1988) and affect priming (Bower, 1981). It outlines the situations in which each process dominates and therefore is the primary method for affect to influence people's thoughts and behaviors. The model accounts well for mood effects on learning and memory (Bower and Forgas, 2000) and a wide array of affective influences on social cognition, including perceptions of others as well as oneself.

The AIM also casts light on the conditions that are more or less likely to evidence mood-congruent effects. Specifically, when processing is easy and familiar, current mood has less of an impact on task performance than when processing is more demanding, more difficult, and more unusual. Hence, it is precisely when people are paying greater attention, considering carefully, and exerting more cognitive effort that they are likely to be biased by their current, and often unrelated, mood state (Forgas, 1995, 2002).

This pattern of results has an important implication, namely, that such performance differences are more than mere responses to demand characteristics created by experimental mood manipulations, one of the oldest and thorniest issues in contemporary cognition/emotion research (see Polivy and Doyle, 1980; Bower, 1981; Ingram, 1989). Since any demand characteristics that exist should be constant across easy and difficult processing conditions, they cannot be responsible for any behavioral differences that are found between these conditions. Consequently, the greater conceptual precision provided by the AIM makes it a more parsimonious explanation of the data set as a whole.

Though the AIM connects and clarifies data from many domains, several findings are difficult to reconcile with the approach. For instance, the model suggests that negative affect encourages bottom-up, externally focused processing, but the literature on self-focused attention in depression (Pyszczynski and Greenberg, 1987) indicates that negative affect leads to more internally focused processing, proposals that are clearly in conflict.

Another troublesome subject for the AIM is mood *in*congruence, a curious phenomenon that has been seen in several studies involving autobiographical memory, person perception, and other social cognitive tasks. Parrot and Sabini (1990, Experiment 2), for instance, found that college students tended to feel happier on clear than on cloudy days – no surprise there. Yet when asked to recollect a salient experience from their high-school years, the students recalled mostly pleasant events on gloomy days and mostly unpleasant events on sunny days.

The causes of such counterintuitive results remain uncertain. The AIM is chiefly concerned with either the presence or absence of mood-congruent effects, not with the reverse. As mentioned earlier, several researchers have suggested that mood incongruence may be related to an individual's ability and desire to strategically regulate his or her mood (e.g., Sedikides, 1994; Forgas and Ciarrochi, 2002), but other factors may also play an important role.

One such factor was discovered accidentally in research (Eich, 1995) dealing with the mood-mediation theory of place-dependent memory: The idea that how well memorial information transfers from one physical environment (e.g., a sunny courtyard) to a different setting (e.g., a dimly lit room) depends not on how similar the two places look but rather on how similar they feel. On this view, place-dependent effects in human memory represent a special, and rather subtle, form of mood-dependent memory (Eich, 2007).

Participants in two studies (university undergraduates) were asked to recollect or generate as many as 16 specific episodes or events, from any time in the personal past, that were called to mind by neutral noun probes, such as ship and street. After recounting the gist of a given event (what happened, who was involved, etc.), students rated the incident along several dimensions, including its original emotionality: How pleasant or unpleasant the event seemed when it took place. Participants completed this task of autobiographical-event generation in one of two environments: either a small, dark, and spartanly furnished basement office or in a warm, inviting, and exquisitely scenic Japanese garden. The expectation, which was confirmed in both studies, was that students would generally feel happier (more pleasant, more energized) when tested in the latter locale.

Nonetheless, neither experiment provided any evidence of an overall mood-congruent effect: Mean ratings of event emotionality were statistically the same for events that had been generated in the garden versus the office. However, a different picture developed when participants were divided into two groups – aware versus unaware – based on statements they made about the aims and methods of the research in an in-depth postexperimental interview. Whereas participants in the aware group recognized that different environments might evoke different moods, those in the unaware group seemed not to appreciate the possibility of an affect/environment connection.

Among aware subjects, there was clear evidence of mood congruence: Averaging across the two studies, ratings of event emotionality were higher (i.e., more positive) for autobiographical events that had been generated in the garden than in the office. Among unaware subjects, however, the tendency was toward mood incongruence: Events generated in the happy garden were rated as being somewhat less pleasant than those that had been recollected in the sad office.

Additional evidence relating to the awareness factor comes from two recently completed studies (Eich et al., unpublished observations) that were methodologically similar to those outlined earlier in all major respects but one: The frequency with which participants were asked to reflect upon and rate their current mood before, during, and after the task of autobiographical-event generation (which again was carried out in either the garden or office locales). Following the lead of Berkowitz et al. (2000), we reasoned that the very act of assessing one's current mood would enhance awareness of a connection between that mood and the environment in which the assessment is made. In line with this reasoning, the percentage of subjects classified as aware was much higher (63% vs. 29%) in the experiment in which the students evaluated their moods repeatedly than in the otherwise identical experiment in which moods were rated infrequently.

Though it appears that awareness of an affect/environment connection helps determine whether autobiographical memories coincide or contrast with a person's current mood, exactly how and why this happens remains to be explained. The search for a theory would be aided by answers to a host of novel questions. For instance, what role does affect/environment awareness play in free association, self-judgment, person perception, and other social cognitive tasks that, like autobiographical memory, are known to be highly sensitive to mood effects? Also, is there a theoretically meaningful nexus between the concept of awareness, as it applies to mood congruence, and its applicability to other aspects of social cognition, including the influence of explicit versus implicit attitudes on behavior (Greenwald and Banaji, 1995; Greenwald et al., 2002) and the conscious versus nonconscious priming of stereotypes (Bargh and Chartrand, 1999; Bargh and Ferguson, 2000)? And is affect/environment awareness relevant not only to mood-congruent memory, but to mood-dependent memory as well (Eich and Macaulay, 2006)?

This concludes our brief look at the concept of mood congruence and of some of the ways in which affective states influence cognition in general and memory in particular. Now we turn attention from memory 'in' affect to memory 'about' affect, and take up the complex, challenging, and controversial matter of memory for traumatic events.

## 2.15.2 Memory about Affect

The effects of emotion on memory for personal events is one of the most controversial issues in all contemporary cognition/emotion research. This issue has been studied in different contexts, and in every case the only conclusion upon which everyone agrees is that the impact of emotion on memory is an extremely contentious topic. For example, in research investigating flashbulb memories for salient news events, some have proposed that emotion enhances event recollection (Conway, 1995), whereas others have argued that flashbulb memories are not especially accurate (McCloskey et al., 1988; Neisser and Harsch, 1992). Similarly, in studies involving eyewitness memory, whereas some have claimed that emotion promotes eyewitness performance (Yuille and Cutshall, 1986), others have maintained that emotion impairs eyewitness memory (Loftus and Burns, 1982). While discussion of the role of emotion has been contentious in both the domains of news events and eyewitness memory (for a review, see Schooler and Eich, 2000), in no domain are the paradoxical claims regarding the effects of emotion on memory more evident than in the territory of trauma. The remainder of the chapter will focus on memory for traumatic events.

### 2.15.2.1 The Memory Wars

How people remember and forget trauma has been among the most polarized, controversial debates in the history of psychology and psychiatry (Loftus, 1997; McNally, 2003). Especially bitter has been the controversy regarding the authenticity of reportedly repressed and recovered memories of childhood sexual abuse (CSA). This controversy has sometimes been dubbed the memory wars (Crews, 1995; Schacter, 1995).

Some scholars believe that the mind protects itself by repressing or dissociating traumatic events from awareness, making it difficult for victims to remember their most horrible experiences until many years later. As Brown et al. (1998: 97) have argued, "when emotional material reaches the point of being traumatic in intensity – something that cannot be replicated in artificial laboratories – in a certain subpopulation of individuals, material that is too intense may not be able to be consciously processed and so may become unconscious and amnesic." Conversely, many psychologists hold that abuse, combat, and other overwhelmingly horrifying events are ostensibly imprinted in memory and are seldom, if ever, truly forgotten (Pope et al., 1999; McNally, 2003; Kihlstrom, 2004). For example, Roediger and Bergman (1998: 1095) remarked that it is "mysterious how painful events, banished to an unconscious state for years through mechanisms of dissociation or repression, could be brought back to consciousness and recollected with great fidelity."

Additionally, skeptics have warned that memories may be susceptible to distortions (Schacter, 1999) and that therapeutic interventions such as hypnosis, dream interpretation, and imagination – intended to recover memories of CSA – may unintentionally foster pseudo-memories of CSA (Loftus, 1993; Lindsay and Read, 1994). Thus, McNally (2005: 815) maintained that "the movement to help survivors recall these allegedly repressed memories resulted in the worst catastrophe to befall the mental health field since the lobotomy era."

### 2.15.2.2 Remembering and Forgetting Trauma

Since the onset of the memory wars, a multitude of studies have addressed whether traumatic memories can be forgotten. A number of retrospective and prospective studies of CSA have found a nontrivial proportion of victims saying that they at some point in their life had not remembered their abuse. For example, in one of the most widely cited retrospective studies, Briere and Conte (1993: 24) asked 450 patients in treatment for CSA the following question: "During the period of time between when the first forced sexual experience happened and your eighteenth birthday, was there a time when you could not remember the forced sexual experience?" Fifty-nine percent of the patients answered that there had been such a time. Accordingly, Briere and Conte concluded that a substantial number of survivors experience sexual abuse-related repression of their traumatic memories prior to recovering the memories later in life.

However, due to methodological limitations, this study cannot be taken as support for massive repression. First, participants in the study were patients possibly exposed to therapeutic techniques likely to foster memories of abuse (Poole et al., 1995). Also, as in many studies in this domain, it was not established whether the recalled abuse had actually happened. Moreover, the duration of amnesia for trauma was unspecified. Perhaps the most important issue concerns the question that respondents were given. In a way, this question was formulated in an ambiguous way. Thus, McNally and colleagues pointed out that participants were more likely answering a different question: "Was there ever a time that you did not think about having been abused?" (McNally et al., 2004: 131). That is why an affirmative answer to this question does not necessarily provide solid evidence for the type of massive repression put forward by CSA researchers. Instead, such a positive reaction might simply mean that those who experienced CSA can sometimes manage not to think about the abuse. These and other critical points have also been made with regard to similar retrospective studies published in the last 15 years.

A much smaller number of studies have used a prospective methodology to assess whether traumatic events can be forgotten. In an influential study by Williams (1994), 129 women with previously documented histories of CSA were interviewed. Of these, 38% failed to report the index event of abuse for which Williams had a record. Some authors have interpreted these data as showing that massive forgetting of trauma is not only possible, but even very common. However, there are several other, more likely explanations. A majority of the participants, 68%, who had apparently forgotten the index event of abuse did report other abuse events, suggesting that the index event may have merely been less traumatic or less important to them than other instances of CSA. Given that several women had been abused when they were younger than 5, not remembering the abuse might be the result of childhood amnesia. Moreover, one can argue that the younger the child at the time of the index event, the more likely she is to fail to understand the abuse as sexual at the time. Also, other women may not have wanted to label themselves as abused and/or disclose such personal matters to the interviewer. Thus, a failure to disclose cannot be regarded as evidence of repression (Loftus et al., 1994).

A study by Goodman and colleagues (2003) provides further data on failure to disclose abuse. They assessed 168 persons who had been involved in legal proceedings concerning sexual abuse. These proceedings occurred when the persons were approximately 9 years old. A survey was administered 13 years after the persons had been involved in the legal proceedings. Questions about sexual abuse were inserted in a longer survey concerning legal attitudes and experiences. Results revealed that about 16% failed to report the target incident during a telephone interview conducted approximately 13 years after the events in question. Nondisclosure dropped to 8% after follow-up by a mailed questionnaire and a telephone interview. Moreover, an in-depth analysis by Goodman and Paz-Alonso (2006) yielded a reduced estimate of 4% for the incidence of traumatic amnesia. As these studies indicate, claims of widespread repression and recovery of childhood abuse have been exaggerated. Accordingly, Goodman et al. (2003) concluded that the findings, rather than supporting the existence of special memory mechanisms unique to traumatic events, instead imply that normal cognitive operations underlie long-term memory for CSA.

### 2.15.2.3 False and Recovered Memories

Another possibility for the impression that one has harbored repressed memories is that a failure to remember traumatic events took place because such events did not actually occur in the first place (Loftus, 1998). On first impression, the idea that someone might remember having experienced a trauma that never took place seems an unlikely account for repression. Yet, people have recollected atrocities that never happened and have been experiencing the emotional pain paralleled with their belief in the authenticity of their memories. Some of the improbable traumatic events for which people claim to have recovered memories in recent years involve satanic ritual abuse (Scott, 2001) and abduction by space aliens (Mack, 1994; Clancy, 2005), memories which are occasionally 'recovered' during psychotherapy. In reviewing the influence of psychotherapy, Lindsay and Read (1994: 304) concluded that "there are good reasons to believe that: (1) some recollections produced by intensive memory recovery may be false; and (2) when such techniques are used it is very difficult to discriminate between clients who are remembering accurately and clients who believe they are remembering accurately but are not."

The fact that a growing number of former patients have retracted their claims of CSA also suggests that false CSA memories can be induced by therapists. Most retractor cases involve adults who had sought psychotherapy for depression or related complaints. During therapy, memories of CSA were recovered. However, later patients come to believe that the 'recovered memories' were only products of therapeutic suggestion (e.g., Ost et al., 2002).

In the 1990s, the experimental research community responded in earnest to these frequent memory reports by patients claiming their experiences had been previously repressed. If these memories were not authentic, where could they have come from? If they were false, how could they develop? With these questions in mind, several lines of research on the development of false beliefs and memories began to flourish (for reviews, see Laney and Loftus, 2005; Smeets et al., 2005). One of the best-known tasks that has been strikingly successful in creating pseudo-memories in the laboratory is the Deese-Roediger-McDermott (DRM) paradigm (Deese, 1959; Roediger and McDermott, 1995). In this task, participants often falsely recall and recognize a nonpresented word or critical lure (such as 'sleep') following presentation of several of its strongest associates ('bed, rest, awake, tired,' and the like).

The DRM paradigm relies on semantic material. Yet, apart from semantic material, research has demonstrated that techniques such as imagination inflation (Garry et al., 1996), dream interpretation (Mazzoni et al., 1999), and suggestions containing incorrect feedback (Crombag et al., 1996; Hyman and Billings, 1998; Jelicic et al., 2006) may create false beliefs and pseudo-memories. Moreover, recent studies have successfully employed doctored photographs (e.g., a youngster riding in a hot-air balloon) to suggest childhood events that never happened to the child or adult participants (Wade et al., 2002). Additionally, studies have shown that experimental manipulations intended to implant pseudo-memories may have overt behavioral consequences (Bernstein et al., 2005).

### 2.15.2.4 Recovered Memories in the Laboratory

Remarkably, until recently no studies had been conducted on the cognitive functioning of people in the center of this recovered-memory debate: those who report repressed and recovered CSA memories. This state of affairs could be due to the fact that few clinicians have expertise in laboratory research and few cognitive psychologists have access to trauma populations (McNally et al., 2004). In fact, Richard McNally and Susan Clancy of Harvard University were the first to apply experimental methods to investigate memory functioning in people reporting repressed and recovered memories of CSA. By doing so, their studies have tested hypotheses relevant to mechanisms implicated in the ability to repress and recover traumatic memories, as well as mechanisms relevant to forming pseudo-memories of trauma (McNally, 2003). For example, they examined whether individuals reporting recovered CSA memories are more prone to false memory effects induced in the laboratory (Clancy et al., 2000). In one of their studies, they used the previously described DRM paradigm to show that, relative to individuals with continuous memories and controls with no history of abuse, individuals reporting recovered CSA memories more often falsely recognized the nonpresented critical lures. Subsequently, these findings were extended to trauma-related material (Geraerts et al., 2005). That is, besides neutral DRM lists (e.g., critical lure 'sleep'), trauma-related lists (e.g., critical lure 'assault') were employed. It was found that individuals reporting recovered abuse memories are more prone to falsely recalling and recognizing neutral and trauma-related words that were never presented.

Several researchers have argued that such susceptibility to false memories may be due to a source-monitoring deficit, that is, incorrect judgments about the origin or source of information (Johnson et al., 1993). For example, subjects may think of the nonpresented lure at study, so then at test they must differentiate between memories of internally generated thoughts versus memories of the studied words. Results reported by Clancy et al. (2000) and by Geraerts et al. (2005) suggest that individuals reporting recovered CSA memories may have a source-monitoring deficit for all types of material, whether the content is neutral or trauma-related. It can be speculated that these individuals have a tendency to adopt an internally generated thought as being a genuine memory. This could have important implications, both in terms of the development of false memories *per se* and in terms of the development of mistaken beliefs. Thus it may be that a subsample of those with recovered memories developed false memories via a subtle interaction between intrinsic source-monitoring difficulties and suggestive therapeutic techniques.

### 2.15.2.5 Underestimation of Prior Remembering

Although the research above suggests that recovered memories are likely to be false memories, Schooler and coworkers (e.g., Schooler et al., 1997; Shobe and Schooler, 2001) described several case studies of individuals who experienced the discovery of apparently long-forgotten memories of abuse, memories for which corroborative information could be found. Interestingly, in two of the cases the partners of the women who reported full-blown recovered-memory experiences said that the women had talked about the abuse before they had the recovered-memory experience. In both cases, the women seemed to be surprised to discover that they had talked about the abuse prior to their recovered-memory experiences. Schooler and colleagues proposed that these cases illustrate a forgot-it-all-along (FIA) phenomenon, which at its core entails the underestimation of prior recollections of past events.

Recent studies have provided elegant laboratory analogs of this FIA phenomenon. For example, a series of experiments by Arnold and Lindsay (2002, 2005) required participants to recall material in qualitatively similar versus different ways on two occasions. They argued that if the retrieval of CSA memories in qualitatively different ways can lead to the underestimation of previous CSA recollections, then this mechanism should transfer into the lab. In the basic procedure, participants studied a list of homographic target words, each accompanied by a biasing context word (e.g., hand: PALM). In Test 1, participants were tested on a subset of the study list, with some of the target items being cued with the studied-context word (e.g., hand: P–M) and the rest of the items cued with another-context word (e.g., tree: P–M). In the final test, participants were tested on all of the studied items, and the studied-context cues were always given as recall prompts. Additionally, after recalling each word, participants were required to judge whether they had recalled that word on Test 1. The key result was that participants more often forgot their prior recall of the words when they had been cued with the other-context cue than with the studied-context cue on Test 1. Hence, these results provided compelling evidence that remembering a past event in a different way can result in a failure to remember a prior instance of recalling that event.

Recently, the link between the FIA effect and recovered memories has been studied in the laboratory by Geraerts et al. (2006). The issue of interest was whether individuals reporting recovered CSA memories are more prone to underestimating their prior remembering, relative to individuals with continuous CSA memories and controls reporting no history of abuse. Using Arnold and Lindsay's (2002) FIA test, Geraerts et al. (2006) found that participants with recovered CSA memories were found to be more prone to forget that they had previously recalled a studied item when they had been cued to think of it differently on two recall tests. That is, the FIA effect was larger in those who reported recovered memories.

In a related study, Geraerts et al. (2006) asked participants to recall autobiographical events (e.g., being home alone as a child) in an emotionally negative or positive framing across three test sessions over a period of 4 months. Given the cue 'being home alone as a child,' for example, a participant assigned a positive framing for that event might recall enjoying the feeling of freedom of having the house to himself/herself; the same participant assigned a negative framing for that event in session 2 might reminisce about feeling lonely after a while.

In the first session, participants were instructed to recall 25 selected events in either a positive or negative frame. After 2 months, participants were asked to recall 16 of the target events a second time. For half of the trials, the framing cue presented with the events corresponded to the negative/positive framing cue presented with the autobiographical events during the first session, whereas for the remaining trials the framing was the opposite from the framing cue presented in the first session (i.e., positive framing if the framing on the first session had been negative, and vice versa). In session 3, again 2 months later, participants were tested on all the target events, accompanied by the framing cues that were presented with the targets during session 1. Again, individuals reporting recovered CSA memories showed an enhanced FIA effect relative to individuals with continuous abuse memories and controls, even when mildly emotional autobiographical material was used over a period of 4 months, conditions that more closely mirror everyday life (if not memories of trauma). These findings imply that some of the participants' recovered CSA memories may be fundamentally accurate, but that these individuals may have underestimated their prior memories for the abuse.

### 2.15.2.6 Discovered or False Memories?

The two basic findings discussed above – source monitoring deficits and the FIA effect – suggest radically different interpretations of recovered memories. On the one hand, studies by Clancy et al. (2000) and Geraerts et al. (2005) show that reports of recovered memories are associated with false memory effects as measured by the DRM task. Conversely, the results reported by Geraerts et al. (2006) indicate that recovered memory reports are intimately related to underestimation of prior remembering. However, it seems implausible that one and the same report of a recovered memory could be linked both to false memory effects and to the underestimation of prior remembering. How can these phenomena be integrated? Careful inspection of the precise types of recovered memory experiences may provide an answer to this question.

Two clearly distinguishable types of recovered memory experiences have been documented in the literature (e.g., Shobe and Schooler, 2001). In one type, people come to believe that they are abuse survivors, commonly attributing their current life difficulties to their repressed memories of abuse. Here, abuse events tend to be recalled gradually over time, often by suggestions of a therapist. People usually indicate that they have 'learned' (e.g., through hypnosis) that the abuse occurred to them. In the other type of recovered memory experience, people are suddenly reminded of events they believe they had not thought about for many years. They are shocked and surprised by their recollection, but not by the content of the memory as such. This kind of recollection differs from the one in which the person is gradually recalling the abuse, often in the course of therapy. For this reason, Schooler and coworkers (Schooler et al., 1997; Schooler, 2001) referred to these suddenly recovered memories as discovered memories, reflecting situations "in which individuals sincerely perceive themselves to have discovered memories of experiences of which they think they had previously been unaware" (Shobe and Schooler, 2001: 100). This term keeps open the possibility that individuals could have discovery experiences corresponding to memories that were not completely forgotten.

Given these two types of recovered-memory experiences, it is not too farfetched to speculate that people who report CSA memories recovered during therapy may score high on tasks yielding false memory effects, like the DRM task. Yet, they may perform similarly to control participants on tasks tapping the FIA effect. Conversely, one would expect that people with spontaneously recovered memories would be especially prone to the FIA effect, whereas they would score similarly to controls on false memory tasks, such as the DRM. Preliminary analyses of the data collected in several studies with individuals reporting recovered CSA memories indicate that this is the case (Geraerts, 2006).

### 2.15.2.7 Corroborative Evidence of Abuse

Recent research supports the view that CSA memories discovered outside of therapy are more likely to reflect genuine events relative to memories recovered in therapy (Geraerts et al., 2007b). In this study, people with recovered CSA memories responded to an extensive memory questionnaire. Participants were asked to characterize their prior degree of forgetting, the quality of their memory recovery if they had one, the nature and context of the abuse, and the qualities of their current memory. Moreover, information was sought to verify or corroborate the CSA memories. Memories were characterized as corroborated if one or more of the following three criteria were met: (a) another individual reported learning about the abuse soon (i.e., within the next week) after it occurred, (b) another individual reported having also been abused by the alleged perpetrator, or (c) another individual reported having committed the abuse him/herself. The presence of corroborative evidence was evaluated by two raters blind to any additional information associated with each case.

Results revealed that memories recovered unexpectedly, outside of therapy, were significantly more verifiable than memories that were reported to have been gradually recovered within the context of therapy. As indicated in **Table 1**, abuse events recovered during therapy could not be verified, while 37% of the CSA memories discovered outside of therapy were independently corroborated; the latter figure is similar to the 45% verification rate found for continuously accessible memories. These results support the view that memories recovered unexpectedly outside of therapy (i.e., discovered memories) are more likely to correspond to genuine abuse events, relative to memories recovered in therapy.

**Table 1** Percentage of memories of childhood sexual abuse that could or could not be corroborated

| | *Corroboration* | |
|---|---|---|
| *Participant group* | *Yes* | *No* |
| Continuous recollection | 45% (32) | 55% (39) |
| Recovered out of therapy | 37% (15) | 63% (26) |
| Recovered in therapy | 0% (0) | 100% (16) |

Number of participants per condition is enclosed in parentheses.
Source: Geraerts E, Schooler JW, Merckelbach H, Jelicic M, Hauer BJA, and Ambadar Z (2007b) The reality of recovered memories: Corroborating continuous and discontinuous memories of childhood sexual abuse. *Psychol. Sci.* 18: 564–568; used with permission from Blackwell Publishing.

Moreover, in this study, 85% of participants reporting recovered memories failed to appreciate their abuse as traumatic at the time it occurred, in part due to lack of understanding the nature of the event (for related results, see Clancy and McNally, in press). In fact, many of them rated the abuse as being more traumatic now than it was at the time of the abuse. This was especially the case for participants who suddenly recalled long forgotten and often corroborated episodes of abuse. Several of them were exposed to one or sometimes more episodes of abuse that were nonpenetrative (e.g., fondling). Such events were experienced as confusing or distressing but not essentially frightening. Individuals reporting them might have managed not to think about these experiences, particularly if retrieval cues were absent (e.g., in cases in which the victim or the perpetrator had moved away). Years later, appropriate retrieval cues might be encountered, triggering the recollection of the long-forgotten abuse experiences, which the person now correctly understands to be sexual abuse. This realization often is accompanied by an onrush of emotions which is interpreted as the impact of remembering something for the first time.

Although such cases undoubtedly qualify as recovered/discovered memories of sexual abuse, they cannot be taken as evidence for amnesia. Contrary to the standard view of repression, people do not forget their abuse in the strict sense of the word, because the abuse was neither perceived as traumatic nor recognized as abuse. No special mechanisms, such as repression or dissociation, have to be put forward to clarify why these misapprehended abuse experiences did not come to mind for many years. Also, no special mechanisms such as repression are needed to explain reports of CSA memories recovered during therapy. Memories recovered during therapy, as well as discovered memories, both render a scenario in which a false impression of previous nonavailability of abuse memories arises, while in fact, no special mechanisms such as dissociation or repression are needed to account for these impressions of repression.

#### 2.15.2.8 Mechanisms of Traumatic Memory

Does traumatic memory involve special mechanisms? According to one popular view known as the trauma-memory argument, memories of traumatic events have special properties that distinguish them from ordinary memories (for a critical discussion, see Kihlstrom, 1996). In this view, traumatic memories are qualitatively different (i.e., processed and stored differently) from other types of memories, thereby involving mechanisms different from those associated with general memory functioning (van der Kolk, 1996). This view asserts that many survivors of a trauma invoke mechanisms such as repression and dissociation, which result in dissociative amnesia for the stressful event itself. Moreover, it is contended that survivors of a trauma suffer from intrusions with strong sensory qualities. This dissociative style of processing would also create a substantial overlap between dissociative and posttraumatic stress disorder symptoms. There are several versions of this theoretical stance (Brewin et al., 1996; Ehlers and Clark, 2000), but the core assumption they have in common is that trauma has a special impact on the way in which memories of the traumatic event are organized (for discussions, see Kihlstrom, 1996; Shobe and Kihlstrom, 1997; Kihlstrom, 2006; for a reply, see Nadel and Jacobs, 1998).

Although the trauma-memory argument has gained popularity among many clinicians, some findings argue against this view. Systematic studies suggest that only a small minority of war victims report dissociative amnesia. For example, Kuch and Cox (1992) studied 124 Holocaust survivors and found that dissociative amnesia, with an estimated lifetime prevalence rate of 3%, was quite rare in this group. Likewise, Merckelbach and colleagues (Merckelbach et al., 2003) found in a group of 29 Dutch concentration camp survivors only one survivor reporting mnemonic experiences that might be taken as evidence for dissociative amnesia. The authors noted that in this case there was a serious possibility that drug abuse contributed to the poor memory of the traumatic episode. Similarly, Geraerts and colleagues (Geraerts et al., 2007a) found that in a sample of Croatian war veterans who had been confronted with extremely aversive events during the Balkan wars, dissociative amnesia was rarely reported. In sum, several recent findings do not support the existence of special memory mechanisms that are unique to traumatic events.

## 2.15.3 Integrating Memory in and about Affect

In the preceding pages, we have treated memory in and about affect as distinct topics. Such a treatment was possible because research on mood-congruent cognition has had relatively little overlap with research on memory for traumatic events. Nevertheless, consideration of these topics together invites exploration of the possible empirical and theoretical issues that might unite them. To this end, we close with a discussion of potential ways in which the principles and findings of mood congruence might apply to understanding the processes leading to reports of recovered memories of trauma.

### 2.15.3.1 Connections between Mood Congruence and Traumatic Memory

According to the AIM, the motivational and resource demands of the situation determine which of two distinct processes – affect priming or AAI – mediate mood-congruent effects. Given the variable conditions under which individuals can think about traumatic experiences, it seems likely that each of these processes might influence recovered memory reports under different circumstances.

#### *2.15.3.1.1 Affect priming*

When individuals are highly motivated, have sufficient resources, and are elaborating on self-relevant information, they are likely to experience affective infusion, whereby the information that is generated/attended to is shaped in accordance with the present mood, presumably through a process of affect priming. When individuals are in therapy they are talking about issues of immense self-relevance. They experience powerful emotions. They are highly motivated to think through their experiences. And with the therapists' support, they are likely to have adequate resources to engage in elaborative systematic processing. Thus therapy potentially provides an extremely fertile ground for the priming of affect-related memories, thoughts, perceptions, and other cognitive constructions. From this perspective, it seems possible that affect priming, when combined with a therapist's suggestions, could spawn false memories. For example, if therapy invokes emotions of betrayal and trauma, then affective infusion might facilitate the adoption of suggested memories that are consistent with those emotions.

Admittedly, negative emotional states can minimize susceptibility to suggestion, whereas the above characterization proposes that therapy-induced negative emotions might enhance suggestibility. Importantly, however, the reduced susceptibility to misinformation reviewed in this chapter involved minor details of little self-relevance, and not in accord with the induced negative affect participants were experiencing. In contrast, therapy-suggested experiences of abuse would be highly self-relevant and likely in accord with the emotional state that the patient is experiencing at the time. Thus, in the context of therapy, the capacity for affect priming to generate affectively matched cognitions may outweigh the capacity for negative emotions to reduce suggestibility, thereby leading to a net increase in false memories.

Though speculative, the suggestion that affect priming could be a source of therapy-induced false memories might be empirically explored by examining whether the match between an affective state and a memory suggestion affects the generation of false memories. For example, in the imagination inflation paradigm (Garry et al., 1996), imagining events, such as putting one's hand through a window or finding a 10-dollar bill, increases the perceived likelihood that these events occurred. If affect priming enhances false memories in therapy, then it seems likely that imagination inflation might similarly be associated with affect-infusion (or mood-congruent) effects. Accordingly, participants may be more likely to believe they had once found a 10-dollar bill if they imagine this in a good mood, or more likely to believe they put their hand through a window, if they imagine this in a bad mood. Such a findings would suggest that affect priming could be an even greater source of false memories in the substantially more emotional and self-relevant context of therapy.

#### *2.15.3.1.2 Affect-as-information*

In the secure atmosphere of therapy, individuals are likely to have the resources to think about traumatic experiences using elaborative systematic processing. However, when memories of abuse arise unbidden and out of therapy, the emotional onrush can be overwhelming. Individuals reporting memory discoveries outside of therapy describe their experience with terms such as stunned, chaos in my emotions, overwhelmed, and like a ton of bricks just hit me (Schooler, 2001).

According to the AIM, in a situation in which cognitive resources are overwhelmed by emotion, it is likely that AAI processes would take place. In keeping with this view, Schooler (2001) speculated that AAI may lead individuals to infer, based on their profound affective experience of discovery, that they must be remembering the abuse for the first time. According to this discovery misattribution account, individuals confuse the emotion associated with discovering a new interpretation of the experience with that of discovering the memory itself.

Several strands of evidence support a discovery misattribution account whereby individuals use the affect associated with discovering a new understanding of their experience to falsely infer that they have discovered a forgotten memory. First, both of the original cases of misconstrued forgetting involved individuals who reported experiencing an overwhelming onrush of emotion after reinterpreting their abuse experiences (Schooler, 2001). For example, one case involved a woman who reported having been raped while hitchhiking. In her recounting of her memory, she reported that originally she had thought of the experience as a sexual experience gone awry, indicating that she had "made such a mess of it . . . by resisting what I thought was supposed to be a sexual experience" (Schooler, 2001: 120). However, following the onrush of emotions associated with her memory discovery, she reported thinking "my God . . . I had been raped! . . . that's a crime! I was 16, just a kid" (Schooler, 2001: 121). Similarly, in the large-scale corroborative effort by Geraerts et al. (2006), change in interpretation was one of the best predictors of memories being characterized as previously forgotten.

Laboratory research also provides evidence for discovery misattribution. For example, the experience of discovering the solution to an anagram can be confused with the experience of remembering having seen the word corresponding to the anagram's solution (S. Dougal and J. W. Schooler, unpublished observations). Together these strands of evidence suggest that the reduced resources associated with the emotional onrush of realizing that one was the victim of abuse, could enable an AAI process whereby individuals misattribute the emotion of discovering a new understanding of the event to that of discovering the memory itself.

### 2.15.3.2 Final Thought

Memory research has come a long way since the time that it shunned emotion. Our review of the role of emotion in and about memory reveals that there is much that simply could not have been known about memory, were memory researchers to have remained limited to the random-word-list paradigms that were the bread-and-butter of memory experiments for so many years. Not only did such paradigms lack the emotional manipulations that have proven to be so informative, but by ignoring elaboration and self-relevance, these procedures were inherently insensitive to many of the consequences of affect. Moreover, understanding memory for emotional events necessarily requires researchers to leave the confines of their laboratories and explore the far more complex situations in which traumatic memories actually take place.

Nevertheless, consideration of the relations between traumatic-memory reports and performance on basic word-list paradigms has yielded critical insights into the processes underlying the formation of recovered-memory reports. Thus, while memory in and about affect illustrates just how far memory research has come, its also illuminates the value of remembering its roots.

## Acknowledgments

Preparation of this chapter was aided by grants from the National Institute of Mental Health (to Eric Eich), the Netherlands Organization for Scientific Research (NWO 446-06-002, to Elke Geraerts), the Social Sciences and Humanities Research Council of Canada (to Jonathan Schooler), and the Australian Research Council (to Joseph Forgas).

# 2.16 Retrieval Processes in Memory

**S. Rajaram and S. J. Barber**, Stony Brook University, Stony Brook, NY, USA

## 2.16.1 Retrieval Processes in Memory

A dominant framework during the past four decades has postulated three critical components to understanding memory – encoding, storage, and retrieval. But the relative importance that researchers have attributed to each of these components has varied over the course of history. In his 2000 chapter for the Tallinn Conference, Roediger traced this history by taking as his departure point Endel Tulving's remark, "the key process in memory is retrieval." Roediger noted that, despite the fact that the role of retrieval had been emphasized since the writings of Wolfgang Kohler (1947) and Richard Semon (1921; see Schacter, 1982, 2001; Schacter et al., 1978), the belief that encoding and storage processes are the key components of memory has persisted through recent history. Roediger then elaborated both the logical and empirical arguments to demonstrate why retrieval is the key process for understanding human memory (Roediger and Guynn, 1996; Roediger, 2000). The purpose of the current chapter is to reinforce and expand upon this argument.

It is reasonable to assume that without encoding and storage of information there can be no retrieval. But the converse is truer – without retrieval there is no evidence that either encoding or storage ever occurred. Furthermore, retrieval can occur even in the absence of encoding, as in the case of false memories. Retrieval processes thus provide a measure of not only what was encoded and stored but also of what constitutes memory from the perspective of the rememberer – regardless of the reality of that memory. In essence, retrieval then is the measure of memory.

In emphasizing the importance of retrieval processes, Tulving and Pearlstone (1966) proposed a critical distinction between the availability and the accessibility of information. Importantly, they proposed that what is available in memory cannot be known unless that information is accessed. If accessibility is the key to determining the availability of memory, then how can we determine what is accessible? The answer to this question depends on our understanding of the retrieval conditions that can successfully detect encoding and storage. In other words, our measure of what is available in memory is contingent on being able to arrange retrieval conditions that can elicit available memories. It follows then that an understanding of retrieval processes is crucial for understanding the nature of memory.

In this chapter, we have organized the discussion of retrieval processes into six sections: (1) task differences – the role of retrieval cues, (2) encoding and retrieval interactions, (3) retrieval mode, (4) repeated retrieval, (5) retrieval in a social context, and (6) retrieval errors and other retrieval effects. Many of these sections are the very topics of some of the other chapters in this volume and are covered comprehensively in those chapters. We bring together these topics here to evaluate their significance specifically in the context of retrieval and to determine how these phenomena and processes reveal something about the nature of retrieval process *per se.*

## 2.16.2 Task Differences – The Role of Retrieval Cues

Numerous studies have now amply demonstrated the critical role retrieval cues play in revealing availability of memory. These studies were inspired by a wide variety of theoretical frameworks, and as such they can be organized under a number of different subtopics. Regardless of the theoretical perspectives that inspired these studies – and we will discuss some of these perspectives in the course of this chapter – we include them here because they also underscore the importance of retrieval cues.

Some retrieval cues are internal, as in the case of the most quintessential of all memory tasks, free recall. In this task, participants are given no cues and are asked to write down all the studied information that they were presented earlier. As such, participants rely on their own internal resources – strategies, organization, and cues – to report studied information while performing the free recall task. Retrieval cues can also be external, and in this case the variety of retrieval tasks designed with different cues can span a wide realm, depending on the experimenter's theoretical needs. The most common of such tasks are cued recall and recognition, and we will discuss some findings that show the efficacy of these tasks in improving accessibility to learned information.

In their seminal study, Tulving and Pearlstone (1966) reported the extent to which accessibility can differ just between free-recall (where the cues are internal) and cued-recall (where the cues are external) tasks. In this experiment, participants studied categorized word lists, which consisted of a category name followed by a list of words (of varying length – 12, 24, or 48 words per list) that represented instances of that category. Later the participants were given either a free-recall test or a cued-recall test, the difference between these two tests being that the cued-recall test provided participants with the category names of each word list. Results indicated that participants were able to recall many more words under cued-recall conditions than under free-recall conditions. Furthermore, the benefit of cued recall over free recall increased as the number of words on the to-be-remembered list increased. These results have been interpreted as evidence that not all information that is available is also accessible. Accessibility depends upon the type of cues provided at test.

This demonstration can be expanded by adding tasks that provide even more external cues than those used in the category/cued-recall task. Under such conditions, we would expect memory output to increase as the information provided by the retrieval cues increases – as long as the encoding conditions across these memory tasks remain the same. This scenario can be found in another landmark paper by Tulving (1985), where he introduced the remember–know paradigm. We will discuss this paradigm in a later section on 'Retrieval mode,' but for now, we focus on the inclusion of a third task in Tulving's study. Subjects first studied category names and exemplars (musical instrument–viola) and later completed three successive memory tasks – free recall, category-cued recall (where the category name served as the retrieval cue, e.g., musical instrument–__________), and category plus letter recall (where, in addition to the category name, the first letter of the exemplar was also presented as the retrieval cue, e.g., musical instrument–v________). As the retrieval cues increased, so did the memory output. A recent study in our lab (Hamilton and Rajaram, 2003) replicated and extended this pattern by adding a fourth memory task to the mix – the recognition-memory task. In this task, the test cues completely recapitulate the study cues and by so doing provide maximal assistance for retrieval. We changed the design further by conducting these tests in a between-subjects design such that successive retrieval was not required and the efficacy of different cues could be assessed without contamination from the other retrieval tasks. Our aim in expanding and changing the design concerned issues of memory experience that we do not discuss here. Instead, we focus here on the overall memory performance across the four tasks. With our design, we replicated and expanded on Tulving's (1985) results such that memory output increased as retrieval cues increased, with the highest level of performance occurring in the recognition task (mean proportions of total items correctly retrieved: free recall = .21; category-cued recall = .40; category plus letter-cued recall = .56; recognition = .87 (Hamilton and Rajaram, 2003, Experiment 2), collapsed across the levels of processing manipulation discussed in the next section). Our results further illustrate how retrieval cues can change accessibility. We will return to role of retrieval cues in a later section on retrieval modes.

To summarize, as the number of cues available at retrieval increases, so does the memory output. This fact is important in distinguishing between memories that are available but simply inaccessible. Information that cannot be recalled during a free-recall task may be available, but currently inaccessible. That same information may be recalled during a recognition task.

## 2.16.3 Encoding and Retrieval Interactions

Studies discussed in the previous section show how increased retrieval cues can improve memory performance. This conclusion rests on the assumption that, when retrieval cues are varied, the encoding conditions are held constant. This assumption is the converse of a popular approach where encoding conditions are varied while the retrieval task is held constant. One of the most robust and enduring examples of the latter approach is the levels-of-processing paradigm. In their classic paper, Craik and Lockhart (1972) presented the levels-of-processing framework in which information encoded for its meaning is predicted to be more memorable than information processed at more 'shallow' levels such as focusing on the sound of the word or the letter patterns. This pattern of performance has now been replicated hundreds of times and is routinely observed in the standard memory tasks (Lockhart and Craik, 1990). For example, in the second experiment of our study described in the previous section (Hamilton and Rajaram, 2003), we observed the levels-of-processing effect within each of the four retrieval tasks – free recall, category-cued recall, category-plus-letter recall, and recognition. That is, within each task the level of memory output was consistently higher for items encoded for meaning than for items encoded at a shallow level. Even so, as we noted before, memory output increased as retrieval cues increased, and this pattern was true both for items that were encoded at a deep level and for items encoded at a shallow level.

Yet task differences can change memory accessibility in another way – different retrieval cues can interact differently with the encoded information when the encoding is also varied. Such encoding–retrieval interactions change memory performance in specific ways in contrast to the general effects illustrated in the empirical example above. The idea of encoding–retrieval interactions is embodied in the encoding specificity principle (Tulving and Osler, 1968; Tulving and Thomson, 1973; Tulving, 1974) and the transfer-appropriate processing framework (Morris et al., 1977; Roediger et al., 1989) – two theoretical approaches that inspired extensive research and have unraveled yet another layer of mystery about memory functions.

### 2.16.3.1 The Encoding Specificity Principle

Studies inspired by the encoding specificity principle have shown findings that seem counterintuitive in the context of the memory effects we discussed in the previous section. It turns out that, contrary to general expectations, an increase in retrieval cues or the provision of strong retrieval cues does not always produce the best memory performance. This is because strong cues are not always the best match for the study material. In a now classic study, Thomson and Tulving (1970) reported the highly counterintuitive finding that even the absence of retrieval cues can sometimes produce better memory than the presence of retrieval cues. Furthermore, strong retrieval cues can be sometimes *less* effective than weak retrieval cues. The design of this study went like this. During encoding, participants studied a list of words that were presented either alone (e.g., BLACK), with a weak associate (e.g., train – BLACK), or with a strong associate (e.g., white – BLACK). Later participants were given one of three types of recall tests – a free-recall test, a cued-recall test with weak associates serving as the recall cues, or a cued-recall test with strong associates serving as the recall cues. Results of this study indicated that it was the degree of match between cues at study and test (rather than the strength of preexisting associations between the cue and test word) that determined recall (**Table 1**). Strong associates aided recall if they were also given at encoding. However, if weak associates were given at encoding, strong associates as test cues hurt recall. In other words, a retrieval cue is effective if and only if it reinstates the original encoding (see also Tulving and Thomson, 1973).

**Table 1** Mean number of words recalled across various encoding and retrieval conditions

| | *Retrieval condition* | | |
|---|---|---|---|
| *Encoding condition* | *Free recall* | *Cued recall with weak associate* | *Cued recall with strong associate* |
| Word only | 14.1 | 11.1 | 19.0 |
| Word with weak associate | 10.7 | 15.7 | 13.9 |
| Word with strong associate | 12.2 | 9.2 | 20.2 |

Adapted from Experiment 1 in Thomson DM and Tulving E (1970) Associative encoding and retrieval: Weak and strong cues. *J. Exp. Psychol.* 86(2): 255–262.

As Tulving (1983) pointed out, the locus of the memory effect then is neither at encoding nor at retrieval *per se* but in the interaction between the two. It is reasonable to wonder at this point whether such an interaction undermines the case that retrieval is the key process for understanding memory. To the contrary, such findings underscore the importance of arranging the retrieval conditions that maximally exploit the features of the encoding conditions. This requirement becomes increasingly important as researchers explore the effects of increasingly complex variables – both at encoding and at retrieval – such as place and the internal state of the individual. We review a selection of studies here to illustrate this point and refer the reader to a comprehensive review by Roediger and Guynn (1996) on this subject.

A number of these studies have used the encoding–retrieval paradigm that Tulving (1983) proposed, where both encoding and retrieval conditions are experimentally manipulated. In its most basic form, it involves an encoding experiment with two (or more) encoding conditions (e.g., A and B) and a retrieval experiment with two (or more) retrieval conditions (e.g., X and Y) being conducted simultaneously. By examining only how A differs from B we are able to determine the influence of encoding. Similarly, by examining only how X differs from Y we are able to determine the influence of retrieval. By manipulating both encoding and retrieval conditions simultaneously we are able to examine the interaction between encoding and retrieval conditions. For example, in the study by Thomson and Tulving (1970) just described, encoding conditions were manipulated such that the words were studied under one of three circumstances (word alone, word paired with a weak associate, or word with a strong associate). Similarly, retrieval conditions were also manipulated. Participants were given either a free-recall test, a cued-recall test with the weak associates as cues, or a cued-recall test with the strong associates as cues. It is only by examining the interaction between encoding and retrieval conditions that Thomson and Tulving (1970) were able to observe support for the encoding specificity principle.

#### 2.16.3.1.1 Place-dependent memory

The introduction of the encoding–retrieval paradigm inspired several studies that focused on two sets of variables – place and internal state – to test the encoding specificity principle. These variables carry wide appeal because they are complex and close to real life. In a frequently cited study, Godden and Baddeley (1975) examined the effects of matching or mismatching the place – including the environment – on memory in a rather interesting way. In their study, subjects studied a list of 36 words either on dry land or under water (**Table 2**). These encoding conditions were later crossed with two retrieval conditions in a 2 × 2 factorial design such that subjects performed a free recall task either in the same place/environment as the encoding condition (dry land–dry land or underwater–underwater) or in a different place/environment (dry land–underwater or underwater–dry land). The findings revealed what is known as place-dependent memory and were consistent with the encoding specificity principle; recall was best when the place/environment matched across study and test regardless of whether the place was on land or underwater.

Researchers have also examined place-dependent memory using more common places such as classrooms

**Table 2** Mean number of words recalled in Expt. 1 as a function of learning and recall environment

| | *Recall environment* | |
|---|---|---|
| *Learning environment* | *Dry* | *Wet* |
| Dry | 13.5 | 8.6 |
| Wet | 8.4 | 11.4 |

Adapted from Experiment 1 in Godden DR and Baddeley AD (1975) Context-dependent memory in two natural environments: On land and underwater. *Br. J. Psychol.* 66(3): 325–331.

(Smith et al., 1978). In a series of experiments, Smith et al. showed that the environmental context effects (manipulated in their study by changing or keeping constant the classroom in which study and test took place) occur reliably. Furthermore, these context effects emerged even if the subjects did not perform the retrieval task in the same room as long as they imagined being in the same room while taking the test. This finding is intriguing because it suggests a strong role of the internal resources in mediating effects related to the external environment.

This implication – that internal resources play an important role in encoding–retrieval interactions – is consistent with the observations that the effects of the encoding–retrieval match are often task dependent. It turns out that place- and context-match effects occur more reliably in free recall but rarely in recognition (see Smith, 1988). This pattern makes sense if internal resources are critical for the encoding–retrieval interactions to occur, because free recall requires internal generation of context, associations, and thoughts, whereas recognition is driven at least in part by the external cues provided to the subject. A number of studies have since reinforced the importance of internal resources in mediating the place-dependent memory effects (Eich, 1985; Fernandez and Glenberg, 1985; McDaniel et al., 1989). As we will see shortly, task selection at retrieval seems to play a significant role in mood-dependent memory as well. Once again, this pattern points to the role of internal origins in mediating the encoding–retrieval interaction effects.

#### 2.16.3.1.2 State-dependent memory

The impact of two interrelated factors we have just discussed – type of retrieval tasks and the involvement of internal resources – has also emerged in two other domains of encoding–retrieval interactions, both of which can be subsumed under the construct of internal states. One concerns state-dependent memory and the other concerns mood-dependent memory. The effects of state-dependent memory have been reported in studies that involved the administration of drugs such as alcohol (e.g., Lowe, 1982) or marijuana. For example, in a study that administered marijuana (e.g., Eich et al., 1975; Eich, 1980), participants encoded information either in a drug state (20 minutes after smoking a marijuana cigarette) or in a sober state (20 minutes after smoking a cigarette that only tasted like a marijuana cigarette). Later, there were four possible recall conditions such that type of test (either free-recall or a category-name cued-recall test) and physiological state (either same as encoding or different from encoding) were crossed with one another. The results indicated that a change of pharmacological state from encoding to retrieval impaired performance on a free-recall test but not on a cued-recall test. Further, even with free recall, it is important to note that drug states, even when matched across study and test, are not the best for improving memory because the best recall was observed when information was both encoded and retrieved in a sober state. Returning to the comparison between free- and cued-recall tasks, the general conclusion of these results was that internal state can sometimes serve as a memory cue (as is the case with the free-recall results of this experiment). However, when there are more effective external cues (such as category names) people do not use the less-effective internal cues (as in the case with the cued-recall results of this experiment).

#### 2.16.3.1.3 Mood-dependent memory

We now turn to mood-dependent effects on memory. These effects are especially intriguing because people have an intuitive sense that memory must be sensitive to how we feel when we learn and when we retrieve the learned information. As we discussed earlier, internal context seems to be quite important for understanding encoding–retrieval interactions, and mood certainly provides a prototypical example of internal context (see Eich, 1985). Yet it turns out that findings in this area of research reveal a complex relationship between mood and memory.

Mood is usually manipulated in studies by using hypnotic suggestion, happy/sad music, or comic/sad video clips, and rating scales are often used to measure the attainment of mood. Early studies reported promising results in that mood match across study and test produced better memory performance. For instance, one study reported such effects in endogenously occurring mood states where psychiatric subjects reproduced more free associations if their mood (manic or normal) matched across the first and second attempts than if it mismatched (Weingartner et al., 1977). In another study, Bower et al. (1978) manipulated happy or sad mood through hypnotic suggestion and observed substantially higher recall of common words had they been studied and tested in the same mood than in different moods. But the empirical story got murky thereafter and led researchers to question mood-dependent memory effects (see Blaney, 1986). In fact, in a later study, Bower and Mayer (1989) failed to replicate the mood-dependent memory effect, and similar failures to replicate started to accumulate in the literature (see Eich, 1995b, for a review).

Two phenomena subsequently clarified when the mood-dependent memory effect is likely to occur, and both of these phenomena are consistent with the notion that internal context (or internal state) is important for observing the expected encoding–retrieval interaction in mood studies. In one study, Eich and Metcalfe (1989) asked subjects to either read the to-be-recalled targets (cold) or generate them from semantically related cues (hot-???). Subjects performed this task in either pleasant or unpleasant moods induced through different types of music. Subjects were later induced to experience the same mood or a different mood before recalling the word pairs under conditions of free recall. Mood-dependent effects appeared only for items that were generated during study and not for items that were simply read (**Table 3**). The authors replicated these findings in other experiments within the series, and this effect has since been replicated by others as well (Beck and McBee, 1995).

Taking a different approach, Eich et al. (1994) investigated this question by asking subjects to generate events from their own lives. The experimenters manipulated mood by inducing either a pleasant or an unpleasant mood while subjects performed this task. Later, subjects were asked to recall the gist of events they had generated earlier while experiencing either the same mood as before or a different mood. Two interesting effects emerged: (1) in the first session, subjects generated events that were consistent with their mood (either pleasant or unpleasant), producing a mood congruency effect (Blaney, 1986); (2) in the second session, subjects were better at recalling those events that matched their mood at retrieval than they were at those that mismatched, thereby producing a mood-dependent memory effect. These studies emphasize the special role of internal states in producing mood effects in line with Eich and Metcalfe's arguments that mood-dependency effects only occur for self-generated activities (i.e., for internally generated thoughts) and not for externally produced events. Furthermore, the role of internal resources becomes even more important when we consider the nature of the retrieval task that effectively produces these effects. As with place-dependent memory, mood-dependent memory effects are also observed more reliably in free recall than in recognition (Eich and Metcalfe, 1989). At a broader level, this cluster of findings from manipulations of place, state, and mood lends further support to the theme that internal resources play an important role in mediating encoding–retrieval interactions.

**Table 3** Probability of recall as a function of item type and encoding/retrieval condition

| | *Test condition* | | | |
|---|---|---|---|---|
| | *Read words* | | *Generated words* | |
| *Encoding condition* | *Happy* | *Sad* | *Happy* | *Sad* |
| Happy | .09 | .04 | .32 | .17 |
| Sad | .05 | .07 | .17 | .27 |

Adapted from Experiment 1 in Eich E and Metcalfe J (1989) Mood dependent memory for internal versus external events. *J. Exp. Psychol. Learn. Mem. Cogn.* 15(3): 443–455.

The place-, state-, and mood-dependent memory effects reviewed so far show the complexities involved in studying variables that are multidimensional. Their complexities pose a challenge to researchers in being able to reinstate the exact conditions across study and test. In fact, some of these variables can sometimes be confounded with each other such that one variable (e.g., mood) can mediate the effects of another variable (e.g., state) and further complicate our understanding of encoding–retrieval interactions. For example, Eich (1995a) has argued that place-dependent memory is actually just a special case of mood-dependent memory. In an experiment examining this hypothesis (Eich, 1995b, Experiment 3), participants generated autobiographical events in a pleasant environment and in a pleasant mood. Later, they were asked to recall this information in one of four distinct conditions defined by the 2 × 2 factorial combination of (1) same versus different place and (2) same versus different mood. In this study, it made no difference whether participants were tested in the same versus a different place. However, there was a significant difference when participants were tested in the same mood (55% recall) versus a different mood (45% recall). Based upon these results, it is possible to conclude that how well information transfers from one place to another depends not on how similar the two locations look, but rather on how similar the two locations feel. A similar argument has been set forth regarding state-dependent memory effects. The drugs that most reliably produce state-dependent retrieval effects (such as alcohol and amphetamines) are accompanied by large mood changes. This led Bower (1981) to conclude that state-dependent effects are achieved as a result of the confounded mood-dependent effects.

In brief, thus far in this section, we have reviewed classic and representative studies that show how encoding and retrieval interactions reveal effects of specificity in memory. Together, studies on place-dependent, state-dependent, and mood-dependent memory also show the importance of the types of cue and the task selection at retrieval for detecting these patterns of specificity.

#### 2.16.3.2 The Transfer-Appropriate Processing Framework

The encoding specificity principle proposes that memories are associated with particular cues, and recall is predicted to be enhanced if the cues at retrieval are the same as those that were encoded in the memory traces formed at encoding. We now turn to a discussion of another influential approach – known as the transfer-appropriate processing framework (Roediger et al., 1989; Roediger, 1990) – that is similar to the encoding specificity principle but emphasizes the processes and procedures of mind (Kolers and Roediger, 1984) rather than its structural contents to explain the interactions between encoding and retrieval. In this processing approach, recall is predicted to be enhanced when the processing at retrieval is the same type of processing as encoding. For example, this approach predicts superior memory for 'shallow' encoding of items if the retrieval task capitalizes on the processing of shallow aspects of the study material (Morris et al., 1977; Roediger et al., 1989). This prediction is at odds with the classic and robust demonstrations of the levels of processing effect we discussed earlier, where information processed for meaning is retrieved better than information processed for its shallow aspects such as phonemic details (Craik and Lockhart, 1972; Craik and Tulving, 1975). But the two phenomena can be reconciled if we take into account the critical role retrieval processes play in tapping the encoded information. In their study, Morris et al. (1977) factorially varied the type of encoding task with the type of retrieval task. In particular, during encoding, participants were asked to determine either whether a given word fit into a sentence (a deep semantic encoding task) or whether it rhymed with another word (a shallow phonetic encoding task). Later, participants were either given a standard recognition task or a recognition task involving rhymes (i.e., "does this word rhyme with a previously seen word?"). When the encoding rhyme questions required 'yes' judgments ("does dog rhyme with hog"?), a very interesting pattern of results emerged on the later memory tasks; while semantic acquisition was superior to rhyme acquisition when tested using a standard recognition task, the converse was true when tested using the rhyme recognition task. Based upon these results, Morris and colleagues concluded that shallow encoding is not necessarily inferior to deep encoding and that the effectiveness of any given encoding task depends upon the relationship between the encoding task and retrieval task.

In the late 1980s and early 1990s, Roddy Roediger and his colleagues (Roediger et al., 1989; Roediger, 1990) published a comprehensive framework for testing the principles of transfer-appropriate processing. This framework inspired an empirical revolution that sought to specify the nature of encoding and retrieval processes and the ways in which the selection of these processes can impair or maximize memory performance. A full description of this framework, its tenets, and the major findings are beyond the scope of this chapter, but we recommend several comprehensive reviews to the reader on the theoretical and empirical developments in this area of research (Roediger et al., 1989, 1990; Roediger, 1990; Roediger and McDermott, 1993). In brief, this framework states that memory performance improves to the extent that cognitive processes engaged during test match the processes that were engaged during study. Consistent with this main tenet, extensive research has now shown that subtleties in the match or mismatch of processes during encoding and retrieval can produce large effects on memory performance. As a result, it is critical to select retrieval tasks that closely match the encoding task in their processing requirements. We will discuss some empirical illustrations of this key conclusion in the next section, where we describe the impact of retrieval mode on memory performance.

To briefly summarize the arguments thus far, the encoding specificity principle postulates that memory is enhanced when the cues at recall match the cues at encoding (as is the case in place-, state-, and mood-dependent memory). In a similar vein, the transfer-appropriate processing approach postulates that memory is enhanced when the processes engaged during recall match the processes engaged during encoding. Together, these studies demonstrate the importance of arranging the retrieval conditions so that we can optimize accessibility to learned information.

## 2.16.4 Retrieval Mode

In his chapter for the Tallinn conference, Roediger (2000) discussed the concept of retrieval mode and its power to reveal aspects of memory that might otherwise remain concealed. We expand upon this notion in this section. We will consider the significance of retrieval mode from two perspectives that Roediger noted: (1) explicit and implicit modes of retrieval and (2) remembering and knowing information from the past. Each perspective has brought into focus many important questions concerning retrieval and has led to substantial empirical and theoretical developments on these issues. We refer the reader to two directly relevant chapters in this volume that tackle each of these topics in depth – one by D. L. Schacter on implicit memory (*See* Chapter 2.33) and another by J. M. Gardiner on remembering and knowing (*See* Chapter 2.17). In this section, we discuss a few examples to demonstrate how a change in the retrieval mode can bring about changes in accessibility to studied information.

### 2.16.4.1 Explicit versus Implicit Memory

The relevance of task differences and encoding–retrieval interactions in improving accessibility comes together in rather dramatic ways when we consider the explicit versus implicit modes of retrieval in which people engage while doing memory tasks. In their seminal papers, Warrington and Weiskrantz (1968, 1970) reported findings that nicely illustrate how retrieval mode can affect the memory product. In these studies, amnesic subjects performed poorly, as would be expected, when asked to think back on the study episode and recall what was studied (as in free recall). But these subjects exhibited, rather surprisingly, normal memory performance when they were asked to complete a memory task with the first response in the manner of problem solving (for example, complete the physically impoverished cues in a word fragment completion task with the first response that comes to mind). Graf and Schacter (1985) introduced the distinction between explicit and implicit memory to respectively capture this difference between a mode of retrieval where people think back on the study episode (all the memory tasks discussed in the other sections of this chapter) and a mode where no reference is made to study episode during test performance.

These differences in the retrieval task instructions can change memory performance of not only individuals who have amnesia but also individuals who possess intact memory functions (see Schacter, 1987, 1990; Roediger et al., 1989, 1990; Roediger, 1990; Roediger and McDermott, 1993, for representative reviews.) We will discuss some findings observed in individuals with intact memory to elaborate this point. In the previous section, we discussed the classic levels of processing effect on tasks such as free recall and recognition (Craik and Tulving, 1975) and the reversal of this effect when the recognition task provided phonemic cues as opposed to the standard cues (Morris et al., 1977). Interestingly, the conceptual advantage of levels of processing disappears if test conditions require implicit retrieval in response to perceptual test cues. In other words, on tasks such as word identification (reading words presented rapidly at threshold durations), word fragment completion (presenting test cues with some letters missing, e.g., _ t r _ _ b _ r _ _), or word stem completion (str_______), completing the cues with the first solution that comes to mind confers little advantage for words studied for meaning compared to words studied for their perceptual features (e.g., Jacoby and Dallas, 1981; Graf and Mandler, 1984; Roediger et al., 1992). Thus, the levels of processing effect can vary as a result of the tasks used; it occurs on free recall and recognition (Craik and Tulving, 1975), reverses on a phonemic cued-recall task (Morris et al., 1977), and disappears on implicit tasks that rely on perceptual processes for completion. These findings once again highlight the importance of retrieval cues in accessing learned information.

The disappearance of study differences on implicit tasks can change the way we theorize about the significance of encoding (or storage) versus retrieval. For instance, the advantage in free recall for concrete words (such as table, bus, strawberry – words that can be imaged or represented as objects) over abstract words (such as pledge, destiny, care) has been attributed to dual storage of concrete words in verbal and image codes compared to single representations of abstract words (only verbal code) (Paivio et al., 1968; Paivio, 1969). Yet, in a study from our lab (Hamilton and Rajaram, 2001) we found that on implicit tests such as word fragment completion (_ t r _ _ b _ r _ _) and implicit general knowledge test (what fruit wears its seeds on its skin?), there was an equivalent

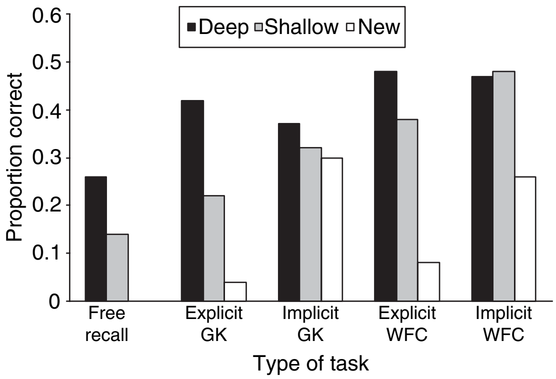

**Figure 1** Mean proportion of correct responses for each item type for each of the five tasks used (GK, general knowledge task; WFC, word fragment completion task). Adapted from Experiment 2 in Hamilton M and Rajaram S (2001) The concreteness effect in implicit and explicit memory tests. *J. Mem. Lang.* 44(1): 96–117.

advantage for producing studied concrete words and studied abstract words over their nonstudied counterparts (**Figure 1**). In other words, on an implicit memory task there was no memorial benefit of concrete words over abstract words. Therefore, the concrete/abstract distinction in memory cannot be discussed only in the context of differential encoding or storage. This distinction demands a more complex explanation because this effect is not ubiquitous – it can be specific to a particular mode of retrieval.

A converse pattern can also emerge by changing the retrieval mode such that some study differences do not affect explicit memory but produce changes in implicit memory. For example, changing the modality of presentation at study – presenting words either in the auditory or the visual modality – does not change the level of free recall (Blaxton, 1989; Srinivas and Roediger, 1990; Rajaram and Roediger, 1993), and this null finding suggests that modality of presentation at study does not matter. However, this conclusion is only partly correct as we (Rajaram and Roediger, 1993) found in our study with four different implicit tasks involving perceptual cues (see **Figure 2**). When subjects were presented with impoverished cues such as word fragments, word stems, rapidly presented words in the word identification task, or anagrams (brtaserwyr) to solve in the anagram solution task (strawberry) and were asked to perform these tasks with the first solution that comes to mind, performance improved on these implicit tests if the study and test materials were presented in the same modality compared to different modalities (see also Jacoby and Dallas, 1981; Kirsner et al., 1983; Graf and Mandler, 1984; Roediger and Blaxton, 1987; Blaxton, 1989; Srinivas and Roediger, 1990; Weldon, 1991). In other words, the impact of a study variable is sometimes detectable only when subjects used the implicit retrieval mode. (As an aside, but consistent with the general argument about the impact of retrieval cues in modulating memory performance, we also found that studied pictures produced the worst performance on these implicit tasks that provided word-based cues. This, of course, is contrary to the pattern that is typically observed in free recall and recognition, where memory for pictures is better than that for words (Paivio et al., 1968; Madigan, 1983; Weldon and Roediger, 1987; Rajaram, 1993).)

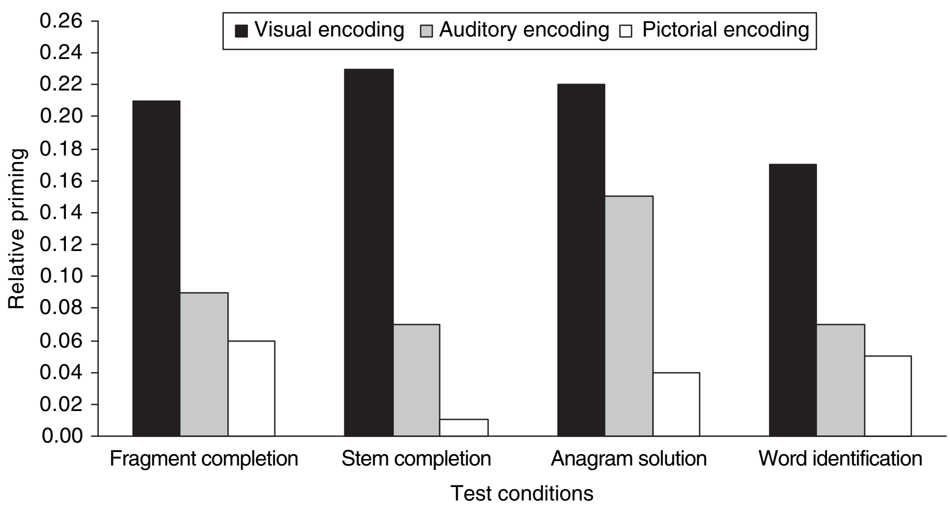

**Figure 2** Relative priming for the four implicit memory tasks across different encoding conditions. Adapted from Rajaram S and Roediger HL (1993) Direct comparison of four implicit memory tests. *J. Exp. Psychol. Learn. Mem. Cogn.* 19(4): 765–776.

The impact of retrieval mode on memory performance can be seen even when the retrieval cues themselves are held constant and only the mode of retrieval is varied through instructions, or when the retrieval intentionality criterion is met by the experimental conditions (Schacter et al., 1989). For example, when performance on free recall is contrasted with performance on a task such as implicit word fragment completion, the retrieval mode changes, but so do the test cues (no test cues in free recall and perceptually degraded cues in fragment completion, e.g., _ t r _ _ b _ r _ _). But the role of retrieval mode in detecting memory would be more persuasive if dissociations between explicit and implicit memory could be observed even when the same test cues were used in both conditions. Graf and Mandler (1984) reported such a dissociation between an explicit word stem cued-recall task and an explicit word stem completion task where the same test cues (e.g., ele_______) were used, and the levels of processing effect occurred on the explicit but not the implicit version of the task. In a large-scale study, Roediger et al. (1992) reported similar patterns of performance when they contrasted explicit and implicit versions of the test using identical stem cues (e.g., ele_______) as well as explicit and implicit versions of the test using identical fragment cues (e.g., _ l _ p _ a n _). Along the same lines, in our study with concrete and abstract words we just described, we found that the presence of the concreteness effect in free recall also extended to the explicit retrieval version of the general knowledge test (complete the following question with a studied word: "What fruit wears its seeds on its skin?") but, as noted earlier, not to the implicit version of the general knowledge test (Hamilton and Rajaram, 2001). In other words, we demonstrated dissociative effects on explicit and implicit versions of a different type of task, namely general knowledge, while holding the test cues constant (see again **Figure 1**).

### 2.16.4.2 Differentiating between Conceptual and Perceptual Retrieval Cues

While explicit and implicit retrieval modes can produce various dissociations of theoretical significance such as the ones just described, dissociations can also occur *within* one retrieval mode – for example, with differences in implicit retrieval cues provided to the participants. In previous sections, we described how differences in retrieval cues can bring about changes in memory performance within the context of explicit memory tasks such as free recall, cued recall, and recognition. The tenets of the transfer-appropriate processing framework (Roediger et al., 1989; Roediger, 1990) predict systematic differences even within implicit memory tasks, depending on the type of process demanded by the tasks. If the implicit memory task largely depends on perceptual processes for its successful completion – as in the cases of word fragment completion, word stem completion, perceptual identification tasks – then encoding orientation produces one type of effect. But if the implicit task mainly relies on conceptual processes – as in the cases of the general knowledge test described earlier and also tests such as implicit category association test (given a category name, participants are asked to produce all the exemplars that come to mind within 30 s) – then the same encoding orientation produces the opposite effect. So, for example, the modality effect observed across different *perceptual* implicit tasks described in the study by Rajaram and Roediger (1993) disappears on *conceptual* implicit tasks because changes in modality of presentation are not important for accessing meaning (e.g., Blaxton, 1989; Srinivas and Roediger, 1990). Encoding variables that differentiate the extent to which meaning (rather than surface information as in the modality manipulation) is varied during study produce the opposite effect: As we described earlier in this section, the levels-of-processing effect that reflects changes in conceptual processing of information disappears on *perceptual* implicit tasks. But this effect is reliably observed on *conceptual* implicit tasks such as the implicit general knowledge test (Hamilton and Rajaram, 2001) and the implicit category association test (Hamann, 1990; Srinivas and Roediger, 1990). Together, these patterns show that, while retrieval modes of explicit and implicit retrieval change accessibility in dramatic ways, the nature of the process demanded by the retrieval task (conceptual versus perceptual) can also change accessibility in a manner that is powerful and that can be orthogonal to the retrieval mode itself.

### 2.16.4.3 Remembering and Knowing

We now turn to a brief discussion of another type of distinction between two retrieval modes – remembering versus knowing one's past. Unlike the explicit–implicit distinction, where people are, respectively, either aware or not aware of the connection between the past and present, the remember–know distinction is made when people are aware of the connection. This distinction instead concerns the quality of retrieval experience that accompanies retrieval (Tulving, 1985). A person is said to engage in remembering if the retrieved memories are vivid and detailed. Remembering involves being able to think back to episodes and mentally reliving the past event, and in this way it is also said to involve mental time travel (Tulving, 2002). In brief, remembering is considered to be the purest measure of episodic memory. The experience of knowing is associated with semantic knowledge. Sometimes, retrieved information is associated with the past (unlike the case of implicit memory), but its rooting in the past lacks a sense of immediacy or detail such that one cannot tell when and where this information was encountered before. Despite having confidence in this type of memory, one experiences less personal connection and more of a generic sense about this information. In brief, Tulving proposed that the experience of knowing provided a measure of semantic memory. Tulving (1985) introduced the remember–know paradigm to enable quantitative measurements of these qualitative distinctions in retrieval.

The remember–know paradigm has been used widely to study the nature of retrieval experience and has produced both a large body of systematic findings and considerable debate (see Jacoby et al., 1997; Rajaram and Roediger, 1997; Gardiner and Conway, 1999; Rajaram, 1999; Gardiner and Richardson-Klavehn, 2000; Roediger et al., 2007, for reviews). For present purposes, we emphasize the dissociations and associations that systematically occur between these two distinct retrieval experiences. We have already discussed ways in which the levels-of-processing effect can vary as a function of encoding–retrieval interactions and explicit–implicit retrieval instructions. The presence of the levels of processing effect in explicit memory retrieval suggests that this effect should manifest itself in both remember and know judgments. However, the findings show that items studied for their meaning are given more remember judgments than items studied for their surface features, but this pattern is not observed for know judgments (Gardiner, 1988; Rajaram, 1993). Thus, retrieval can vary for the same set of encoding conditions even within the domain of explicit memory, once again emphasizing the important role that retrieval probes play in revealing the nature of memory.

In summary, we use the term retrieval mode to refer to distinct methods and experiences of retrieving information. Explicit retrieval refers to the conscious and intentional recall of previous experiences. In contrast, implicit retrieval refers to performance changes that are a result of prior experience but are unaccompanied by intentional or conscious recall of previous learning. Dissociations can occur between these two retrieval modes such that some factors (e.g., concrete/abstract words) can influence explicit memory but not implicit memory, while other factors (e.g., modality of presentation) can influence implicit memory but not explicit memory. Interestingly, the distinction between explicit and implicit memory retrieval is modified by the processing demands of these retrieval tasks such that dissociations can also occur *within* a particular mode of retrieval if the retrieval cues rely on different types of processes. As a result of this, *conceptual* implicit cues reveal the levels-of-processing differences but remain insensitive to modality changes, whereas *perceptual* implicit memory cues produce a reverse pattern of memory performance.

The notion of changes in the retrieval mode can also be applied to a distinction within explicit memory in terms of remembering and knowing – a distinction that is based on the quality of the information that is recalled. Remembering refers to recall that is accompanied by vivid details and a sense of mental time travel. In contrast, knowing refers to recall without specific details or a sense of when the information was encountered before. A dissociation also occurs between these two retrieval modes such that some factors (such as depth of processing) can influence remembering but not knowing. A variety of studies have also shown reverse dissociations and some associations as well between these two experiential modes of retrieval.

## 2.16.5 Repeated Retrieval

In previous sections, we focused on changes in the retrieval context – task differences, the match between encoding–retrieval interactions, and changes in the retrieval modes – to explore how retrieval processes affect detection of memory. We now review a class of retrieval phenomena that are quite different from the preceding ones but are equally important in revealing the nature of memory. These phenomena have to do with repeated attempts at thinking about a particular event. It is common experience to repeatedly try to recall something from the past that simply eludes us at a given moment. Are such efforts useful? In a research context, we might ask, do repeated attempts at recall improve memory performance? The brief answer to this question is yes. As Roediger and Karpicke (2006b) recently noted in their comprehensive review of research on testing effects,

> . . . testing not only measures knowledge, but also changes it, often greatly improving the retention of the tested knowledge. (Roediger and Karpicke, 2006b: 181)

Improvement in memory performance through repeated retrieval attempts can be understood by examining two related but distinct phenomena – hypermnesia and repeated testing. Hypermnesia refers to an improvement in the total amount of material recalled across repeated attempts, and it is usually obtained with free recall and not so often with other tasks. Repeated testing benefits occur when having taken a prior test – either recall or recognition – improves performance on a later test – again, either recall or recognition. We will review selective studies on both these phenomena as they reveal the importance of retrieval attempts.

Systematic efforts toward understanding the positive effects of repeated attempts – or hypermnesia – can be traced back to Ballard's (1913) and W. Brown's (1923) classic papers. Ballard proposed the concept of reminiscence and defined it as, "the remembering again of the forgotten without re-learning" (Ballard, 1913: 17). W. Brown introduced the phenomena of inter-test forgetting – the number of items that were recalled on the first attempt but not on the second – and inter-test recovery – the number of additional items recalled on the second attempt – to capture the effects of repeated recall on memory output. W. Brown's findings showed that repeated attempts at recalling a list of studied words (or recall of states) resulted both in inter-test forgetting and inter-test recovery, but there was an overall improvement in memory performance such that inter-test recovery exceeded inter-test forgetting across recall attempts. Erdelyi and Becker (1974) termed this reliable net gain across repeated attempts at recall as hypermnesia. Modern interest in research on hypermnesia can be traced back to the findings that Erdelyi and colleagues reported in the 1980s (see Erdelyi and Kleinbard, 1978; Erdelyi, 1984; Erdelyi et al., 1989).

Interestingly, for memory to improve with repeated testing, recall attempts do not have to occur necessarily in the form of consecutive and distinct recall tests. Roediger and Thorpe (1978) asked subjects to study 60 words or 60 pictures and attempt recall either in three successive recall tests (each lasting 7 min) or a single recall test that lasted 21 min. In both testing conditions, subjects were asked to draw a line after each minute of recall. Pictures produced greater hypermnesia than did words, a finding that seems to hold in other studies as well (see also Erdelyi and Becker, 1974; Payne, 1986), and this was true for three successive recalls as well as for one long recall that was equal in duration to three successive recalls. More relevant to the present point is the finding that recall increased over time in both retrieval conditions, and it did so at the same rate. An important implication of this finding for educational purposes is that having more time to retrieve information benefits performance even when the study efforts remain the same.

The presence of hypermnesia in Roediger and Thorpe's (1978) design shows that repeated retrieval effort over an extended period of time is the key to improving memory. But could memory improve simply by increasing the time that elapses between study and recall? This is, of course, a counterintuitive possibility because we expect delay to worsen memory, not improve it. However, in a standard repeated-testing design, the delay between study and a given recall test is confounded with the timing of multiple tests. That is, the second test comes much later in time than the first, and so on. Also, Shapiro and Erdelyi (1974) found that recall of studied pictures improved when the delay between study and recall was 5 min compared to when it was 30 s. The key to understanding this unexpected outcome may lie in the instructions subjects received during the 5-min delay; subjects were asked to covertly review the materials they had studied earlier. As Roediger and Payne (1982) argued, when subjects engaged in thinking about the study materials in Shapiro and Erdelyi's study, this act amounted to repeated retrieval practice and produced memory benefits despite the delay between study and recall.

To address this possibility, Roediger and Payne systematically examined the selective influence of delay between study and test and of the number of prior recall tests in a repeated testing design. In their study, all the subjects performed three recall tasks, but one group started the sequence after a short delay, the second group started the sequence at the time when the first group performed the second recall test, and the third group started the sequence at the time the first group performed the third recall test (**Table 4**). As the recall findings from this study show, recall was equivalent on the first recall test

**Table 4** Mean recall on the three successive tests for each delay condition

| *Condition* | *Items recalled* | | | | |
|---|---|---|---|---|---|
| Immediate | Test 1<br>25.6 | Test 2<br>27.9 | Test 3<br>30.1 | | |
| Short delay | | Test 1<br>25.1 | Test 2<br>27.5 | Test 3<br>29.8 | |
| Long delay | | | Test 1<br>25.6 | Test 2<br>28.9 | Test 3<br>31.3 |

Adapted from Roediger HL and Payne DG (1982) Hypermnesia: The role of repeated testing. *J. Exp. Psychol. Learn. Mem. Cogn.* 8(1): 66–72.

regardless of when the first test occurred (short delay, 25.6; intermediate delay, 25.1; long delay, 25.6). In contrast, recall increased during the same temporal window if the number of prior recall tests increased (the first test for the long-delay group, 25.6; the second test for the intermediate-delay group, 27.5; and the third test for the short-delay group, 30.1). Interestingly, many of these findings in hypermnesia studies have been secured with the study of pictures but not always with the study of words. We refer the reader to comprehensive reviews by Payne (1987) and Roediger and Challis (1989) for discussions on this and other complicating issues as well as for theoretical considerations in hypermnesia research. Regardless, these studies decisively point to the critical and specific role played by repeated attempts at retrieval in improving memory.

Repeated retrieval improves access to studied material in yet another way. Sometimes, the differential effects of different study methods that do not emerge on the first recall test are revealed on a later second test. For instance, in a study by Wheeler and Roediger (1992), subjects studied 60 pictures either presented one by one and accompanied with auditory presentation of the names or presented in the same manner visually but accompanied with an auditory presentation of a story. Shortly after completing a distractor task, subjects recalled the names of the pictures on one, two, or three successive tests. All the subjects returned 1 week later and also completed a final free-recall test. Their performance on this final test distinguished between the benefits of multiple retrievals for different study methods. Subjects' final recall was substantially higher for pictures that were embedded in a story than pictures that were presented without a story during study, and this difference became increasingly pronounced as the number of prior recall tests increased. Once again, we see the power of retrieval processes in that repeated retrieval can increase not only memory output when the study conditions remain the same; it can do so by bringing out the differential efficacy of study methods that might otherwise remain obscure.

As the preceding discussion shows, repeated retrieval clearly increases accessibility and produces improvements in memory. But in a discussion that emphasizes the importance of retrieval, it is important to ask what is more effective – repeated retrieval or repeated study? After all, a vast empirical literature in cognitive psychology shows that repeating information at study reliably improves recall and recognition (*see* the chapter by R. L. Greene in this volume on repetition and spacing effects; Chapter 2.06). There are many interesting phenomena associated with repetition at study, including the nearly ubiquitous demonstration that spaced repetition at study – that is, repeating items with one or more intervening trials in the study list – produces better memory compared to massed presentation – that is, repeating items twice or more in consecutive trials in the study list. Given the beneficial effects of repeated study, it is logical to ask how repeated retrieval fares in comparison. This question has been tested in many ways and from different theoretical as well as applied perspectives. Yet, the answer is impressively consistent. Repeated retrieval not only benefits memory, it does so to a greater extent than does repeated study. We recommend Roediger and Karpicke's (2006b) review that we earlier referenced for an in-depth discussion of different theoretical and empirical issues related to this broad question, and for the practical implications from this research for improving educational practices. Here, we will review a selection of studies that demonstrate this conclusion. In these studies, the focus is not on hypermnesia that arises when the same test is taken multiple times but on benefits of repeated testing where the successive tests are not necessarily identical, but having taken the prior tests nevertheless improves performance on the later tests.

As early as the first quarter of the twentieth century, two studies demonstrated many of the key findings from repeated-testing designs. In one study, Gates (1917) varied the amount of time given to subjects for only studying versus for recalling while being able to refresh memory for the forgotten material. On a final (serial) recall test of the studied material (nonsense syllables or biographies), Gates found that spending more time on recall with opportunities to refresh the forgotten information produced better final recall than more time devoted only for study – provided that a certain, minimum amount of time was first spent for study in the former condition (see also Thompson et al., 1978).

In another study, Spitzer (1939) found that two attempts at retrieval improved memory on a multiple-choice recognition memory test. Furthermore, the sooner the first test was administered, the less was the forgetting and the higher was the performance on a later second test. The inoculating effects of the first test, and of its timing, have received considerable attention in the repeated-testing literature. While the inoculating effects of the first test on later memory seem secure (Wheeler and Roediger, 1992), the specifics concerning the optimal timings of multiple tests continue to be investigated (Landauer and Bjork, 1978; Balota et al., 2006, 2007; Logan and Balota, in press).

The early intimations of a relative advantage of increased testing over increased studying in the studies by Gates (1917) and Spitzer (1939) have been systematically tested from various perspectives in the modern literature and have produced a very nice body of data. A key factor in predicting the relative advantage of repeated study versus repeated retrieval concerns the delay between study and the final memory test. In a seminal study, Tulving (1967) used a comprehensive design that included comparisons of various study–test schedules for a total of 24 trials each and had subjects study a total of 36 words – alternating study and test (STST, STST, and so on), three study and one test (SSST, SSST, and so on), and one study and three tests (STTT, STTT, and so on.) Also critical for present purposes, subjects were given 1 s per item to study and an equivalent total of time for test (so, subjects received 36 s to recall all the studied items.) The results showed that recall performance was comparable over the 24 trials across the three different study-test schedules. In other words, repeated testing did not improve memory over repeated study.

Tulving's findings were surprising in light of the general conclusion we have already stated, but these findings were replicated by others (e.g., Lachman and Laughery, 1968; Rosner, 1970; Birnbaum and Eichner, 1971; Donaldson, 1971). Also, these findings make sense if we consider them in light of Roediger and Thorpe's (1978) findings we discussed earlier; recall improves as subjects receive additional time to do the task. However, in Tulving's experiment subjects were given only 36 s to recall 36 words. Even if the words had been perfectly learned, this is a very short time period with which to recall them. Initial support for this possibility was found in a study where subjects either studied a list of 40 words four times or studied it once and recalled it three times (Hogan and Kintsch, 1971; see also Thompson et al., 1978). In a final recall test conducted 2 days later, prior training with multiple tests produced 5% better recall than prior training with multiple study.

Roediger and Karpicke (2006a, Experiment 2) recently published a study using educational materials that provides an impressive resolution to the question concerning the relative importance of repeated study versus repeated tests. Subjects studied prose passages on scientific topics and were tested on a recall test that was similar to essays in its format. In one condition, subjects studied the passage four times (SSSS). In a second condition, subjects studied the passages three times and were tested once (SSST), and in the final condition, subjects studied the passages once and were tested three consecutive times (STTT). Subjects also took a final recall test either 5 min or 1 week after this learning sequence. As can be seen in **Figure 3**, more idea units were recalled following repeated study if the final recall test occurred after a short delay of 5 min. But the final recall performance was better after repeated testing if

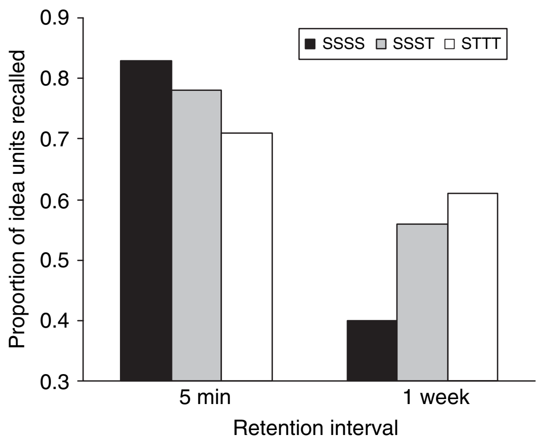

**Figure 3** Mean proportion of idea units recalled on the final test after a 5-min or 1-week retention interval as a function of learning condition (SSSS, SSST, or STTT). The labels for the learning conditions indicate the order of study (S) and test (T) periods. Adapted from Experiment 2 in Roediger HL III and Karpicke JD (2006a) Test-enhanced learning: Taking memory tests improves long-term retention. *Psychol. Sci.* 17(3): 249–255, with permission from Blackwell Publishing.

the final test occurred after a long delay of 1 week. In summary, these findings pinpoint the key conditions that are responsible for when study and retrieval repetitions can produce differential benefits in memory; repeated study improves memory in the short term, but repeated testing produces improvements in the long term. This long-term advantage of repeated testing over repeated study seems secure because it has been shown to also occur with word lists (Wheeler et al., 2003).

A general explanation for why repeated retrieval benefits long-term retention more than repeated study harkens back to the principle of transfer-appropriate processing we discussed in earlier sections on encoding–retrieval interactions and retrieval mode (Morris et al., 1977; Roediger et al., 1989). Roediger and Karpicke (2006b) recently noted that one reason for the superiority of repeated retrieval is that the same processes are engaged when people retrieve information again, whereas, as McDaniel (2007) has argued, different processes are often engaged across learning and testing situations. The match in processes in the former condition illustrates the operation of transfer-appropriate processing.

Another explanation of the benefit of repeated testing is that initial testing results in the creation of multiple retrieval routes to the to-be-remembered item, thus making recall more likely at a later test. In a study by McDaniel and Masson (1985), subjects were given either a phonemic or a semantic encoding task followed by a cued-recall test with either semantic or phonemic cues. Thus, half of the subjects received the same type of information at encoding and the first test, and half of the subjects received a different type of information at encoding than at the first test. Later, subjects were able to recall more information on a second test when the cues from the first test had not matched the original encoding. This finding is consistent with the idea that the initial test improves recall on a later test if it is able to produce an elaboration of the existing memory trace by increasing the variability of the encoded information (see also McDaniel et al., 1989). From a retrieval point of view, this means not only that retrieval is changing the existing memory representation, but that varied changes make subsequent retrieval more and more likely to occur.

Roediger and Karpicke (2006b) have reviewed a sizeable literature that points to yet another related but distinct basis for benefits from repeated retrieval, namely the process of generation. Briefly, just as the generation processes at encoding improve memory such that items generated from semantic cues are later recalled and recognized more often than items that were simply read, generation of studied items during first recall improves performance on a following test (see Jacoby, 1978; Bjork and Bjork, 1992; Bjork, 1994, 1999; Roediger and Karpicke, 2006a). Consistent with this idea, a prior recall test that requires generation of studied information (such as providing short answers) improves performance on later recall (short answers) as well as recognition (multiple-choice format), whereas a prior recognition test (that does not require generation because the studied items are presented again) does not produce comparable benefits on later tests (Kang et al., 2007). Recent work (McDaniel et al., 2007) has also demonstrated this effect in a college course. In this study a benefit was found for short-answer quizzes (a recall test) over additional study but not for multiple-choice quizzes (a recognition test) over additional study on a final exam. This is particularly impressive given not only the variability of additional studying and motivation of the students within the class, but also the fact that the quizzes were administered up to 5 weeks prior to the final exam. Findings such as these reveal the specificity of effects that prior retrieval produces on later retrieval and point to the underlying processes that mediate such patterns.

In conclusion, testing – or retrieval – not only has a powerful influence on long-term retention but is also an effective learning device with important educational implications. The judicious use of testing in educational settings should benefit students' performance. This goal is embodied in recent cognitive research that aims to identify optimal retrieval practices for improving retention and academic performance. We refer the reader to M. A. McDaniel's chapter on 'Education and Learning' in this volume (*see* Chapter 2.43) for an in-depth discussion of these important issues.

## 2.16.6 Retrieval in a Social Context

For decades now, experimental studies on memory have typically focused on the individual, and the study of retrieval processes has been no exception. But just as we retrieve the past not just once but often repeatedly, we also retrieve the past not just alone but often in collaboration with others. People recall the past in dyads (e.g., friends and couples), triads (e.g., friends, colleagues), or in larger groups. It was only around the mid- to late 1990s that research on the effects of social context on memory started to gain momentum. We review some of the core findings from this area of research as relevant to the process of retrieval here and refer the readers to scholarly reviews by Weldon (2001) for the historical antecedents and the emerging research on social processes in memory, and by M. Ross (*see* Chapter 2.47) and J. V. Wertsch (*see* Chapter 2.48) in this volume on the nature of social memory processes and collective memory, respectively.

Both the early neglect of group processes and the recent focus on group processes make sense on theoretical and empirical grounds, because assessment of how social processes influence retrieval first requires a clear understanding of how individual memory processes work in isolation. Now that a substantial body of evidence and major theoretical frameworks are in place on the nature of individual memory, researchers have the necessary empirical and theoretical bases against which the social influences on individual memory can be measured. Similarly, researchers can also test for potential similarities and differences between individual memory and group memory processes.

We first focus on group memory because retrieval processes appear to play a central role in mediating group memory effects. Studies that report group retrieval – or collaborative memory – effects typically compare collaborating groups to nominal (or control) groups. In collaborative groups, members collaborate during retrieval. In nominal groups the nonredundant responses of an equal number of individuals who worked alone are pooled together (Basden et al., 1997; Weldon and Bellinger, 1997). Collaboration in the experimental group is instantiated by asking subjects to contribute their retrieved responses in any order or in a turn-taking order. Results do not seem to change as a function of the particular procedure used for collaboration (Basden et al., 1997; Weldon and Bellinger, 1997; Weldon et al., 2000; Wright and Klumpp, 2004).

The central finding in group retrieval studies turns out to be counterintuitive. Collaborating groups recall significantly fewer studied items than nominal groups (Basden et al. 1997; Weldon and Bellinger, 1997), a phenomenon that Weldon and Bellinger (1997) call collaborative inhibition. In Weldon and Bellinger's experiment, participants encoded a list of words alone. Later, they were asked to recall the information either individually or in a collaborative group of three individuals. When the participants recalled individually, a nominal group score was created that consisted of counting up all the nonredundant answers of three individuals. The results indicated that, while collaborative groups recalled more than the average individual, the nonredundant responses of three individuals recalling alone (i.e., nominal groups) exceeded collaborative group performance.

Collaborative inhibition appears to be largely a retrieval phenomenon, as this effect is reliably observed when the encoding conditions are held constant across the nominal and collaborative groups. The retrieval basis of this effect is further supported by the proposal that collaborative inhibition is similar to another well-known retrieval phenomenon, namely, the part-list cuing inhibition effect (Slamecka, 1968; Basden et al., 1977; Roediger and Neely, 1982; Basden and Basden, 1995). The part-list cuing inhibition refers to yet another counterintuitive phenomenon in memory; when subjects are presented with a partial list of studied words during recall and are asked to recall the remaining studied words, their recall is poorer for the remaining subset compared to a condition where none of the studied items are provided during recall. Thus, having access to a part of the studied lists inhibits the recall of the remaining words. The locus of this effect appears to be at retrieval because recall for the remaining subset improves on a later trial if the partial list is no longer provided. Thus, the dip in recall during the first trial turns out to be temporary and does not reflect poorer encoding or storage in the part-list condition. This finding then begs the question – why do partial lists inhibit recall? Evidence shows that individuals develop their own idiosyncratic organization of the studied material and use it during recall (Tulving, 1962; Roenker et al., 1971; Rundus, 1971). The presence of a subset of items during recall disrupts such organizational and retrieval strategies and leads to suboptimal recall performance (Basden and Basden, 1995).

B. H. Basden and colleagues extended the logic of retrieval disruption to the collaboration situation and tested the idea that collaborative inhibition observed in group memory is similar to the part-list cuing inhibition effect in individual memory. The logic behind this theoretical extension goes like this. Recall of a given member is reduced in a collaborative group because responses produced by other group members serve as part-list cues and disrupt the idiosyncratic retrieval strategies on which each individual member relies during group recall. Such retrieval disruption – resulting from the input of other group members – reduces the individual contributions from each member and leads to lowered group recall.

B. H. Basden et al. (1997) reported evidence that supports the retrieval disruption hypothesis. In this series of experiments, B. H. Basden and colleagues also reported the same pattern of results as Weldon and Bellinger (1997), showing that nominal recall was greater than collaborative recall. However, they also showed that this effect was mediated by the extent to which collaboration disrupts the individual's organizational structure. For example, in their first study, participants were given one of two types of encoding tasks. Some participants were asked to learn many (15) instances of a few (6) categories. Other participants were asked to learn few (6) instances of many (15) categories. D. R. Basden and Draper (1973) had previously argued that within-category organization is more likely to occur with large categories. As a result, each individual's retrieval strategy should be at more variance from another individual's retrieval strategy when the categories are large. If collaborative inhibition is due to retrieval disruption, there should be greater collaborative inhibition for participants who studied large categories (15 instances of 6 categories) than for participants who studied small categories (6 instances of 15 categories). Consistent with this hypothesis, the magnitude of collaborative inhibition varied as a function of list structure. In fact, collaborative inhibition was found only for participants who studied large categories and not for participants who studied small categories.

The collaborative inhibition effect in group retrieval and the part-list cuing inhibition effect in individual retrieval are related in yet another interesting way. As we have described, both phenomena are said to occur because of retrieval disruption during retrieval. It turns out that in both cases retrieval disruption does not impair individual memory beyond the conditions where it operates. As we noted earlier, in the case of part-list cuing inhibition, there is evidence that, if the part-list cues are removed during subsequent individual recall, subjects elicit previously blocked studied words (Basden et al., 1977). Similarly, after the completion of the group retrieval session, if each group member individually recalls studied items, the 'lost' items during collaboration resurface in later individual recall (Finlay et al., 2000; see also Weldon and Bellinger, 1997). These interesting parallels suggest that group retrieval can be sensitive to the same cognitive mechanisms that mediate individual retrieval.

In an earlier section on task differences, we discussed the critical role retrieval cues play in determining the accessibility of studied information. Initial evidence from studies on collaborative memory suggests retrieval cues also modulate the key finding on which we have focused here – collaborative inhibition in group retrieval. Collaborative inhibition typically occurs when a collaborative group engages in free recall (Basden et al., 1997; Weldon and Bellinger, 1997). This outcome is consistent with the retrieval disruption account because, as we have noted, free recall relies heavily on the internal organization and strategies of each participant, and the disruption of this strategy lowers each member's contribution to the group product.

This logic predicts that, if more cues are provided as external aids during retrieval, each participant group member would need to rely much less on internal resources. As a result, disruption is less likely to be a factor during the process of collaboration when retrieval cues are present. Current evidence supports this argument. While collaborative inhibition consistently occurs in free recall, this effect disappears in a paired-associate recall task that provides partial study cues, and even reverses in a recognition memory task that recapitulates the entire study item. Finlay et al. (2000) reported a study in which subjects studied pairs of weakly related words. At test, subjects received the first word of the studied pair and recalled the second pair either individually or in pairs. Nominal dyad performance (nonredundant, pooled recall of two individuals who worked alone) did not differ from that of the collaborating dyads even though the typical collaborative inhibition effect occurred with the free-recall task.

Clark and colleagues (2000) used the recognition memory task in their study on collaborative memory with the aim of elucidating the nature of the collaboration process from a different perspective. But their findings are interesting in the present context for yet another, related, reason – the effects of maximal retrieval cues on mediating collaborative memory. Subjects studied a list of unrelated words and were later tested on a recognition memory task that consisted of an intermixed list of studied and nonstudied words. These researchers assessed the performance of three-member collaborative groups against three measures derived from the nominal groups of same size – the best group member, the majority vote, and the average of the group. In all three comparisons, the recognition performance of the collaborative groups exceeded that of the nominal groups. In other words, Clark et al. reported that there was a collaborative facilitation effect in recognition memory.

We have focused on group retrieval to discuss the role of retrieval in assessing memory in a social context. We close this section by briefly describing evidence that has just started to emerge on how social processes can affect individual retrieval. As we noted earlier, the disruptive effects of collaboration are temporary, and later individual recall shows recovery of studied items that were not produced during collaboration.

In a study from our own lab, we examined this effect in recognition. We presented subjects with a list of unrelated words to study and later gave a recognition task in which we assessed effects of collaborative discussion on individual memory (Rajaram and Pereira-Pasarin, 2007). We found that collaborative discussion just prior to making individual recognition responses led to more accurate performance (in both d′ and hits–false alarm measures) than in a retrieval condition that required no prior collaboration. The beneficial effects of collaboration here are impressive because collaboration can potentially affect individual recognition in a negative or a positive direction. It can increase an individual's propensity to go along with the group's input regardless of whether or not it is correct. Individuals can accept nonstudied items as studied, reject studied items, or do both, thereby producing lower memory accuracy. Or, individual subjects can reject more nonstudied items or accept more studied items, or do both, thereby increasing memory accuracy. Yet, group input in our study enhanced individual recognition, and this advantage persisted up to 1 week (see **Figure 4**). As we discuss in a later section titled

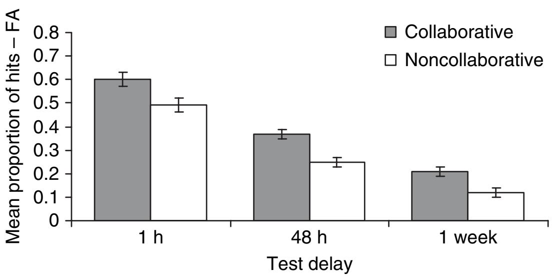

**Figure 4** Mean proportion of hits minus false alarms (FA) as a function of collaborative and noncollaborative conditions and retention interval. Adapted from Experiment 2 in Rajaram S and Pereira-Pasarin L (2007) Collaboration can improve individual recognition memory: Evidence from immediate and delayed tests. *Psychon. Bull. Rev.* 14: 95–100.

'Retrieval errors and other retrieval phenomena,' such benefits do not always occur, because other researchers have shown that input from other group members can sometimes increase memory errors. Regardless, this cluster of findings shows that encoding in and of itself does not determine how much or what an individual will ultimately remember. Retrieval processes – either inherent in the individual or modified by social input – play a large role in determining the final memory output.

As Gardner (1985) noted, researchers have tended to set aside social, emotional, and cultural processes in the pursuit of understanding cognition. In other words, researchers have typically viewed social, emotional, and cultural processes as contextual factors whose influences need to be controlled for rather than as key components in understanding cognition. But memory – or more specifically, retrieval – is usually a social process (Weldon, 2001). Not only do people often recall with others (as discussed in this section, and to some extent also in a later section on retrieval errors), but how the recalled information is interpreted is often a function of the person's sociocultural environment. Theories of memory that are based only on the individual are therefore incomplete. The initial evidence (briefly presented earlier; *see* Chapter 2.47) provides initial support for these conclusions and also suggests that future research should focus on social processes of memory as a factor rather than a confounding variable.

To summarize, collaborative inhibition is the counterintuitive finding that collaborative groups are able to recall less information than the pooled nonredundant responses of nominal groups of equal size. This is theorized to be a retrieval effect similar to the part-list cuing effect. Retrieval disruption (created by the recall products of other group members in the case of collaborative retrieval) disrupts individuals' idiosyncratic retrieval strategies and causes poorer overall memory performance. However, this disruption does not seem to impair subsequent individual memory, and in some cases (for instance, as with recognition memory) may actually enhance individual memory.

## 2.16.7 Retrieval Errors and Other Retrieval Phenomena

Earlier, we reviewed research that shows that repeated retrieval improves memory. As Bjork (1975) noted, retrieval is a memory modifier. Interestingly, the act of retrieval can also reduce memory accuracy. People recall emotional, significant, or entertaining events from their lives often, and it is all too common to embellish the events from one telling to the next or from one audience to another. Bartlett's (1932) classic study is often cited to illustrate how memory output can change from one recall to the next. In this study, people were asked to read a Native American story called 'The War of the Ghosts.' Importantly, the significance of many details in this story was not apparent to people of different cultural backgrounds. The more times that people were asked to retell the story, the more the stories became distorted such that subjects omitted unfamiliar details and inserted materials to make the story consistent with their schemas. These dramatic changes across repeated retrievals have since been replicated in a study by Bergman and Roediger (1999).

Bartlett's (1932) study and Bergman and Roediger's (1999) critical replication show that individuals modify story output even without any intervention from outside sources. It is easy to imagine then that the social situations individuals encounter can change the contents of what individuals might retrieve from one occasion to the next. For example, social situations often dictate whether a story should be told in an accurate or entertaining fashion. In a study by Dudukovic et al. (2004) participants were asked to either retell a story with a goal to be accurate, or with a goal to be entertaining. While the participants did not differ on a later recognition test, they did differ on a later recall test. The participants who had originally told the story accurately recalled more information with less exaggeration than the participants who had originally told the story for entertainment. Thus, the way that we recount information to others influences the way that information is later recalled. As we will describe next, retrieval errors can also creep into individual performance when others provide input during retrieval.

In a previous section on retrieval in a social context, we discussed evidence that shows positive influences of input from others. But individuals also make more retrieval errors under certain conditions if they previously received erroneous input from others. In a study that assessed the effects of social contagion, Roediger et al. (2001) presented subjects with everyday scenes (e.g., a kitchen) during the study phase. Later, subjects recalled the scenes along with a confederate who inserted related but nonstudied items during recall (e.g., toaster). On a final test where subjects engaged in recall alone, they falsely recalled related but nonstudied items more often if they had been inserted by a confederate in the earlier recall phase than if no mention of them had been made.

Basden et al. (2002) reported similar effects of social input in a study where they presented semantically related 'DRM' (Deese-Roediger-McDermott) lists during study and constructed a perceived group-recall situation with the use of interconnected computers. DRM lists consist of thematically related words such as 'dream,' 'bed,' 'night,' etc., where a critical word such as 'sleep' is missing. In individual memory studies, subjects erroneously recall these critical nonpresented words at levels as high as true recall and also give 'remember' responses indicating vivid memory for having seen them before (Roediger and McDermott, 1995). In Basden et al.'s study, subjects engaged in perceived group recall followed by individual recall. During perceived group recall, the subjects were led to believe that they viewed the responses of other group members on the computer screen during recall but in fact the generated responses were controlled by the experimenter. In one condition of perceived group recall, subjects saw the critical, nonpresented lures, and in another condition these items were not included in the supposed responses from other members. Subjects included more erroneous responses in their final individual recall protocols if they had previously participated in one of the two perceived group-recall phases than if they had not participated in the perceived group-recall phase. In this way, individual retrieval can be socially influenced. The process of collaboration can lead to individual retrieval benefits as discussed in the previous section but also to retrieval errors, as these studies show (also see Basden et al., 2000, 2002; Reysen, 2005, for related findings).

Another topic of considerable interest in memory retrieval focuses on the subjects' ability to identify the source of information they recall – a phenomenon called reality monitoring (Johnson and Raye, 1981) The general approach here is to ask subjects whether the item they recalled (or recognized) was presented to them (i.e., the item originated from perception) or was internally generated (i.e., the item was something they imagined or dreamed). According to this framework (e.g., Johnson, 1991; Johnson et al., 1993), people do not explicitly tag memories with source information. Rather, they typically make source attributions based on a generalized evaluation of whether a memory's qualities match expectations. These judgments capitalize on the average differences of the characteristic qualities of memories from different sources. For instance, perceived events tend to include more information about perceptual, temporal, spatial, and affective characteristics and less information about cognitive processes than imagined events. A judgment of 'perceived' rather than 'imagined' should therefore be given if the evaluation of a memory's qualities results in a great deal of information about perceptual and spatial details, accompanied by little information about the cognitive processes that took place during encoding. Attributing a memory to the source for which that memory's qualities are most characteristic maximizes the odds of accurately judging the memory's source. Reality-monitoring failures occur when people falsely claim either that something was perceived when it was actually internally generated or that something was internally generated when it was actually perceived. A detailed review of this topic can be found in a chapter on source monitoring by S. Lindsay (*see* Chapter 2.19) in this volume.

These processes in reality monitoring constitute yet another form of retrieval, one that is characterized by metamemory judgments, because subjects make judgments about information retrieved from memory. In an earlier section on retrieval mode, we described remember and know judgments, which can also be considered metamemory judgments because subjects report the quality of memory for the information they retrieve (see Rajaram and Roediger, 1997; Rajaram, 1999; Roediger et al., 2007). There are also other well-known metamemory judgments such as feelings of knowing (see Koriat, 1995) and the tip-of-the-tongue state (see Brown, 1991; Schwartz et al., 2000) that researchers study to find out subjects' sense of what they can retrieve even when recall does not succeed. These judgments reveal interesting – metacognitive – aspects of the retrieval process as subjects make judgments about the likelihood of retrieval under certain circumstances. In the feeling-of-knowing state (see Koriat, 1995) subjects can reliably report whether they can recognize an item on a multiple-choice test even though they were unable to recall that item, and in the tip-of-the-tongue state, people can reliably indicate whether or not the information they are trying to retrieve is on the tip of their tongue and could be retrieved. We recommend chapters by A. Koriat on control processes in remembering (*see* Chapter 2.18) and by A. S. Brown on the tip-of-the-tongue states (*see* Chapter 2.22) for detailed discussions of these topics.

In conclusion, the ways in which retrieval conditions are arranged to a large extent determine how much memory accessibility can improve. But in many situations, retrieval can also act as a memory modifier and can do so in systematic ways. Such situations can lead to systematic errors in retrieval, as revealed by the DRM effect. Furthermore, when recalling information, people are motivated not only to present a coherent story, but also to tell the story with a particular purpose (for example, to be entertaining). Both of these motivations can serve to lower overall memory accuracy. Retrieval errors can also be the result of social influences (believing that you saw something that someone else endorsed seeing), or reality monitoring errors (believing that you saw something that you only imagined seeing). Finally, many meta-memory processes such as the tip-of-the-tongue phenomenon also modulate the success of retrieval.

## 2.16.8 Concluding Comments

As we noted in the introduction, much of memory research has been guided by a focus on three putative components – encoding, storage, and retrieval. But from the perspective of the rememberer, it is the act of retrieval that constitutes memory. In this chapter, we have taken this perspective to explore various phenomena in memory research that tell us something important about the process of retrieval and ways in which this process enables access to what we have learned. The phenomena and findings reviewed in this chapter point to the unique role that retrieval processes play in modifying the effects of different encoding processes. Above all, these findings show that, without a proper understanding of the nature and power of retrieval, our understanding of how memory works is not only incomplete but also flawed.

# 2.17 Remembering and Knowing

**J. M. Gardiner**, University of Sussex, Brighton, UK

> This ultimate puzzle, the subjective experience of consciousness, is perhaps a good place for any purely scientific survey, namely one of objective facts, to cease.
>
> (Greenfield, 1997: 192)

> . . . the peculiarity of individual experience does not place the subject of individual experience outside the realm of scientific inquiry. Any explanation of consciousness must account for subjective states of awareness. . .
>
> (Searle, 1997: 49–50)

## 2.17.1 Introduction

The mystery of consciousness seems to have resisted scientific investigation for at least two main reasons, first, because consciousness is apparently unitary and, second, because it is subjective. It is difficult for science to deal with phenomena that cannot be broken down into constituent parts that can be investigated separately, as well as in conjunction. Thus, little theoretical progress was made in memory research for so long as memory was thought of as being a single mental faculty – memory is memory – and significant progress has been made only since memory began to be classified into various systems and component processes. Similarly, little progress can be made in understanding consciousness for so long as consciousness is thought of just as consciousness. Consciousness has to be broken down and classified into different natural kinds as a precondition for scientific inquiry. This chapter concerns one such classification, a simple classification of consciousness in relation to memory that was proposed by Endel Tulving, along with a paradigm for investigating the different kinds of consciousness (Tulving, 1983, 1985).

Tulving's (1983, 1985) original proposal was of three kinds of consciousness, each reflecting one of three memory systems. The three kinds of consciousness were autonoetic, noetic, and anoetic, which respectively mean self-knowing, knowing, and not knowing. The three corresponding memory systems were episodic, semantic, and procedural memory. Only autonoetic and noetic consciousness involve awareness of memory. Anoetic consciousness is bound to the present, not the past, and involves awareness of the current situation. Autonoetic consciousness allows awareness of oneself in a previous situation, in the sense of what has been called mental time travel. It allows one to reexperience previous events and to relive them mentally, including one's own part in them. It is characteristic of episodic memory, which therefore entails something more than, or other than, autobiographical memory.

Autobiographical memory includes facts known about one's past in an abstract, historical sense, without any-ability to reexperience those autobiographical events or relive them mentally. It is noetic consciousness that gives rise to awareness of this kind, and it is characteristic of semantic memory, which also includes all the general knowledge that one has acquired about the world.

The remember-know paradigm was introduced by Endel Tulving (1985) as a procedure for obtaining what have been called subjective (or first-person) reports of autonoetic and noetic awareness. In this paradigm, for each item retrieved participants are instructed to report "whether they actually 'remember' its occurrence in the list or whether they simply 'know' on some other basis that the item was a member of the study list" (Tulving, 1985: 8). The proportion of remembered items gives a direct measure of autonoetic awareness, whereas the proportion of known items reflects noetic awareness. It follows that remembering, as a state of awareness, gives a better measure of retrieval from episodic memory than other more traditional measures such as recall or recognition.

Since the introduction of this paradigm, it has been significantly modified and very widely used, such that there is now a substantial body of research in which participants have been required to make remember and know responses at the time of retrieval. A large number of empirical facts about autonoetic and noetic awareness have been established. Other theoretical accounts than that provided by the distinction between episodic and semantic systems have also been invoked to account for these facts. These include dual-process models of recognition that distinguish between two independent processes, recollection and familiarity, which are assumed to respectively give rise to corresponding recollective experiences (that is to remembering) and to feelings of familiarity (Mandler, 1980; Jacoby, 1991). Another processing account distinguishes between the distinctiveness and the fluency of the processing involved, with distinctiveness giving rise to remembering and fluency giving rise to knowing (Rajaram, 1996). A third approach has been to try to model remember and know responses using signal detection measures of trace strength and response criteria in recognition tests. According to some of these models, remembering simply represents the adoption of more stringent response criteria than that adopted in deciding whether the item was a member of the study list (Donaldson, 1996; Hirshman, 1998; Inoue and Bellezza, 1998).

Studies using the remember-know paradigm, particularly the early ones, were widely criticized because of the so-called subjectivity of remember and know responses, which to some critics puts the paradigm outside the realm of scientific inquiry. However, such criticism has become more muted of late, mainly by virtue of the empirical facts that have been discovered and the theoretical understanding of them that has been achieved. There are also purely rational arguments against the overly narrow view of scientific method and explanation that this criticism embodies.

The aim of this chapter is to survey what has been achieved by studies that have made use of the remember-know paradigm. To that end, the paradigm itself is described in more detail in the next section of the chapter. This is followed by a section that argues, on rational grounds, for the objectivity of the subjective experiences of consciousness measured by remember and know responses. The next section of the chapter surveys many of the empirical facts that have been gleaned experimentally, especially from earlier studies. After that, the major theoretical accounts are briefly outlined. Next follows a lengthy section concerned with more recent empirical findings and current theoretical issues. The chapter concludes with a critical theoretical evaluation.

## 2.17.2 The Paradigm

Although in introducing the paradigm Endel Tulving (1985) used free recall, cued recall, and recognition tests, nearly all the subsequent studies that made use of it used recognition tests. The two most significant modifications to the paradigm in part reflect this rather restricted usage. The first modification was to identify know responses in the instructions given to participants closely with familiarity rather with some other basis. This modification has occurred gradually, over a period of years, in different studies. Instructions often emphasize the importance of having strong feelings of familiarity or knowing, or being highly confident of such feelings. The second modification was to add a guess response (Mantyla, 1993; Gardiner et al., 1996). Both these modifications have some theoretical importance. Identifying know responses with familiarity links those responses more directly to semantic memory and to the familiarity process in dual-process models. The addition of a guess response has implications both for a familiarity process and for signal detection models. But the primary reason for allowing this response was methodological. It allows for recognition decisions that are more strategically based and not associated either with experiences of remembering or with knowing. Guess responses therefore remove a potential confounding of such strategically based recognition decisions with remember or know responses. They also provide a default response if participants realize that their initial recognition decision was mistaken. There are thus good methodological reasons for recommending that the paradigm should usually include guess responses (Gardiner and Conway, 1999). This paradigm is summarized schematically in **Table 1**. For a full version of typical written test instructions that includes those for guess responses, see Gardiner and Richardson-Klavehn (2000).

It is also good practice to check the validity of remember, know, and guess responses by having participants provide descriptions of the reasons underlying a random selection of them after the test is over. It is important that participants provide evidence of contextually relevant mental details for remember responses and do not provide such evidence for know or guess responses. And such descriptions can be of considerable interest in their own right (Gardiner et al., 1998a). Neither the use of guess responses nor that of posttest checks of the validity of all three kinds of responses has become universal practice, however, even in more recent studies, despite the increased risk of obtaining potentially misleading results (see, e.g., Gardiner et al., 1996, 1997).

**Table 1** The usual remember-know (guess) paradigm in recognition memory tests

| |
|---|
| ***Procedure*** |
| Study tasks |
| Retention interval |
| Recognition tests (Old/New) |
| If Old, then Remember, Know, or Guess |
| ***Response definitions*** |
| Old/New: Test item occurred/did not occur in the study list |
| Remember: Test item brought back to mind some specific recollection of something you thought about when it occurred in the study list |
| Know: Test item does not bring back to mind something you thought about when it occurred in the study list, but it seemed strongly familiar in the experimental context |
| Guess: Test item did not give rise either to experiences of remembering or of knowing it occurred in the study list, but you have other reasons for guessing that it might have done |

## 2.17.3 The Objectivity of Subjective Experiences of Consciousness

Criticism that the subjectivity of the states of awareness reported by remember and know responses means that those responses do not yield scientific data is misguided. In effect, this criticism argues that a recognition response is objective but a remember or know response is subjective. But remember and know responses (guess responses, too) are simply a partitioning of the recognition response into some constituent components, and so, by the same token, the recognition response is simply based on the sum of those components. A recognition response also reflects subjective states of awareness. It is difficult, looking at the four response definitions given in **Table 1**, to make a convincing case for there being between the first definition and the three definitions that follow it a categorical shift from objectivity to subjectivity.

Remember and know responses, respectively, reflect distinct populations of experiences of autonoetic and noetic awareness, and it is critical for a scientific approach that these natural kinds of subjective experiences are treated at the population level, not at the level of individual instances of such experiences, which are inevitably idiosyncratic (Gardiner, 2001). Psychology is a biological science, not a physical one, and biology is characterized by population thinking, not by essentialism (Mayr, 1982). Every individual instance of remembering may be unique, just as every individual member of a biological species is unique. In each case, that which is uniquely individual may be impenetrable to science, but the population to which individual instances conform is not impenetrable to science, whether of a biological species or of a mental state of awareness. Therein lies the importance of a conceptual classification of so-called subjective consciousness.

But, as the saying goes, the proof of the pudding is in the eating. For data to be amenable to science, those data must yield phenomena that are systematic, replicable, and intelligible theoretically. It was by no means a foregone conclusion that this would turn out to be the case using the remember-know paradigm, and early studies using the paradigm were primarily concerned with seeing whether such a case could be established empirically. That is, they were concerned initially with whether or not, and then under what circumstances and for what reasons, functional dissociations might be observed between the reported states of awareness. Functional dissociation refers here to the discovery of dissociative effects of experimental manipulations on the reported states of awareness or of dissociative effects between them in comparing different subject populations. The first such study was by Gardiner (1988), who found that the beneficial effects both of deeper levels of processing and the detrimental effects of longer retention intervals were essentially confined to remembering. This kind of outcome was soon replicated by other studies that included the effects of word frequency (Gardiner and Java, 1990), undivided versus divided attention, use of a digit-monitoring task (Gardiner and Parkin, 1990), and the picture superiority effect (Rajaram, 1993). The first study reporting dissociative effects among different subject populations was by Parkin and Walter (1992), who found that reports of remembering were greatly reduced in older compared with younger adults. This kind of outcome that was soon replicated by other studies that included patients with Alzheimer's disease (Dalla Barba, 1997), patients with schizophrenia (Huron et al., 1995), and amnesic patients (Knowlton and Squire, 1995).

## 2.17.4 Functional Dissociation

It is important to appreciate that functional dissociation between remembering and knowing cannot reliably be inferred from more familiar measures of recognition memory such as old versus new. To illustrate this, each of the following subsections of the chapter begins with a figure that simply shows overall proportions of correct responses from four different studies, and then goes on to show how those proportions were partitioned between remembering and knowing. This initial survey ignores false alarm rates, not because they are unimportant but because they do not much affect the conclusions to be discussed.

### 2.17.4.1 Experimental Manipulations

**Figure 1** shows the proportions of study list items that were correctly identified as old from each of four studies involving different experimental manipulations. The first example is taken from a levels-of-processing study (Gardiner et al., 1996) in which participants had to either report a semantic associate for a presented word or to report any two letters not present in the word, and it shows a large levels-of-processing effect. In the second example, study list words were presented rapidly with the instruction to monitor the number of words that contained letters that were blurred (there were none), a task intended to encourage perceptual processing and discourage conceptual processing (Gregg and Gardiner, 1994). At test, half the words were presented in the same visual mode, and half were presented auditorily. Recognition was much more likely when study and test modes were the same. In the third example, participants studied a mixed list of words and pronounceable nonwords (Gardiner and Java, 1990), but this material manipulation had little effect on recognition. And in the final example, participants heard a set of musical phrases taken from folk songs in a culture with which they were unfamiliar (Polish, for English participants, and vice versa) either just once or on three successive study trials before the test (Gardiner and Radomski, 1999). Not surprisingly, the musical phrases were much more likely to be recognized following three study trials than following only one.

**Table 2** summarizes the full partitioning of these recognition data between remember and know responses, and it illustrates four different kinds of outcome. The levels-of-processing effect occurred in remember but not know responses. The effects of study/test mode occurred in know but not remember responses. For words and nonwords, there was a crossover effect such that word recognition was accompanied by more remember than know responses, whereas nonword recognition was accompanied by more know than remember responses. But the effect of study trials on the recognition of musical phrases was similar for both responses, with increased remembering and increased knowing.

What is important about the pattern of results illustrated in **Table 2** is that it demonstrates what has been termed functional independence between remembering and knowing (Gardiner and Conway, 1999). That is, there are variables that affect remembering but not knowing; variables that affect knowing but not remembering; variables that have opposite effects on remembering and knowing; and variables that have similar effects on remembering and knowing. Experimental conditions can affect the two states of awareness, separately or jointly, in ways that cannot be inferred from the overall proportions of items that are correctly recognized.

These kinds of outcomes have been replicated many times in various different studies. Among many other examples, selective advantages to remembering have been found for intentional versus incidental learning (Macken and Hampson, 1993), for slow versus fast presentation rates (Dewhurst and

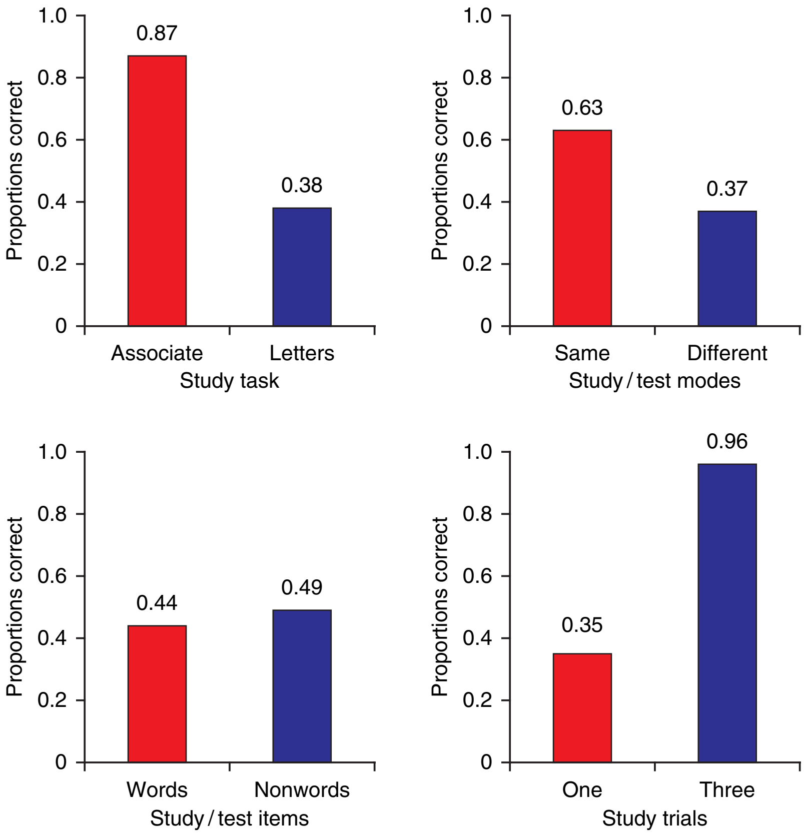

**Figure 1** Effects of some experimental manipulations on overall recognition (correct 'old' response proportions). These examples, going clockwise from the top left-hand corner, are taken, respectively, from experiments by Gardiner JM, Java RI, and Richardson-Klavehn A (1996) How levels of processing really influences awareness in recognition memory. *Can. J. Psychol.* 50: 114–122; Gregg VH and Gardiner JM (1994) Recognition memory and awareness: A large effect of study-test modalities on "know" responses following a highly perceptual orienting task. *Eur. J. Cognit. Psychol.* 6: 137–147; Gardiner JM and Java RI (1990) Recollective experience in word and nonword recognition. *Mem. Cognit.* 18: 23–30; and Gardiner JM and Radomski E (1999) Awareness of recognition memory for Polish and English folk songs in Polish and English folk. *Memory* 7: 461–470; all figures used with permission.

Anderson, 1999), and for orthographically distinctive versus orthographically common words (Rajaram, 1998). Serial position effects occur in remembering and not in knowing, and prior recall tests boost remembering but do not boost knowing (Jones and Roediger, 1995).

Selective increases in knowing but not in remembering have been found to result from presenting identical (Rajaram, 1993) or associatively related (Rajaram and Geraci, 2000) test primes and from cohort activation in a preceding lexical decision task (Dewhurst and Hitch, 1997). Dividing attention by suppressing the processing of foveal information also selectively facilitates knowing (Mantyla and Raudsepp, 1996). Opposite effects on remembering and knowing have been found for massed versus spaced repetitions of study list items (Parkin and Russo, 1993); for the revelation effect, which occurs when gradually revealing words at test compared with presenting them normally (LeCompte, 1995); and from encoding faces with respect to their similarity versus encoding them with respect to their distinctiveness (Mantyla, 1997). Parallel increases in both remembering and in knowing have also been found when manipulating response deadlines in recognition tests to compare speeded with unspeeded recognition decisions (Gardiner et al., 1999).

### 2.17.4.2 Special Populations

Figure 2 shows the proportions of study list items that were correctly identified as old from each of four studies involving different special populations. The first example is taken from a study involving amnesic

**Table 2** Effects of some experimental manipulations on remembering and knowing (for correct 'old' response proportions)

| *Manipulation* | *Condition* | *Remember* | *Know* |
|---|---|---|---|
| Study tasks | Associate | .72 | .15 |
| | Letters | .18 | .20 |
| Study/test modes | Visual/visual | .11 | .52 |
| | Visual/ auditory | .10 | .27 |
| Study/test items | Words | .28 | .16 |
| | Nonwords | .19 | .30 |
| Study trials | One | .14 | .21 |
| | Three | .37 | .32 |

These examples are taken, respectively, from experiments by Gardiner JM, Java RI, and Richardson-Klavehn A (1996) How levels of processing really influence awareness in recognition memory. *Can. J. Psychol.* 50: 114–122; Gregg VH and Gardiner JM (1994) Recognition memory and awareness: A large effect of study-test modalities on ''know'' responses following a highly perceptual orienting task. *Eur. J. Cognit. Psychol.* 6: 137–147; Gardiner JM and Java RI (1990) Recollective experience in word and nonword recognition. *Mem. Cognit.* 18: 23–30; and Gardiner JM and Radomski E (1999) Awareness of recognition memory for Polish and English folk songs in Polish and English folk. *Memory* 7: 461–470.

patients (Schacter et al., 1997a). In the second example, the study compared the performance of younger with older adults (Perfect et al., 1995). The third example is taken from the study by Huron et al. (1995) involving schizophrenic patients. And the final study involved high-functioning adults with autistic spectrum disorders or Asperger's syndrome (Bowler et al., 2000). In the first three of these special populations, recognition performance was impaired to varying degrees, but there was little difference between the performance of adults with autistic spectrum disorders and that of an appropriately matched control group.

**Table 3** summarizes the full partitioning of these recognition data between remember and know responses. The pattern of results here is rather different from that in **Table 2**, but it is clear that the two states of awareness differ in different populations in ways that cannot be inferred from the overall proportions of items that are correctly recognized. Remembering but not knowing was greatly reduced in the amnesic patients. Remembering was also greatly reduced in older compared with younger adults, but this reduction was largely offset by increased knowing. Schizophrenic patients also remembered less than an appropriately matched control group, but there was little difference in the amount of knowing. And, though overall recognition was much the same for adults with autistic spectrum disorders as for the control group, this masked a trade-off between reduced remembering and increased knowing.

Although these kinds of outcomes have also been replicated in other studies, there is considerable variability among some of these studies. Other studies involving amnesic patients have found reduced knowing as well as reduced remembering (Knowlton and Squire, 1995). Other studies involving older adults found increased knowing, as well as reduced remembering (Parkin and Walter, 1992), particularly when encoding was not controlled by specific study tasks (cf. Perfect et al., 1995). Further studies have confirmed the selective deficit in remembering in schizophrenic patients (Danion et al., 1999) and in adults with autistic spectrum disorders, though in the latter case this deficit is not always accompanied by increased knowing (Bowler et al., 2007).

Other special populations in which remembering and knowing have been investigated include epileptic patients with temporal lobe lesions. Blaxton and Theodore (1997) found that patients with left temporal lobe lesions reported far more knowing than remembering, whereas patients with right temporal lobe lesions reported far more remembering than knowing. There is also some evidence of reduced remembering in recognition memory for threat-related words in clinical anxiety states (Mogg et al., 1992). Alcohol (Curran and Hildebrandt, 1999) and other drugs such as lorazepam (Curran et al., 1993) and midazolam (Hirshman et al., 2002) can also adversely and selectively affect remembering, but emotionally negative stimuli tend to be better remembered than positive or neutral stimuli (Ochsner, 2000).

## 2.17.5 Major Theories

Such findings have attracted considerable theoretical interest, and at least four major theories were initially advanced to account for them.

### 2.17.5.1 Episodic and Semantic Memory Systems

According to Tulving (1983, 1985), remembering is an expression of autonoetic consciousness and hence retrieval from episodic memory, and knowing is an expression of noetic consciousness and hence retrieval from semantic memory. Thus, retrieval from both systems contributes to performance in recognition

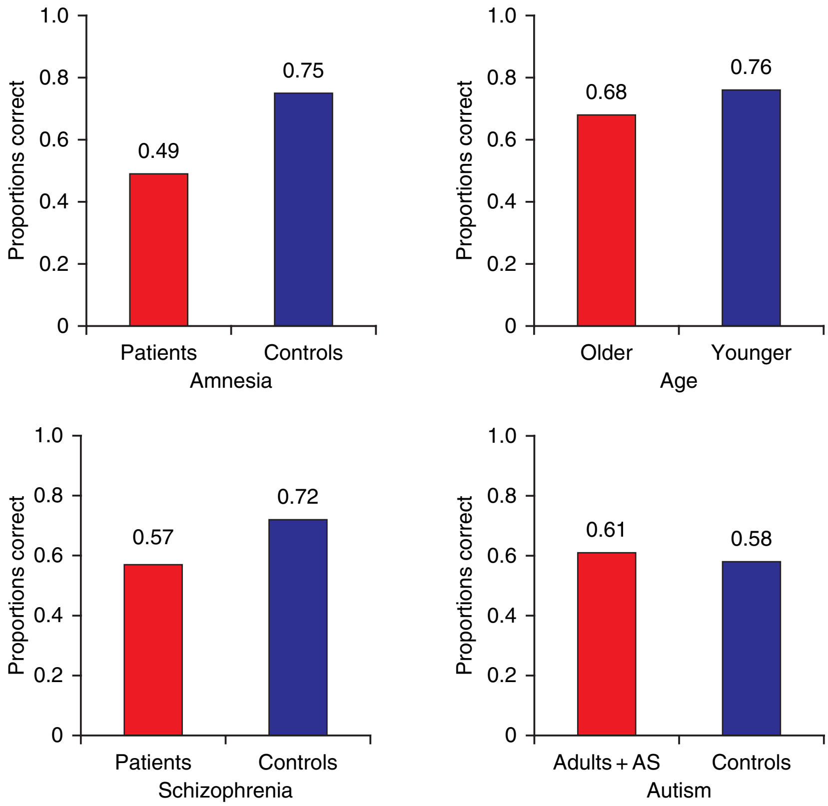

**Figure 2** Differences between recognition (correct 'old' response proportions) in some special populations. AS stands for Asperger's syndrome, a mild form of autism. These examples, going clockwise from the top left-hand corner, are taken, respectively, from experiments by Schacter DL, Koutstaal W, Johnson MK, Gross MS, and Angell KE (1997a) False recollection induced by photographs: A comparison of older and younger adults. *Psychol. Aging* 12: 203–215; Perfect TJ, Williams RB, and Anderton-Brown C (1995) Age differences in reported recollective experience are due to encoding effects, not response bias. *Memory* 3: 169–186; Huron C, Danion JM, Giacomoni F, Grange D, Robert P, and Rizzo L (1995) Impairment of recognition memory with, but not without, conscious recollection in schizophrenia. *Am. J. Psychiatry* 152: 1737–1742; and Bowler DM, Gardiner JM, and Grice S (2000) Episodic memory and remembering in adults with Asperger's syndrome. *J. Autism Dev. Disord.* 30: 305–316; all figures used with permission.

tests, among others. Tulving (1995) additionally proposed an SPI model of relations between these systems such that that encoding into semantic and episodic systems is serial (S), storage is parallel (P), and retrieval is independent (I). Given some minimal registration of the occurrence of an event, that event may only be stored in the semantic system. Given more attention at encoding and more conscious control, the event may be further encoded into episodic memory. Events may be stored in both systems but retrieved independently from them. Tulving (1993) also proposed a coordination hypothesis, which concerns the relation between awareness at encoding and awareness at retrieval. According to this hypothesis, the retrieval of information from a system is possible only at a level of awareness that does not exceed the level of awareness achieved at encoding. In other words, it is not possible for the retrieval of information that has only been encoded into the semantic system to give rise to autonoetic awareness, however much time and conscious effort goes into the retrieval attempt.

Much of the evidence is consistent with this account, but more critical to it is recent evidence concerning the underlying neuroanatomical substrates of episodic and semantic systems. For example, in an event-related potentials (ERP) study, Mangels et al. (2001) showed that whereas some minimal level of encoding (with divided attention) is sufficient to lead to knowing in recognition memory, remembering depends on more

**Table 3** Differences between remembering and knowing in some special populations (for correct "old" response proportions)

| *Condition* | *Group* | *Remember* | *Know* |
|---|---|---|---|
| Amnesia | Patients | .21 | .28 |
| | Controls | .50 | .25 |
| Age | Older adults | .17 | .51 |
| | Younger adults | .53 | .23 |
| Schizophrenia | Patients | .23 | .34 |
| | Controls | .39 | .33 |
| Autism | Adults with Asperger's | .36 | .25 |
| | Controls | .47 | .11 |

These examples are taken, respectively, from experiments by Schacter DL, Koutstaal W, Johnson MK, Gross MS, and Angell KE (1997a) False recollection induced by photographs: A comparison of older and younger adults. *Psychol. Aging* 12: 203–215; Perfect TJ, Williams RB, and Anderton-Brown C (1995) Age differences in reported recollective experience are due to encoding effects, not response bias. *Memory* 3: 169–186; Huron C, Danion JM, Giacomoni F, Grange D, Robert P, and Rizzo L (1995) Impairment of recognition memory with, but not without, conscious recollection in schizophrenia. *Am. extensive brain activity, including sustained interaction of frontal and posterior regions. Other studies (to be discussed later) have provided evidence that implicates hippocampal as well as frontal regions of the brain in remembering (Eldridge et al., 2000; Wheeler and Stuss, 2003), and there is increasing evidence of functional dissociations between remembering and knowing at the level of the brain (Wheeler and Buckner, 2004). As Tulving (2002) put it in the title of a recent review, episodic memory now extends "from mind to brain."

### 2.17.5.2 Memory Process Accounts

Among the most prominent alternative theories are those that distinguish between two kinds of processes, rather than two memory systems.

#### *2.17.5.2.1 Recollection and familiarity*

Dual-process models of recognition memory distinguish between recollection and familiarity processes, each of which is assumed to give rise to corresponding experiences of recollection and familiarity (Mandler, 1980; Jacoby, 1991). These two processes are assumed to be independent and to vary in the extent to which they are consciously controlled. Recollection is generally thought to be a relatively slow, effortful process that depends on conscious control, whereas familiarity is thought to be a relatively fast, automatic process that does not depend on conscious control. Because experiences of recollection and familiarity are indicated by remember and know responses, the remember-know paradigm is also a procedure that can be used to test the relative contributions these two processes make to recognition. The independence assumption means that some recognition responses are based jointly on recollection and familiarity, and so an independent remember-know model is used to provide estimates of the two processes (Yonelinas and Jacoby, 1995). In this model, remember responses are taken to provide a relatively direct estimate of the recollection process, but the familiarity process is estimated by dividing the proportions of know responses by one minus the proportions of remember responses. For a version of the paradigm that allows independence between remember and know responses, see Higham and Vokey (2004).

The use of this procedure to provide such process estimates has proved to be quite controversial (Richardson-Klavehn et al., 1996; Jacoby et al., 1997). Nonetheless, in a comprehensive review Yonelinas (2002) showed that there is quite good agreement between the conclusions drawn from this procedure and from other procedures used to provide estimates of recollection and familiarity, namely, the process-dissociation procedure (Jacoby, 1991) and receiver operating characteristics (ROCs). Moreover, although the processes of recollection and familiarity offer an alternative theory to that offered by the distinction between episodic and semantic memory systems, there is in broad terms a great deal of convergence between these two accounts. Even know responses, which have generated more controversy, have a parallel meaning from each theoretical perspective. In dual-process models, they indicate familiarity in the absence of recollection. In the systems approach, they indicate semantic memory in the absence of episodic memory. But theorists who have adopted this process account are primarily concerned with the underlying processes rather than with remembering and knowing *per se*, whereas theorists who have taken the systems approach focus more on the actual states of awareness. So one important difference between the two approaches is whether the primary data are regarded as estimates inferred from remember and know responses or remembering and knowing as such.

#### 2.17.5.2.2 Distinctiveness and fluency

Results of earlier studies using the remember-know paradigm suggested that remember and know responses were influenced, respectively, by conceptual and perceptual variables and hence by conceptual and perceptual processes (Rajaram, 1993), thereby linking them with the transfer-appropriate processing framework (Roediger et al., 1989). However, results from more recent studies forced a revision of this view, as some perceptual variables were found to influence remembering but not knowing, and some conceptual variables were found to influence knowing but not remembering. Rajaram (1996), for example, found that a size congruency effect, that is, superior recognition memory for pictures presented in the same size at study and test rather than in alternative sizes, occurred only in remembering. And Mantyla (1997) found that grouping faces that seemed similar into several conceptual categories, a relational task that depends on the use of schema in semantic memory, increased knowing. He also found that rating the facial distinctiveness of different faces increased remembering.

Such findings led to the proposal of a distinctiveness/fluency framework according to which remembering benefits from the distinctiveness of the processing and knowing benefits from its fluency, regardless of whether that processing is conceptual or perceptual (Rajaram, 1996, 1999). It is important to note that in this approach, the distinctiveness or fluency of processing is not inferred from remember and know responses but independently based on other theoretical considerations. Though this approach offers a different theoretical perspective, nonetheless in some respects it complements memory systems and dual-process models. Distinctiveness implies greater attention and more elaborative processing, which will increase encoding into episodic memory or enhance a recollection process. Fluency implies less attention and minimal processing, which may increase encoding into semantic but not into episodic memory or enhance a familiarity process.

### 2.17.5.3 Signal Detection Models

The three foregoing theories all converge on the conclusion that remembering and knowing reflect two distinct underlying components of memory, though they differ in their characterization of those components. The possibility that remembering and knowing might simply reflect a single memory component has been raised by signal detection models. That remembering and knowing might simply map onto single-trace strength, with higher or lower degrees of confidence, had been discounted on the basis of some early studies in which sure versus unsure recognition responses were shown to yield different patterns of results to remember versus know responses (Gardiner and Java, 1990; Parkin and Walter, 1992; Rajaram, 1993). However, Donaldson (1996) showed that a single-trace signal detection model could provide an approximate fit to results from the remember-know paradigm, and this approach has recently been followed up by other theorists (Hirshman and Henzler, 1998; Dunn, 2004; Wixted and Stretch, 2004). The essential claim is that remembering and knowing reflect decision processes rather than memory and are simply a matter of confidence. A more stringent response criterion is set for remember responses, and a more lenient criterion, corresponding with the overall criterion for recognition, includes know responses.

This approach has been supported by meta-analyses of results from many different studies as well as by results from individual experiments, but it has also been strongly criticized on various grounds, and there are quite technical arguments involving the appropriateness of the various different assumptions and measures that can be used in signal detection models. The assumptions and measures used by Donaldson (1996) have subsequently been shown to support a dual-component interpretation, not his original model, by yielding higher estimates of trace strength when those estimates are derived from both know and remember responses rather than from remember responses alone (Gardiner and Gregg, 1997; Gardiner and Conway, 1999; Gardiner et al., 2002). If remembering and knowing merely reflect different response criteria such estimates should be the same. But the assumptions and measures that yield those outcomes have been discredited in favor of others that have been shown to support a one-dimensional signal detection model (Dunn, 2004; Macmillan et al., 2005).

## 2.17.6 Further Empirical Extensions and Theoretical Issues

In recognition memory, noetic awareness usually corresponds with familiarity in the sense of some recent but unremembered encounter with the test item. But with respect to general knowledge in semantic memory, noetic awareness does not refer to some recent but unremembered encounter but rather to "just knowing" that something is so. Conway et al. (1997) gave UK undergraduate students forced-choice tests of knowledge acquired in various courses immediately at the end of the courses and again some months later at the end of the academic year. In these tests, students reported whether they remembered their answer, just knew it, chose it because it seemed more familiar (in the sense of having been encountered recently), or had simply guessed. In the initial tests, top-scoring students reported more remembering than students with lower scores. In the final tests there was a 'remember-to-know' shift. Those same top-scoring students reported more just knowing the answers than students with lower scores. Lower-scoring students showed a similar remember-to-know shift, but it was less pronounced. There were no such trends in reported familiarity or guessing. These findings have been replicated in a similar study carried out in Australia (Herbert and Burt, 2001). They illustrate the role of remembering in the acquisition and schematization of knowledge. Initially, remembering the learning episodes is helpful, but over time, with further study and coursework, the ability to remember the original learning episodes is lost and knowledge acquired from them becomes schematized in semantic memory.

But remembering may not be necessary for the acquisition of knowledge. There are amnesic patients who seem to have acquired normal semantic memory knowledge despite showing little or no evidence of any experiences of remembering. One such case, initially reported by Vargha-Khadem et al. (1997), is that of Jon, a young adult with early-onset developmental amnesia caused by selective bilateral damage to the hippocampus. Jon has above-average intellectual abilities, and he has acquired good general knowledge, including good language skills. Nonetheless, though he understands the distinction between remembering and knowing and will follow instructions for remember and know responses in recognition tests, there is no evidence that he experiences remembering in such tests (Baddeley et al., 2001; Gardiner et al., 2006a). When asked to describe what it was that he remembered about those items he claimed to remember, Jon could only say again that he remembered them. His recognition performance was not enhanced by task enactment compared with reading a phrase that described an action task. Task enactment normally boosts remembering (Engelkamp, 1998). Nor did Jon's ERPs show the normal late positive component (LPC) that has been associated with remembering; they did show an earlier negative component (the so-called N400 effect) that has been associated with knowing (Rugg et al., 1998). Jon also claimed to remember general knowledge facts that he knew prior to a laboratory study of how he acquires novel facts, unlike participants in a control group who (correctly) claimed just to know them. Jon did successfully learn quite a few of the novel facts that he knew prior to an unpublished study, albeit at a greatly reduced rate compared with that of the control group. This reduced learning performance reflects Jon's inability to use remembering of the learning episodes as an aid to knowledge acquisition.

At the other extreme, knowledge of an event that has occurred recently but which cannot be remembered also gives rise to noetic awareness and represents a minimal level of encoding in semantic memory. Encoding at this level can be fostered by having very rapid, perceptually oriented study conditions of the sort used by Gregg and Gardiner (1994; see also Gardiner and Gregg, 1997) or by having divided instead of full attention at study (Mangels et al., 2001). Under these conditions, there are at least some effects in memory that occur in knowing instead of remembering.

Shown in **Figure 3** is an example of the size congruency effect in picture recognition memory with either full attention or divided attention at study (Gardiner et al., 2001). Divided attention reduced recognition performance but did not influence the size congruency effect. **Table 4** includes the partitioning of these data between remember and know responses. With full attention, the size congruency effect occurred in remembering, replicating results first reported by Rajaram (1996; see also Yonelinas and Jacoby, 1995).

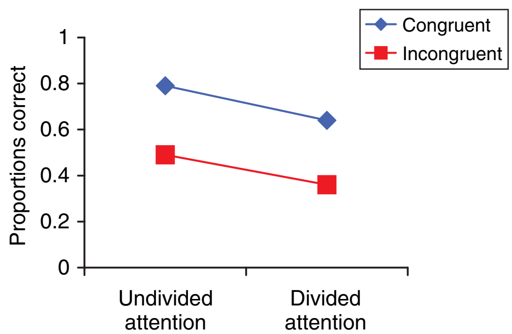

**Figure 3** Effects of attention and picture size congruence on overall recognition (correct 'old' response proportions). Adapted from Gardiner JM, Gregg VH, Mashru R, and Thaman M (2001) Impact of encoding depth on awareness of perceptual effects in recognition memory. *Mem. Cognit.* 29: 433–440, Table 1, with permission from The Psychonomic Society.

**Table 4** Further effects (shown in bold) of some experimental manipulations on remembering and knowing (for correct 'old' response proportions)

| *Manipulations* | *Study/test congruency* | *Remember* | *Know* |
|---|---|---|---|
| Full attention | Same size | **.53** | .26 |
| | Different size | **.37** | .27 |
| Divided attention | Same size | .15 | **.34** |
| | Different size | .12 | **.22** |
| Full attention (with words) | Same voice | **.44** | .31 |
| | Different voice | **.34** | .33 |
| Divided attention (with nonwords) | Same voice | .18 | **.38** |
| | Different voice | .16 | **.28** |
| Longer study time | Same size | **.42** | .14 |
| | Different size | **.32** | .14 |
| Shorter study time | Same size | .22 | **.28** |
| | Different size | .19 | **.18** |

These examples are taken, respectively, from experiments by Gardiner JM, Gregg VH, Mashru R, and Thaman M (2001) Impact of encoding depth on awareness of perceptual effects in recognition memory. *Mem. Cognit.* 29: 433–440; Karayianni I and Gardiner JM (2003) Transferring voice effects in recognition memory from remembering to knowing. *Mem. Cognit.* 31: 1052–1059; and Nega C (2005) Perceptual effects and recollective experience in face recognition. *Exp. Psychol.* 52: 224–231.

With divided attention, however, the effect occurred in knowing. Similar results, also shown in **Table 4**, obtain for congruency of male or female speaker's voice (Karayianni and Gardiner, 2003) and, with a manipulation of study time duration rather than of attention, for facial size congruency (Nega, 2005). For reasons that remain unknown, other similar conditions do not reveal this transfer of effects from one state of awareness to the other. Curran and Hildebrandt (1999), for example, found that although alcohol selectively reduced remembering, the generation effect (better memory for study list words participants generate rather than read) remained in remembering. It did not emerge in knowing.

That following relatively impoverished study conditions some effects occur in knowing instead of in remembering supports the SPI model of relations between semantic and episodic systems (Tulving, 1995). Impoverished encoding conditions reduce the more elaborative and consciously controlled encoding necessary for episodic memory, but do not much affect the more automatic and less consciously controlled encoding sufficient for semantic memory. By the same token, these findings support the distinctiveness/fluency framework (Rajaram, 1996) and confirm that the distinction between conceptual and perceptual processing is orthogonal to the distinction between the two states of awareness, because similar perceptual effects can occur in either state. Impoverished encoding conditions presumably reduce the opportunity for more distinctive processing without much affecting processing fluency.

Another general theoretical issue concerns the relations between consciousness of memory, in the sense of remembering versus knowing, and consciousness of task control, whatever the task may be. It has been rather generally assumed that whereas remembering is consciously controlled, knowing is not. These assumptions have not only been central to dual-process models, according to which recollection is a controlled process and familiarity is an automatic process, but they have also been made in relation to episodic and semantic memory systems. Access to episodic memory usually requires conscious effort, whereas access to semantic memory tends to be automatic (Tulving, 1983).

Conscious control at encoding can easily be manipulated by comparing full with divided attention, as in **Table 4**. Such manipulations are less effective for retrieval in recognition tests but conscious control there can be effectively manipulated by using a response deadline procedure that compares speeded with unspeeded recognition. Because more automatic retrieval is thought to occur more rapidly than consciously controlled retrieval, fast recognition decisions are assumed to be more automatic and slower ones more controlled. The data summarized in **Table 5** show the effects of fast (under 700 ms) compared with slow (over 3000 ms) recognition decisions on voice congruence effects following either full attention or divided attention at encoding. In the preceding examples of results, false alarms, and also guess responses (if included in the paradigm), were omitted, but in **Table 5** the complete results are shown.

With full attention at encoding, the voice congruence effect occurred in remembering, and with divided attention at encoding the effect occurred in knowing, as found by Karayianni and Gardiner (2003). In neither case was the voice congruence effect influenced by response deadline. This suggests that though the state of awareness with which the voice congruence effect is associated depends on the degree of conscious control at encoding, it does not depend on the degree of conscious control at retrieval. That the effect in knowing remained in knowing even with slower more effortful recognition decisions is consistent with

**Table 5** Mean proportions of responses for fast and slow recognition as a function of voice congruence and following full or divided attention at study

| | *Congruent* | | *Incongruent* | | *New items* | |
|---|---|---|---|---|---|---|
| *Attention/response category* | *Fast* | *Slow* | *Fast* | *Slow* | *Fast* | *Slow* |

Adapted from Gardiner JM, Gregg VH, and Karayianni I (2006b) Recognition memory and awareness: Occurrence of perceptual effects in remembering or in knowing depends on conscious resources at encoding, but not at retrieval. *Mem. Cognit.* 34: 227–239, Tables 2 and 4. with permission from The Psychonomic Society.

Tulving's (1993) coordination hypothesis, according to which however much time and effort goes into the retrieval attempt, the resulting state of awareness cannot exceed the level of awareness achieved at encoding. That the effect in remembering remained in remembering, even with faster more automatic recognition decisions, is consistent with the view that remembering can be more automatic, as well as being more effortful and consciously controlled. Finally, that knowing, as well as remembering, generally increased with slow recognition decisions is consistent with the view that knowing, as well as remembering, can be more effortful and consciously controlled, as well as being more automatic. Similar results were obtained by Konstantinou and Gardiner (2005) in a recognition study of famous faces (see too, Gardiner et al., 1999). There is also evidence that when response times are measured, instead of being manipulated, recognition decisions associated with remember responses are made more rapidly than those associated with know responses (Dewhurst and Conway, 1994; Dewhurst et al., 2006). Those results imply that, if anything, it is remembering that is more automatic and knowing that is more consciously controlled.

There is other evidence that remembering and knowing may both be more consciously controlled, or more automatic, depending on encoding and retrieval conditions, from studies in which word-stem cued recall (e.g., DEF. . . .: What study list word does this remind you of?) is compared with incidental word-stem completion (e.g., DEF. . . .: Complete this word stem with the first word that comes to mind). In such comparisons, generating compared with reading words at study leads to superior recall (the generation effect), but the words that were read at study are more likely to be those that come to mind in incidental word-stem completion (the priming effect). Java (1994; see also Java, 1996) replicated this reversal of the generation effect and showed that both tests gave rise both to remembering and to knowing. Moreover, though the generation effect in recall occurred in remembering, the read superiority effect in incidental word-stem completion was restricted to words participants reported as not being in the study list. Such results underscore the need for a distinction between the voluntary (intended) or involuntary (unintended) retrieval of study list words, as evidenced by the reversal of the generation effect, and awareness of memory, as evidenced by remember and know responses. This distinction between retrieval volition and awareness of memory has been discussed in some detail by Richardson-Klavehn et al. (1996) and it has been supported by the results of other empirical studies (e.g., Richardson-Klavehn and Gardiner, 1996, 1998; see also Richardson-Klavehn et al., 2002).

The guess responses shown in **Table 5** are fairly typical, especially when, as here, the instructions discourage guessing. Guess response rates to study list items have generally been found to be little different from those for unstudied items, that is, false alarms (Gardiner and Conway 1999; Gardiner et al., 2002). Hence, when participants report guessing, they do seem to be guessing. There are also usually more know false alarms than remember false alarms, again as shown in **Table 5**. False alarms are by definition inaccurate with respect to identifying previously studied items but they are not necessarily inaccurate with respect to indicating states of awareness, nor should they be if reports of those states of awareness are valid. It is perfectly natural that participants may have some genuine experiences of remembering and some genuine experiences of knowing when deciding about test items that did not occur in a study list. Moreover, the extent to which people have such genuine experiences will naturally vary depending on experimental conditions.

Experimental conditions have been deliberately designed to manipulate the extent to which people have such 'false' memories, but genuine experiences include those intended to foster illusions of memory. Roediger and McDermott (1995) reintroduced such experimental conditions in revising a converging associates paradigm originally used by Deese (1959). In this paradigm, participants study lists of words that are all highly associated with target associates that are not presented (e.g., study 'bed, rest, awake, tired, dream, . . . etc.,' for the target associate 'sleep'). In one of their experiments, Roediger and McDermott (1995) gave participants either immediate free recall tests or an arithmetic filler task before giving them a recognition test that included the target associate (termed the critical lure) as well as other lure items unrelated to the study lists.

Participants recalled the critical nonpresented word for 55% of the lists, which proportionally approximated the rate of recall for the words from the middle of the studied lists. The recognition results are shown in **Table 6**. The critical lure was recognized to practically the same extent as were the study list words. Moreover, recognition of the critical lure was associated primarily with remember responses, though know responses too were somewhat greater for the critical lure than for other unrelated nonstudied words.

**Table 6** Mean proportions of responses for studied words, critical lures, and nonstudied words

| *Item type and condition* | *Old* | *Remember* | *Know* |
|---|---|---|---|
| Studied | | | |
| Study + recall | .79 | .57 | .22 |
| Study + arithmetic | .65 | .41 | .24 |
| Nonstudied | .11 | .02 | .09 |
| Critical lure | | | |
| Study + recall | .81 | .58 | .23 |
| Study + arithmetic | .72 | .38 | .34 |
| Nonstudied | .16 | .03 | .13 |

Reprinted from Roediger HL and McDermott KB (1995) Creating false memories: Remembering words not presented in lists. *J. Exp. Psychol. Learn. Mem. Cognit.* 21: 803–814, Table 2, with permission from The American Psychological Association.

Such striking illusions of memory have since been replicated many times. For example, Düzel et al. (1997) investigated the ERP correlates of remembering and knowing using the converging associates paradigm. They found that the patterns of neural activity for remembering and knowing when recognizing studied words and when falsely recognizing critical lures were indistinguishable. The patterns of neural activity were predicted by the states of awareness not by the accuracy of the recognition judgment. Schacter et al. (1997a) extended the paradigm by also presenting lists of perceptually similar words (words that all looked and sounded alike). They found that with perceptually rather than conceptually induced false recognition, the recognition of critical lures was mainly associated with knowing, rather than with remembering. And in a long-term diary study, Conway et al. (1996) also found that false recognition of lures that were plausible diary entries (altered or false records of events and thoughts) was associated mainly with knowing, especially for thoughts. Other memory illusions in knowing, as well as in remembering, have been reported (see, e.g., Dewhurst and Hitch, 1997).

Illusions of memory can be understood within an attributional approach to memory (Jacoby et al., 1989). Experiences of remembering or of knowing are attributed to particular circumstances or situations, sometimes correctly, sometimes not. Thus, illusions of memory, and false alarms generally, may reflect genuine experiences of memory that are then misattributed to the prior occurrence in a studied list of the items that gave rise to those experiences. Such attributions implicate source memory and reality monitoring, and they have been widely studied within a source-monitoring framework (Johnson et al., 1993). A number of these studies have used memory characteristics questionnaires to provide a more fine-grained analysis of differences between remembering and knowing, both for veridical and for illusory memories (Mather et al., 1997; Schacter et al., 1997b). In general, remembering when veridical seems characterized by the availability of sharper perceptual detail and sometimes by less affect than when illusory. A multinomial model of multidimensional source information that incorporates remember and know responses has been proposed by Meiser and Broder (2002), who replicated previous findings that memory for source is more accurate with remembering than with knowing (Conway and Dewhurst, 1995; Dewhurst and Hitch, 1999). They also found that source memory for different contextual features was stochastically related for remembering but independent for knowing. Creating an episode that will be remembered involves the binding together of different contextual features, but the occurrence of each of those individual features may be known without retrieving the episode. In a somewhat similar vein, Sikstrom and Gardiner (1997) found that whereas the words that were remembered from the same study list in successive tests of recognition and cued recall (the 'recognition-failure' paradigm) were stochastically related, there was no such relationship between the words that were known in each test. People can also predict which state of awareness they will experience when recognizing items that they cannot recall (Hicks and Marsh, 2002).

There is evidence that remember and know responses are influenced by test–list context. Bodner and Lindsay (2003) found that how much people reported remembering and the relative weighting they assigned to different aspects of what they remembered were affected by whether word lists that had been studied at a medium level of processing were tested along with other words that had been studied at either a shallow or deep level of processing. When asked to report their strongest recollections, the main recollections were of list source (the level of processing), of some thought or association, and of some visual image. The proportions of these different recollections given as the strongest recollection accompanying remember responses varied considerably as a function of test–list context. Importantly, performance in direct tests of memory for source was not influenced by study–test context. These findings support a functional view that places some emphasis on the uses to which mental experiences of memory are put, and how people come to define remembering and knowing under various task demands and conditions, as well as on the experiences as such (see also Whittlesea, 2002a,b).

Clearly, people make decisions about their experiences of memory, but the idea that remembering and knowing just reflect decision making and differ only quantitatively, not qualitatively, is misconceived. This is the claim made in a signal detection model that assumes a single trace strength with different response criteria for remembering and for knowing (Donaldson, 1996; Hirshman and Master, 1997; Hirshman, 1998; Inoue and Bellezza, 1998). This model can simulate dissociative effects between remembering and knowing by assuming that different experimental conditions affect the placement of the response criteria. Bodner and Lindsay (2003) are among others (e.g., Gardiner et al., 1998b) who have strongly criticized this model on the grounds that it provides no explanation as to why the placements of response criteria are affected by different experimental conditions and in different populations in the ways that they are. Nor do changes in criteria provide any account of how such different experiences of consciousness come to mind, only of how, once they have come to mind, decision processes may operate on responses based on them. Moreover, experimental manipulations of response criteria run the risk of invalidating the responses. Participants are given somewhat contradictory instructions when told to respond with very lenient or with very strict response criteria but at the same time only to respond according to the definitions given in **Table 1**. This may be partly why false alarm rates have been exceptionally large in some studies that have manipulated response criteria and why one such study found effects of response criteria on both know and remember responses (Hirshman and Henzler, 1998), another study on know but not remember responses (Strack and Forster, 1995), and other studies only on guess responses (Gardiner et al., 1997, 2002). There is also some evidence of small effects on response criteria depending on whether remember and know responses are given after an old/new responses, or in parallel, that is, remember or know or new. The latter, one-stage procedure, leads to a more lenient response bias (Hicks and Marsh, 1999; Eldridge et al., 2002; Gardiner et al., 2005).

Though studies in which confidence judgments have been directly compared with remember and know responses as, for example, by substituting sure and unsure judgments for those responses, have consistently found that the confidence judgments yield different patterns of results (e.g., Gardiner and Java, 1990; Perfect et al., 1995; Mantyla, 1997; Holmes et al., 1998; Gardiner and Conway, 1999; Rajaram et al., 2002), both Dunn (2004) and Wixted and Stretch (2004) have shown how differences between remember/know responses and sure/unsure judgments are not inconsistent with the signal detection model, which can fit these data too. Wixted and Stretch (2004) suggested that rather than representing a single process, the strength dimension might represent the sum of recollection and familiarity. They also listed various findings that are consistent with this model, such as the finding that in meta-analyses of different experiments, remember and know hit rates and false alarm rates are correlated. But one could list other findings that are inconsistent with this model, which include evidence that remembering and knowing may differ substantially in the absence of any differences in trace strength, as measured from overall recognition scores (Conway et al., 2001; cf. Hirshman and Lanning, 1999) and evidence that the ROC curves predicted by this model have the wrong slope (Rotello et al., 2004).

A two-dimensional signal detection model proposed by Rotello et al. (2004) is more in keeping with Tulving's (1985) original proposal. According to their sum-difference (S) theory (T) of remembering (RE) and (A) knowing (K), both remembering and knowing contribute to the sum of the overall trace strength, on which old-new judgments are based. Remember and know responses, however, are based on a weighted difference between the two contributing dimensions. Rotello et al. showed how STREAK can account for new ROC curves, including those derived not only from confidence in old-new judgments but also confidence *in* remember and know responses (see too, Rotello and Macmillan, 2005).

Word frequency effects in recognition memory have also proved controversial theoretically. The discovery that the superior recognition of low-compared with high-frequency words occurred in remembering, not in knowing (Gardiner and Java, 1990), ruled out earlier suggestions that this effect was due to greater increments in familiarity (Mandler, 1980). Since then, other kinds of dual-process accounts of word frequency effects using the remember-know paradigm have been developed (Guttentag and Carroll, 1997; Joordens and Hockley, 2000; Reder et al., 2000). These accounts are specifically directed at the word-frequency mirror effect, that is, the finding that whereas there are more correct old judgments for low- than for high-frequency words, there are also more incorrect new judgments for high- than for low-frequency words. According to these theories, the low-frequency advantage in correct old judgments arises from their greater distinctiveness in the experimental context, which boosts recollection and hence occurs in remembering. In contrast, the finding of more incorrect new judgments for high- than for low-frequency words is attributed to greater semantic activation from their greater preexperimental familiarity. Hence this effect should occur in knowing. Moreover, for the same reason, old high-frequency words should also give rise to more know responses than the old low-frequency words. Reder et al. (2000) found good support for these predictions, and they developed a computational model (SAC: Source of Activation Confusion) to account for them. This model distinguishes between word or concept nodes and episode nodes, the activation of which respectively gives rise to familiarity and to recollection, hence to know and remember responses. See Diana et al. (2006) for further discussion of this model.

Joordens and Hockley (2000) also proposed a similar dual-process account, though without the aid of a computational model. Some of the effects they found are illustrated in **Table 7**. Furthermore, Gregg et al. (2006) found that with a divided attention task at study there was a high-frequency advantage not simply in the number of know responses (i.e., both hits and false alarms), as found in previous studies, but in their accuracy (i.e., in corrected recognition scores). This outcome suggests that under at least some circumstances that reduce remembering, the high-frequency advantage in knowing can be driven more by experimental than by preexperimental familiarity.

Further support for this kind of dual-process account of word frequency effects was found by Hirshman et al. (2002), who used midazolam to induce amnesia with the assumption that this drug would have larger effects on recollection than familiarity. The effects of the drug were to remove the usual low-frequency advantage in remembering the old words but to leave the high-frequency advantage to both old and new words unaffected, with the result that the traditional word frequency effect – higher hit rates for the low frequency words – was reversed (see also Balota et al., 2002).

**Table 7** Mean proportions of responses for low- and high-frequency words

| | *Old items* | | *New items* | |
|---|---|---|---|---|
| *Response category* | *High freq.* | *Low freq.* | *High freq.* | *Low freq.* |
| Immediate test | | | | |
| Old | .83 | .90 | .12 | .08 |
| Remember | .60 | .68 | .04 | .02 |
| Know | .23 | .22 | .08 | .06 |
| Delayed test | | | | |
| Old | .63 | .68 | .26 | .18 |
| Remember | .36 | .47 | .08 | .06 |
| Know | .27 | .21 | .19 | .12 |

Adapted from Joordens S and Hockley WE (2000) Recollection and familiarity through the looking glass: When old does not mirror new. *J. Exp. Psychol. Learn. Mem. Cognit.* 26: 1534–1555, Table 1, with permission from The American Psychological Association.

However, Malmberg et al. (2004) have shown that these results, and by implication other findings taken to support dual-process accounts, are also consistent with a variety of single-process, retrieving effectively from memory models (Shiffrin and Steyvers, 1997) that, rather like signal detection models and other global models of memory, assume that recognition is based on a continuous random variable that may be conceptualized as trace strength or familiarity. Thus, here too data that seem to support dual-process accounts may also be consistent with single-process accounts, though, as Malmberg et al. (2004) pointed out, that does not necessarily mean that dual-process models are incorrect. There continues to be controversy about the extent to which such effects in remembering and knowing are best explained by dual-process accounts or by global models of memory (see, e.g., Park et al., 2005).

Studies involving amnesic patients have yielded a similar kind of theoretical problem. Yonelinas et al. (1998) reported a convergence of remember-know, process dissociation (Jacoby, 1991) and ROC data from amnesic patients and matched controls and concluded that these data all supported a dual-process account, rather than a single-process one, partly on the grounds that the patients' ROC curves were symmetrical, whereas the ROC curves for the controls were asymmetrical, as is more usual. But there is also evidence that once differences in the strength of memory are taken into account, ROCs for patients and for controls are similar (Wais et al., 2006). Such findings are relevant to debate about the role of the hippocampus with respect to remembering and knowing in amnesic patients and about whether the hippocampus supports both states of awareness or selectively supports remembering, with the implication that other parts of the medial temporal lobe may support knowing. Although there are studies that strongly imply a selective role for the hippocampus in remembering (e.g., Aggleton et al., 2005; Gardiner et al., 2006a), others find that patients with selective hippocampal damage are similarly impaired in both remembering and knowing (e.g., Manns et al., 2003). At the moment, it remains unclear how this important issue will be resolved.

Further evidence relevant to this issue comes from studies of brain imaging in normal adults. For example, in a functional magnetic resonance imaging (fMRI) study Eldridge et al. (2000) showed that the hippocampus is selectively active when recognition is accompanied by remembering but not when it is accompanied by knowing. In another fMRI study, Henson et al. (1999) found several brain regions that were differentially activated when remembering or when knowing, and that greater activation in anterior left prefrontal, left parietal, and posterior cingulate regions was associated with remember responses. Wheeler and Buckner (2004) also used fMRI, and they too found functional dissociations between remembering and knowing. Lateral parietal regions responded preferentially with remembering, whilst other medial regions responded strongly both with remembering and with knowing.

In discussing implications for theories of remembering, Wheeler and Buckner (2004) pointed out that the evidence, particularly from parietal regions, suggests at least a partially shared neural basis for remembering and for knowing. But as well as sharing certain memory-related neural processing with knowing, remembering has additional and distinct neural correlates. This interpretation runs counter to the assumption of independence between recollection and familiarity as conceived in some dual-process models, and it seems more consistent with the SPI model (Tulving, 1995), according to which events are encoded serially into semantic and episodic systems. Moreover, evidence that remembering involves distinct neural processes that lead to the retrieval of the content of qualitatively distinct phenomenal experiences is quite beyond the scope of single-process theories, according to which remembering falls along a continuum of familiarity and is simply a matter of decision criteria or confidence.

Other brain regions that seem crucial for remembering include the frontal lobes. Some studies, though not all, have found correlations between measures of frontal lobe function and the amount of remembering reported (e.g., Parkin and Walter, 1992). Wheeler and Stuss (2003) compared patients with injuries restricted to the frontal lobes that were either centered in the frontal poles or confined to the dorsolateral prefrontal context. Overall recognition performance in the two patient groups was very similar to that in a matched control group. But although patients with the dorsolateral injuries were unimpaired either in remembering or in knowing, patients with polar injuries were selectively impaired in remembering. Some of these results are summarized in **Table 8**. This dissociation links remembering to other cognitive functions that seem to depend on polar regions of the frontal lobes, such as theory of mind and the concept of self, self-monitoring, and planning for the future. These broader implications of remembering were also emphasized by Levine

**Table 8** Mean proportions of responses for patient and control groups

| | *Studied* | | | *Unstudied* | | |
|---|---|---|---|---|---|---|
| *Response category* | *Old* | *Remember* | *Know* | *Old* | *Remember* | *Know* |
| Dorsolateral | .70 | .52 | .18 | .04 | .01 | .03 |
| Polar | .60 | .16 | .44 | .02 | .01 | .01 |
| Patient mean | .65 | .34 | .31 | .03 | .01 | .02 |
| Control mean | .67 | .36 | .31 | .03 | .01 | .02 |

Adapted from Wheeler MA and Stuss DT (2003) Remembering and knowing in patients with frontal lobe injuries. *Cortex* 39: 827–846, Appendix B, with permission from Masson SPA.

et al. (1998; see also Levine, 2000) in their investigation of remembering and knowing in another patient with brain injuries to the frontal cortex, particularly the right ventral frontal lobe. This patient too showed similar levels of recognition performance to that observed in a control group, but with selectively impaired remembering. Levine et al. also found that their patient was significantly impaired in self-regulation and suggest that his behavior generally is driven by generic knowledge in semantic memory, rather than by goals and intentions that arise from a sense of his own identity.

Thus, although there is still a great deal to be learned about the brain mechanisms underlying experiences of remembering or of knowing, it has already become clear that the extended networks likely to be involved are at least partially distinct in critically important ways and in ways that relate the two states of awareness to much broader aspects of cognitive function, especially those related to the sense of self. Other recent studies that converge on this conclusion include those concerned with normal aging (e.g., Bunce and Macready, 2005), during which autonoetic awareness diminishes, and those concerned with autism (e.g., Bowler et al., 2007) and schizophrenia (e.g., Tendolkar et al. 2002; Danion et al. 2003), two disorders that are also associated with reduced autonoetic awareness and, to widely varying extents, an altered sense of self.

## 2.17.7 Theoretical Evaluation

Although all of the theories that have been put forward to account for remembering and knowing help elucidate these states of awareness, none provides an entirely satisfactory account of them. The distinction between episodic and semantic systems is in some respects compelling, and there has to be at least a partially distinct and dissociable neural basis for remembering and knowing, even if it is not yet entirely clear what this basis is. One major problem for this theory concerns the interface between episodic remembering and autobiographical memory (see Conway and Pleydell-Pearce, 2000; see also Rubin et al., 2003), which may be a part of the semantic system that includes not only facts known about oneself but also a more generic kind of remembering and which, indeed, can perhaps simulate remembering. The distinctiveness/fluency framework continues to provide useful guidelines with respect to which variables are likely to influence each state of awareness (e.g., Brandt et al., 2003; Dewhurst et al., 2005) but does not take us very much further. The earlier dual-process models continue to provide a reasonably good account for much of the evidence (see Yonelinas, 2002), but there is other evidence against some of their commonly held assumptions, such as those about conscious control and independence. Other dual-process models have been developed, initially in relation to word frequency effects (e.g., Reder et al., 2000; Diana et al., 2006). The attributional approach and the source-monitoring framework offer a more functional view, but perhaps have limited scope. Signal detection models are overly focused on modeling responses rather than on understanding the states of awareness that give rise to them and, as Dunn (2004) pointed out, the challenge for this approach is to develop more psychologically meaningful accounts.

There has recently been a spate of formal quantitative models. But the increasing technical sophistication and complexity of some of these models and the rather general ability of most of them to provide a reasonably good fit to the data make it increasingly difficult to see how to distinguish between them empirically (see, e.g., Rotello and Macmillan, 2005; Macmillan and Rotello, 2006; Murdock, 2006). Confronted by a plethora of alternative versions of such models, it is hard (despite the claims sometimes made for this approach) to see any great advantage of quantitative modelling over a less mathematically, more conceptually driven approach. Nor should it be forgotten that many of the most important advances made in the last 50 years or so were spearheaded by the introduction and empirical refinement of new concepts, concepts such as those of retrieval, levels of processing, and memory systems.

Remembering and knowing are natural mental phenomena that evolved for some purpose and so have adaptive significance, both for the species and for the individual. Individuals make judgments, reach decisions, and take action on the basis of these states of awareness. So in one sense their true significance, with respect to adaptation and behavior, if not with respect to memory theory, lies in the personal and social uses to which they are put. This is another reason why it has been important to study these states of awareness experimentally and to discover how they are influenced by different conditions and what their neural correlates are. Gaining a better understanding of remembering and knowing theoretically will depend on further evidence that links these states of awareness not only with behavior but also with the brain. The most promising new cognitive theories are likely to be those that have some conceptual correspondence with what is known about neuroanatomical function (see Roediger et al., 2007), and no theoretical assumptions that seem inconsistent with neuroanatomical function should be seriously entertained.

# 2.18 Controlled Processes in Voluntary Remembering

**A. Koriat, M. Goldsmith, and V. Halamish**, University of Haifa, Haifa, Israel

## 2.18.1 Introduction

The focus of this chapter is on voluntary remembering, in which memories are retrieved through a deliberate, goal-directed search process. Voluntary remembering occurs either in response to an external query or to a query that is generated internally by the person, usually in order to achieve some higher-order goal. For example, a person may try to recall the name of a person, to answer an exam question, or to recount an entire episode to a friend.

This type of remembering can be contrasted with involuntary memory, in which past events come to mind spontaneously and automatically, without any conscious intention to conjure them up. Involuntary memory often occurs during routine daily activity, without any apparent cue (Berntsen, 1996, 1998; Kvavilashvili and Mandler, 2004). An important subclass of involuntary memory that has received special attention is that of intrusive memories. Such memories, typically of traumatic events, occur not only in the absence of an intention to retrieve the events but also against the person's will (Koutstaal and Schacter, 1997; McNally, 1998). Intrusive memories reflect a failure of control over retrieval, because the person is unable to prevent these memories from arising, or fails to terminate them once they arise.

Although we concentrate here on voluntary remembering, we stress that the distinction between voluntary and involuntary memory processes is not sharp, and that any particular act of remembering may involve a mixture of these types of processes. For example, during the deliberate scrutinizing of one's memory for a particular detail, various memory fragments may suggest themselves, diverting the search in new directions. Sometimes, such fragments may even 'intrude' against the rememberer's will, blocking access to other, desired pieces of information.

## 2.18.2 Processes Involved in Remembering

We begin by outlining some general memory principles. In particular, we discuss (1) the role of retrieval cues and retrieval-encoding interactions in determining the accessibility of stored information and (2) the role of metamemory processes in monitoring and controlling the retrieval and reporting of that information. We then integrate these elements within a schematic framework that will guide a more detailed treatment of controlled processes in remembering.

### 2.18.2.1 Retrieval Cues and Retrieval-Encoding Interactions

The amount of information stored in memory exceeds by far the amount of information that can be accessed at any given point in time. In the terminology introduced by Tulving and Pearlstone (1966), much more information is *available* in memory than is *accessible* at any moment. Thus, although we may momentarily fail to retrieve the name of an acquaintance, we may still be able to recall it on some later occasion or recognize it from among several alternatives. The discrepancy between the availability of information and its accessibility to consciousness testifies to the critical role of retrieval processes in bringing stored information to mind (*See* Chapter 2.16; Roediger, 1999).

What prevents all of the available information from being accessed? What is the process by which people search for and recollect stored information from long-term memory?

Tulving (1983) promoted the now-accepted idea that memory is a joint product of stored memory traces and the cues that are present when retrieval is carried out. Thus, given the same conditions of study, retrieval success can vary greatly depending on the conditions of testing. For example, memory is generally better under cued than under uncued recall testing (Tulving and Pearlstone, 1966). The conditions that instigate retrieval often provide many useful retrieval cues. In externally posed queries, some of the cues can be found in the query itself, whereas others may be available in the more general retrieval context. Even when these cues are not sufficient to directly elicit the target item, they can help delimit the memory regions in which that item is likely to be found.

Cues differ considerably in their effectiveness for aiding retrieval. Research examining the effectiveness of extralist words in prompting the recall of studied words (Nelson et al., 2005) indicates that retrieval success varies with a large number of associative properties of the cue and of the target. For example, the larger the number of words that a cue word elicits in word association norms, the lower its effectiveness in facilitating the retrieval of a studied word. The most effective cues for retrieving an event are personal cues associated with the encoding of that event, because these cues are well integrated into the memory trace of the event (e.g., Mantyla, 1986). Many standard mnemonic techniques have people encode the target information together with specific cues that can later be used to prompt retrieval.

In a landmark article, Tulving and Thomson (1973) formulated the *encoding specificity* principle, which states that a cue presented during testing will be effective in aiding retrieval to the extent that it has been encoded together with the solicited memory target at study. A large amount of research has provided evidence for this principle (Tulving, 1983). It has also been extended in the form of the more general principle of *transfer-appropriate processing,* according to which retrieval is effective to the extent that the processing that occurs during retrieval reinstates the processing that took place during encoding (Kolers and Roediger, 1984; Srinivas et al., 1998).

In line with these principles, retrieval efficiency depends on the extent to which the testing conditions reinstate the overall conditions of study. Thus, retrieval is *context dependent,* in that memory is best when testing occurs in the same physical environment in which learning took place. For example, Godden and Baddeley (1975) found that divers who studied a list of words, either on land or underwater, performed better when tested in the same environment as at study rather than in the other environment. Participants have also been found to recall a larger number of words when tested in the same room in which they studied the words than when tested in a different room (Smith et al., 1978). Context-dependent effects are more likely when the environmental contexts differ substantially and when participants deliberately associate the studied material with features of the study environment (Smith and Vela, 2001). These effects are generally obtained for recall but not for recognition (Eich, 1985), suggesting that context reinstatement specifically facilitates retrieval.

Similar evidence exists for the state dependency of memory, indicating that memory performance is best when learning and testing occur under the same internal state. For example, what participants learn while drunk, they remember better while drunk than while sober, and vice versa (Goodwin et al., 1969). A similar pattern has been observed for the effects of marijuana (Eich et al., 1975) and mood (Eich and Metcalfe, 1989). Like context dependence, state-dependent memory benefits are more clearly observed for free recall than for recognition or cued recall (Eich, 1980).

### 2.18.2.2 Metacognitive Monitoring and Control Processes

Much of the work on the effects of cueing and retrieval-encoding interactions has been conducted within a conceptual framework that views the rememberer as a passive conduit through which information flows. For example, the work reviewed in the previous section has mainly emphasized the automatic effects of external and internal retrieval cues and retrieval-encoding interactions on memory performance. In recent years, however, there has been an increased emphasis on the active role of the rememberer in strategically regulating the process of remembering. This new emphasis is most prominent in the area of metacognition research, in which monitoring and control processes have been shown to play a critical role throughout the various phases of remembering (Barnes et al., 1999; Koriat, 2007): They are involved in deciding whether to initiate a memory search, what type of search and retrieval process to use, where in memory to search, when to terminate the search, whether or not to report the retrieved information, and at what level of precision or coarseness to report it. Such decision processes are integral components of remembering – influencing its course and the quality of its products. Traditional memory research has generally avoided the investigation of rememberer-controlled memory processes, perhaps because the operation of these processes was seen to conflict with the desire to achieve strict experimental control (Nelson and Narens, 1994; Koriat and Goldsmith, 1996a).

In the following section, we introduce a schematic framework to help identify and conceptualize the memory and metamemory processes involved in remembering, taking into account the critical role of retrieval cues and encoding-retrieval interactions, just described. This framework will guide the discussion of controlled processes in remembering throughout the remainder of this chapter.

### 2.18.2.3 A Schematic Framework

Let us consider the simple case in which a person is presented with a memory query in the form of a question. How does one come up with an answer to that query? Figure 1 presents a schematic framework for the processes involved in remembering. Broadly speaking, we first *search* our memory for the best answer we can find and then decide whether and how we want to *report* it. For simplicity, we describe the processes involved in remembering sequentially, although we assume that they are actually somewhat overlapping and parallel.

Memory search is conceptualized here as an iterative process. First, the rememberer sets parameters that define what he or she is looking for in memory and determine broadly the manner in which that information will be accessed. The search parameters include cues that are provided explicitly in the memory query and additional cues that are available in the overall retrieval context or generated by the rememberer in response to the query (cf. target descriptions in Norman and Bobrow, 1979). The parameters also include search criteria that define what will be considered a satisfactory answer to the query (verification criteria in Norman and Bobrow, 1979) and a rough metacognitive assessment of the accessibility of the answer. Another important parameter is the search strategy that will be invoked.

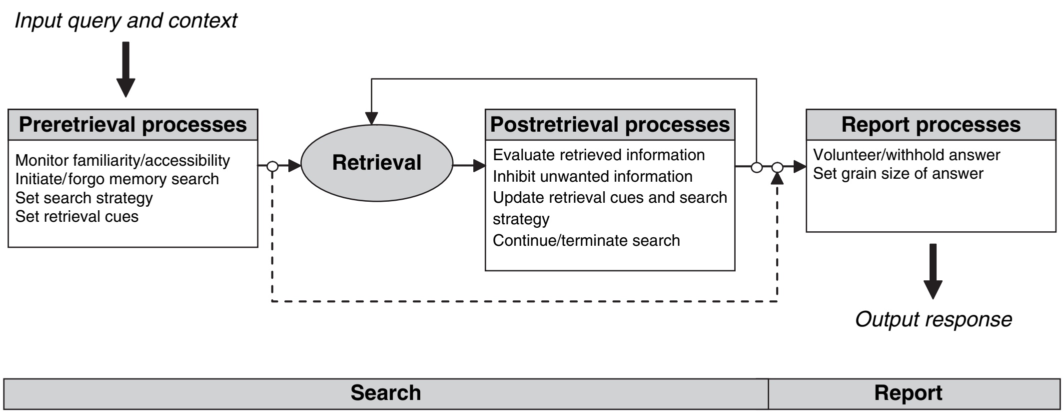

**Figure 1** A schematic framework for the memory and metamemory processes involved in remembering (dashed line represents the decision to forgo a memory search).

These parameters determine the initial course of the retrieval of information from memory, as well as whether retrieval will be attempted at all. Because it appears to capture much of the mainstream thinking about memory retrieval, we adopt Tulving's (1983) concept of *ecphory* to describe the specific operation of retrieval during a (sometimes) more prolonged memory search process. According to this concept, when an item of information is encoded, a memory trace (engram) is created that includes not only the item itself but also other information from the cognitive context at the time of encoding (related thoughts, for instance). During retrieval, parts of the encoded engram combine synergistically with the search cues to produce "a conscious memory of particular aspects of the original event" (Tulving, 1976, p. 40). Consequently, the retrieved (ecphoric) information that comes to mind is actually a combination of the search cues and stored information. We assume that, although rememberers cannot control the process of ecphory itself, which is conceptualized here as an automatic, ballistic operation (Moscovitch, 1994; Guynn, 2003; but see Naveh-Benjamin et al., 2000), they can influence the outcome of a memory search by controlling the parameters that are used for the individual operations of retrieval and the overall strategy that determines the number and nature of these operations.

A very different conception of remembering is offered by the reconstructive approach (Bartlett, 1932; Neisser, 1967; Barclay, 1986), in which remembering is assumed to involve reconstructive inferences that may supplement the retrieval process. In terms of the framework presented here, however, it should not matter much whether a candidate answer is produced by a retrieval process such as ecphory or, instead, by some type of inferential, schema-based reconstruction process; much of the surrounding control processes would remain essentially the same. In any case, there has been very little work, if any, detailing the processes involved in reconstructive remembering.

The results of each retrieval (ecphory) attempt are evaluated by the rememberer to determine whether the sought-for information has been reached. If not, the search parameters may be refined, and a fresh retrieval attempt is made. Because of the critical role that search parameters play in retrieval, the metacognitive control exerted in the evaluation of results and in the consequent updating of these parameters has a high impact on remembering. The iterative search process is terminated either when the rememberer gives up (e.g., after drawing a blank or running out of time) or when a retrieved answer is identified as the best one that can be found.

Once a best-candidate answer has been reached, other factors now come into play in converting that answer into an overt memory response (Tulving, 1983). For example, the decision whether to report the best answer or withhold it and respond "don't know" (Koriat and Goldsmith, 1996b), and the decision regarding the level of generality or precision (grain size) at which to report the answer (Goldsmith et al., 2002), are both under the strategic control of the rememberer.

In what follows, our discussion of controlled processes in remembering will be divided in terms of the processes that take place before retrieval, those that take place after the retrieval of some candidate answer, and finally, the processes that take place in deciding what to report, and how.

## 2.18.3 Controlled Preretrieval Processes

### 2.18.3.1 Deciding Whether to Initiate or Forgo a Memory Search

When confronted with a memory query, one does not always proceed immediately to initiate retrieval. Rather, in many cases a preliminary feeling of knowing (FOK) may signal that it is not worthwhile to search for the answer, either because it is not in memory or because it might require more time and effort than is warranted under the circumstances. Thus, a preliminary monitoring stage may be postulated in which one makes a rough assessment regarding the availability of the answer in memory and the effort needed to access it. The initial FOK is assumed to rely on the overall familiarity of the query (Schwartz and Metcalfe, 1992; Nhouyvanisvong and Reder, 1998) and the extent to which it brings to mind some fragmentary clues (Koriat, 1993, 1995). Reder (1987) argued that a fast, preretrieval FOK is routinely and automatically made in response to the familiarity of the terms of a memory query. She found that the latency of making a fast FOK is shorter than that of accessing the answer, suggesting that preliminary FOK is not based on the retrieval of an answer. If the question does not produce a feeling of familiarity, chances are that one will not initiate a deliberate search for the answer. Glucksberg and McCloskey (1981; see also Kolers and Palef, 1976), for example, showed that people answer "I don't know" more rapidly when no potentially relevant information is accessible ("Does Margaret Thatcher use an electronic toothbrush?") than when some information can be retrieved ("Is Kiev in the Ukraine?"). They proposed that low preliminary FOK can cause people to forgo a memory search. Note, however, that a preliminary 'Don't Know' response appears not to prevent automatic activations that may ultimately evoke the solicited target (Koriat and Lieblich, 1977).

Using an episodic cued recall task, Malmberg (in press) has recently shown that enhanced cue familiarity increases the time participants search for the answer before giving up and also increases the likelihood of retrieving the correct answer. Familiarity, however, appeared to have little effect when participants were led to believe that familiarity was not correlated with the memorability of the target. Thus, it would seem that the effects of preliminary FOK on the initiation of a memory search are at least partly strategic. In fact, Reder and her associates argued that preliminary FOK can guide the choice of question-answering strategy, as discussed in the next section. Note also that cue familiarity may affect not only the initiation of the search for the target but also the continuation of the search after it has been initiated, as suggested, perhaps, by the results of Malmberg.

### 2.18.3.2 Choosing a Search Strategy

Several strategies of memory search have been discussed in the literature. The strategy used to search memory determines in part the context of retrieval, the generation of additional retrieval cues, and the ways those cues are used to retrieve information from memory. By controlling the choice of search strategy, either initially or after a previous strategy has failed, the rememberer can influence the course of remembering as well as its results.

One prominent strategy is embodied in the classic two-stage generate–recognize model (Bahrick, 1969, 1979). In this strategy, the rememberer uses the available cues to define a region in memory in which the solicited item is likely to reside (e.g., "vegetables," "words strongly related to *doctor*," "Spanish family names"). Candidate items are then generated, and a subsequent monitoring process is used to select (recognize) the target from among them. For example, when trying to recall the name of an old acquaintance, one might run through a number of female names in one's head and hope that one of the names will be recognized as the target. In response to theoretical and empirical challenges (e.g., Thomson and Tulving, 1970; Tulving and Thomson, 1973; Wiseman and Tulving, 1976), more recent versions of the generate–recognize model (Jacoby and Hollingshead, 1990; Weldon and Colston, 1995; Higham and Tam, 2005, 2006) acknowledge that generated candidates may be a joint product of semantic and episodic influences (*See* Chapter 2.27). Nevertheless, these models continue to embody a memory search strategy that might be portrayed as 'casting a wide net' rather than trying to retrieve the target item directly.

Metacognitive knowledge about subtle characteristics of the encoding and retrieval contexts can guide the controlled use of the generate–recognize strategy. For example, Higham and Tam (2005) found that participants were sensitive to the strength of the semantic cue–target relations in studied lists of paired associates, and that this awareness influenced the set of plausible candidates that were generated during a cued-recall test: When participants expected weak cue-to-target relations, they were not likely to generate targets strongly related to the retrieval cues. Koriat and Lieblich (1974) also observed that participants' guesses of a target word while in a tip-of-the-tongue (TOT) state are sensitive to the specific definition of the population from which the target is said to have been drawn.

Clearly, however, rememberers do not always resort to a generate–recognize strategy. As Bahrick (1979) has observed, one does not recall the name of his wife by generating a series of female names and selecting the correct name. Instead, in this case and many others, a direct-retrieval process is invoked, in which relatively specific and constrained retrieval cues allow one to 'home in' directly on the target representation in memory. This process is assumed to be automatic and effortless. In fact, Bahrick (1979) suggested that only when direct retrieval fails do people resort to other strategies. Guynn and McDaniel (1999) proposed that, when a large amount of contextual information has been encoded along with the target, rememberers prefer direct retrieval over the generate–recognize strategy because the contextual information facilitates a narrowly focused ecphory operation. Higham and Tam (2005) suggested that direct-retrieval and generate–recognize strategies can be conceived as lying along a continuum representing the degree to which retrieval is constrained.

Jacoby and colleagues proposed a controlled mode of retrieval that they call source-constrained retrieval – the deliberate use of target-source information to constrain what comes to mind during retrieval. In a series of experiments (Jacoby et al., 1999, 2005a,b), participants studied a list of words under shallow or deep encoding and were tested using an old/new recognition test. When they were later tested for their memory of the foils that appeared on the first test, their performance was better for the foils that had appeared on a test of deeply encoded study items than for those that had appeared on a test of shallowly encoded study items. This result was taken to suggest that the participants had used their metacognitive knowledge of the original encoding operations to constrain their retrieval on the first test by applying these same operations to the test probes. The same pattern was not found for elderly participants, presumably because elderly people fail to take advantage of their knowledge about encoding operations to constrain their retrieval.

The next strategic choice to be considered involves basing one's answer on reconstructive inference rather than on the reproductive retrieval of stored information (Neisser, 1984; Hall, 1990). Several researchers have proposed that the choice between reconstructive and reproductive remembering is, at least partly, under the control of the rememberer (Reder, 1987; Ross, 1989). Reder (1987) showed that, when the familiarity of the question is low, people tend to answer the question by making plausible inferences about the answer on the basis of a variety of cues, rather than by attempting to retrieve the answer directly from memory. She also suggested that the tendency to rely on plausible inference increases in old age (Reder et al., 1986). Similarly, Ross (1989) proposed that, when accuracy motivation is low, people tend to utilize a schema-based reconstruction strategy rather than engaging in an effortful reproductive retrieval. For example, in attempting to recall one's past attitudes, a person might use his or her present attitudes as a benchmark against which to reconstruct the past attitudes in light of an implicit theory of stability or change. To reconstruct how one felt 5 years ago, one might ask oneself: Is there any reason to believe that I felt differently then than I do now (Ross, 1989)? Several studies have shown that people tend to exaggerate the similarity between their present and past attitudes (e.g., Bem and McConnell, 1970).

Finally, a fourth general strategy can be identified that might be called 'mediated' retrieval, in which one initially sets out to retrieve contextual information that may then assist in generating further cues to guide more direct retrieval attempts (e.g., Williams and Hollan, 1981; Reiser et al., 1985). For example, when trying to remember the gifts one received at one's last birthday party, a person might first try to retrieve the general party context, including the friends who attended, in order to make the subsequent retrieval of the gifts themselves more efficient.

#### 2.18.3.3 Specifying the Initial Context of Search and Generating Internal Retrieval Cues

As discussed earlier, retrieval cues play a critical role in the efficient retrieval of information from memory. That role begins with the cues that are presented explicitly in the memory query and those that are available implicitly in the more general retrieval context. Such cues may aid retrieval either automatically or in a more deliberate and controlled manner. The controlled exploitation of cues is particularly transparent when retrieval is difficult and prolonged.

One searches one's memory in a controlled manner by specifying certain characteristics of the solicited information as retrieval cues. Norman and Bobrow (1979) termed such specifications 'descriptions.' Descriptions may include the context of the solicited event (e.g., time, place) and additional information. Norman and Bobrow suggested that the descriptions are continually updated after each retrieval attempt. Following up on these ideas, Burgess and Shallice (1996) proposed a controlled descriptor process that is responsible for translating memory queries into a form that corresponds to the way the relevant information is stored in long-term memory. They suggested that one of the causes of clinical confabulation disorder is impaired descriptor processes.

Other researchers have put forward similar ideas. Norman and Schacter (1996; Schacter et al., 1998), for example, used the term 'focusing' to describe the preliminary stage in retrieval in which the rememberer refines the description of the characteristics of the sought-for episode. Similarly, Moscovitch and Melo (1997) suggested that confabulators might be impaired in the strategic use of general and personal knowledge to constrain their memory search so as to home in on the target. Dab and colleagues (Dab et al., 1999) described a patient whose confabulations apparently stem from deficient cue setting. In contrast to other confabulators, this patient had preserved memory and postecphoric verification abilities but exhibited a selective impairment of the search descriptor process. Finally, the work of Jacoby and colleagues on source-constrained retrieval, mentioned earlier (Jacoby et al., 2005a,b), suggests that rememberers use contextual knowledge to constrain their retrieval queries, and that elderly people may be particularly deficient in this type of retrieval control.

Once an initial search description has been formed, further cues may be recruited during the search. Indeed, several studies have identified a reiterative pattern that occurs in the course of arduous remembering. Williams and Hollan (1981), for example, proposed that remembering consists of a series of kernel retrieval processes, each including three stages: a memory region is specified in which a search is to be conducted, that region is searched for additional clues, and the information retrieved is evaluated. Information that passes the evaluation is then used to guide the next retrieval attempt. This cycle is repeated, gradually refining the description of the information to be searched, until the search closes in on the target. Thus, in attempting to retrieve the names of high school classmates, participants in Williams and Hollan's (1981) study produced an enormous amount of information that was incidental to the task of recalling the names, including details about the school, about where people lived, and so forth. Examination of this information suggested that its main function was to probe one's memory for additional clues that could better specify a new context for search.

Similarly, Reiser and his associates (Reiser et al., 1985, 1986), in studying the recall of autobiographical episodes, also emphasized that one memory retrieval can be undertaken in order to provide cues for a subsequent retrieval. According to their context-plus-index model, specific personal episodes are recalled by first recovering the general context in which they were likely to have been encoded and then specifying the features that uniquely distinguish these experiences from others in that context. They proposed that scripts (e.g., 'eating in restaurants'; Schank, 1982) typically serve as convenient retrieval contexts. Burgess and Shallice (1996) also noted that participants did not always retrieve the target memory record directly but sometimes recovered a useful cue first. For example, it was not uncommon for participants to answer the question "What was the weather like yesterday morning?" by trying to remember first what they were wearing.

Similar processes appear to take place in retrieving information from semantic memory. A study by Walker and Kintsch (1985) suggests that retrieving the members of natural categories also relies on the recovery of context. Verbal protocols suggested a series of two-stage cycles: generating a context in which category members are likely to be found, and then using that context as a retrieval cue to produce the category members themselves. Interestingly, most of the contexts generated were episodic rather than abstract-semantic (e.g., in searching for automobiles, one might visualize the cars in a parking lot or in front of one's dormitory).

We noted earlier that retrieval is more efficient when the retrieval context closely matches the encoding context. Rememberers can take advantage of this principle by deliberately attempting to reinstate the encoding context. Thus, for example, a study by Smith (1979) suggests that mental reinstatement of the learning environment may be almost as beneficial for retrieval as actual, physical reinstatement. Notably, mental context reinstatement has been incorporated into the Cognitive Interview (Fisher and Geiselman, 1992) as a means of facilitating witness recollection; prior to answering specific questions about a past event, witnesses are instructed to mentally recreate the context or state that existed at the time of the original event. Another memory principle that can be taken advantage of in a controlled manner is the effect of schema activation on retrieval. For example, in Anderson and Pichert's (1978) classic experiment, participants read a story about two boys playing in a house from one of two perspectives, that of a home buyer or that of a burglar. After a standard recall task, participants were asked to recall the story again, now adopting the other perspective. The participants could now recall additional details that were related to the new perspective.

So far we have emphasized the deliberate use of retrieval cues in remembering. However, throughout the search, automatic activations can bring to mind a variety of associations and memories. Thus, retrieval often involves a complex interplay between a controlled process and the automatic involuntary emergence of ideas and associations (Collins and Loftus, 1975; Nelson et al., 1998) that emanate from the retrieval context or from the information already recovered (Moscovitch, 1989; Jacoby, 1991). Sometimes the controlled process will seize onto ideas that emerged involuntarily and use them as intermediate cues on the way to the sought-for target. In other cases they may be recognized as unwanted 'interlopers,' and effort will be exerted to oppose their interfering influence (section 2.18.5.3; Jones, 1989).

## 2.18.4 Retrieval (Ecphory)

As explained in section 2.18.3.2, in this chapter the retrieval-ecphory operation is treated as an automatic, ballistic process whose course is not under the control of the rememberer. Understanding the nature of this process has been one of the longstanding goals of memory research, and many formal models have been proposed to describe it (e.g., Raaijmakers and Shiffrin, 1980, 1981; Hintzman, 1987; Murdock, 1993). We assume that rememberers can exert control over retrieval only by affecting the input to the retrieval operation. Such control, as the preceding discussion suggests, can have a very large impact on the outcome of the retrieval operation in particular, and on the search process generally. In addition, rememberers also make use of the retrieval output to guide subsequent retrieval operations and to convert the retrieved information into an overt response. These aspects of postretrieval control are covered in the following sections.

## 2.18.5 Controlled Postretrieval Processes

As noted earlier, search and retrieval can be conceptualized as a reiterative process in which a description is formed, cues are recruited to facilitate the search, candidate answers are evaluated, and – depending on the results – the search may be terminated or the cycle may continue. In this section we focus on processes that take place following the retrieval of candidate answers. These include monitoring and control processes that aid in achieving one's goals. First, rememberers monitor whether the search is on the right track and, if necessary, refine and reformulate the memory description or change the retrieval strategy. Second, they evaluate the correctness of retrieved candidate answers in deciding whether or not the target has been reached. Third, inhibition may be applied to reduce the interference from items of information that come to mind but are judged to be incorrect. Finally, in deciding whether to continue or terminate the search, rememberers may assess the likelihood of success and the additional time and effort needed to reach the target. Such an assessment may be particularly important when remembering is done under pressure, for example, when a lecturer quickly decides to settle for 'several researchers have shown' instead of continuing to search for the specific names of the researchers. We examine each of these processes in turn.

### 2.18.5.1 Updating and Refining the Search Strategy and Internal Retrieval Cues

In the previous section we emphasized the control exerted by rememberers in setting up the initial search parameters (internal retrieval cues and overall search strategy). We also noted, and reemphasize here, the reiterative-cyclical nature of the search process. After each retrieval attempt, these search parameters may be refined and reformulated in light of the information that has been retrieved. As observed by Norman and Bobrow (1979) and by several researchers subsequently, the 'descriptions' of the sought-for information are continuously updated during the retrieval cycle, based on newly retrieved information.

Search strategies may also be changed in light of the retrieved information. For example, participants may abandon one strategy in response to the retrieval of information that appears to be particularly useful in the context of a different strategy (Williams and Santos-Williams, 1980). When a controlled, deliberate search proves unsuccessful, however, rememberers may decide to relinquish strategic control altogether, adopting a passive-receptive attitude. Nickerson (1981) noted that, in retrieving words from lists, participants often begin with a passive attitude and then switch to an active, systematic search when the passive approach no longer yields a satisfactory return (see also Walker and Kintsch, 1985). Koriat and Melkman (1987) observed a similar pattern and also showed that, when attentional resources are diverted, the retrieval of words from a list becomes less controlled, moving along associative links between the words rather than along conceptual-logical relations.

### 2.18.5.2 Evaluating the Correctness of Retrieved Information

A great deal of work emphasizes the importance of postretrieval monitoring processes that evaluate the relevance and correctness of retrieved information (e.g., Burgess and Shallice, 1996; Kelley and Jacoby, 1996; Schacter et al., 1998; Koriat, 2000; Mitchell and Johnson, 2000). On the basis of these processes, one decides not only whether each piece of information that comes to mind is correct or not but also whether the search is on the right track, whether to continue searching for additional candidate responses, and which of the many candidates that came to mind is the best candidate answer. In a later section we discuss the further crucial role of monitoring processes in deciding whether or not to report the best candidate answer, and in what form. The operation of these processes is particularly important in real-life situations (e.g., eyewitness testimony) in which a premium is placed on accurate reporting.

Discussions of metacognition generally distinguish between two basic types of monitoring processes (Koriat and Levy-Sadot, 1999). Information-based processes involve analytic, deliberate inferences in which beliefs and knowledge in long-term memory are consulted and weighed to reach an educated judgment. Experience-based processes, in contrast, are sensitive to online mnemonic cues, such as retrieval fluency, that derive from the experience of remembering itself. These cues give rise to subjective feelings (e.g., a sense of conviction), which then serve as the bases for metacognitive judgments (Strack, 1992; Kelley and Jacoby, 1996; Koriat and Levy-Sadot, 1999).

As an example of information-based, analytic monitoring, rememberers may base their confidence in the correctness of a particular candidate response on the weight of the evidence that they can marshal in favor of that candidate relative to the evidence in support of the alternative candidates (e.g., Koriat et al., 1980; Griffin and Tversky, 1992; McKenzie, 1997; Yates et al., 2002). Rememberers may also base their confidence on metacognitive beliefs about their own competence and skills (Dunning et al., 2003; Perfect, 2004) and about the way in which various factors can affect memory performance (Dunlosky and Nelson, 1994; Mazzoni and Kirsch, 2002).

In contrast to this type of analytic and deliberate evaluation, experience-based monitoring relies on mnemonic cues that derive from the online processes of remembering. Such cues as the ease with which information comes to mind, or its vividness, may contribute implicitly to the subjective confidence in the correctness of that information. For example, it has been observed that the more effort and the longer the deliberation needed to reach an answer, the lower is the confidence in that answer (e.g., Nelson and Narens, 1990; Robinson et al., 1997; Koriat et al., 2006). Kelley and Lindsay (1993) showed that when priming speeds up the emergence of an answer, confidence judgments also increase accordingly. This effect occurred even for plausible but incorrect answers. Although typically correct answers are associated with shorter latencies than incorrect answers, so that response latency is diagnostic of the correctness of the answer that is retrieved or recognized, there are situations in which retrieval fluency can be misleading (Chandler, 1994). For example, asking participants to imagine some childhood events increased confidence that these events did indeed happen in the past (Garry et al., 1996). Merely being asked about an event twice also increased subjective confidence. Possibly, imagining an event or attempting to recall it increases its retrieval fluency, which in turn contributes to the confidence that the event has occurred.

A prominent theory that includes both automatic and controlled monitoring processes is Johnson's (1997) source monitoring framework. According to this framework, in discriminating the origin or source of information, people take advantage of the fact that mental experiences from different sources (e.g., perception vs. imagination) differ on average in their phenomenal qualities such as visual clarity and contextual details (*See* Chapter 2.19). Although these diagnostic qualities can support a rapid, heuristically based source monitoring, sometimes more strategic, deliberative processes may be applied. Both types of processes require setting criteria for making a judgment and procedures for comparing activated information to the criteria. Closely related processes have been discussed in the context of Jacoby and Kelley's attributional approach to memory (e.g., Jacoby et al., 1989; Kelley and Rhodes, 2002) and in Whittlesea's SCAPE framework (e.g., Whittlesea and Williams, 2001a,b; Whittlesea, 2002).

Many memory errors are the result of source confusions – the attribution of retrieved elements to the wrong context (Johnson, 1997). For example, the effects of misleading postevent information have been attributed, at least in part, to deficient source monitoring, by which the postevent misinformation is wrongly attributed to the witnessed event (see Lindsay, 1994; Mitchell and Johnson, 2000). Source confusions can arise when the activated information during retrieval is incomplete or ambiguous, or when the cues used in attributing information to sources are not diagnostic. Divided attention during encoding has been found to impair source monitoring (Craik and Byrd, 1982), presumably because they disrupt contextual binding. High perceptual similarity between two sources, as well as similarity in the encoding processes, also increase source confusions (Ferguson et al., 1992; Dodson and Johnson, 1996). Although vividness and perceptual detail are generally diagnostic of actual memories (Conway et al., 1996), thinking about imagined events also increases their vividness, thereby impairing reality monitoring for these events (Suengas and Johnson, 1988).

Several mechanisms have been proposed that can help reduce source confusions and reject false memories (see Odegard and Lampinen, 2006). For example, distinctive encoding manipulations have been shown to reduce the occurrence of false recall and recognition. Such manipulations include presenting each word together with a picture representing it (Israel and Schacter, 1997; Schacter et al., 1999), visual rather than auditory presentation (Smith and Hunt, 1998), having participants say the words out loud at study (Dodson and Schacter, 2001), or having the participants rate the pleasantness of the words during study (Smith and Hunt, 1998). Schacter et al. (1999) have explained such findings in terms of a *distinctiveness heuristic,* a mode of responding based on participants' metacognitive belief that true memory of studied items should include recollection of distinctive details. Participants can use this heuristic to reject foils that evoke memorial experiences lacking the distinctive qualities known to be present at study. A similar metacognitive strategy has been suggested by Strack and Bless (1994) to underlie judgments of nonoccurrence. They showed that, if an event is judged to be memorable (salient) but elicits no clear recollection during testing, it can be rejected with high confidence as not having occurred. In contrast, in the absence of a clear recollection of a nonmemorable event, rememberers may infer that the event actually had occurred but had simply been forgotten. Also, studying material under conditions unfavorable for learning (or expecting fast forgetting, Ghetti, 2003) results in a relatively high rate of false alarms for nonmemorable distractors.

In the framework of Fuzzy Trace Theory, Brainerd et al. (2003) proposed recollection rejection as another mechanism for identifying and editing out false memories. By this mechanism, a distractor that is consistent with the gist of a presented item may be rejected when the verbatim trace of that item is recollected. Thus, participants can reject 'SOFA' as having occurred in the study list if they recall that the word 'COUCH' was in the list and if they have noticed that all words in the study list were unrelated to each other. Recollection rejection has been shown to operate in rejecting false narrative statements (Brainerd et al., 2006) and may also occur for self-generated candidate responses that emerge during recall.

Finally, Burgess and Shallice's (1996) model, mentioned earlier, also includes a mechanism for the screening of retrieved information. The model assumes that 'editor' processes are initiated whenever a descriptor is set. These processes check that retrieved memory items do not contradict previously retrieved elements of the event, and that they are compatible with the overall descriptor requirements. Evidence for the operation of such a mechanism comes from error corrections in verbal protocols obtained during autobiographical recollections of recent everyday events. One participant, who was asked to describe the first thing that came to mind that happened to him in January, was recorded thinking:

> Something that happened in January? . . . I completed a major sale. No! I didn't complete a major sale in January at all. I didn't sell anything at all in January because I remember looking at the board and that was blank." (Burgess and Shallice, 1996: 382)

Applying their model to the study of confabulations, Burgess and Shallice (1996) pointed to impaired editor processes, along with insufficiently focused retrieval descriptions, as two of their main causes.

### 2.18.5.3 Inhibiting Wrong/Irrelevant Information

As noted earlier, a great deal of unwanted information is retrieved during the search for a solicited target, which must be cast aside as the search continues. Therefore, a potentially important contributor to successful retrieval is the efficient inhibition of such incidental information and, in particular, the inhibition of rejected candidate answers that would otherwise keep coming to mind and interfering with the search. The effect of such interference has been emphasized in studies of the TOT phenomenon, in which the failure to retrieve the correct target while in the TOT state is attributed, in part, to the interfering effect of 'interlopers' – plausible but wrong candidate answers that share some features with the target (Reason and Lucas, 1984; Jones, 1989; Burke et al., 1991).

It has been observed that retrieving some items of a studied list with the aid of category cues impairs the later recall of other studied items from the same category, but not of other unrelated studied items (Anderson et al., 1994; Anderson and Spellman, 1995; Anderson, 2003). This retrieval-induced forgetting has been attributed to inhibitory mechanisms that operate to suppress unwanted information in order to overcome retrieval competition (Anderson et al., 2000; Levy and Anderson, 2002). Hasher and her colleagues (Hamm and Hasher, 1992; Hasher et al., 1999) suggested that inhibitory processes are used to suppress goal-irrelevant information that has been activated in working memory, or to prevent candidate answers from being immediately reported, so that other candidates can also be retrieved and considered (Hasher and Zacks, 1988; Hasher et al., 1999; Radvansky et al., 2005). May and Hasher (1998) demonstrated that the controlled inhibition of the irrelevant contents of working memory is deficient in older adults, and in young adults during their off-peak time of the day.

*Directed forgetting* is another example of controlled inhibition in memory. Research indicates that, when people are instructed to forget a previously learned piece of information, they are often successful in reducing or eliminating the interference between that information and the subsequent retrieval of to-be-remembered information (Bjork and Woodward, 1973; Bjork, 1989). The underlying mechanism seems to involve inhibiting the retrieval of the to-be-forgotten information. Indeed, when memory is tested through recognition or relearning, or when it is tested through indirect measures of memory such as priming, performance on the to-be-forgotten items is typically comparable to that of to-be-remembered items (Basden et al., 1993; Bjork and Bjork, 1996).

#### 2.18.5.4 Deciding Whether to Continue or Terminate the Search

We have characterized the search process as reiterative, but it is, of course, not endless. At some point, the memory search must terminate – either when no relevant information can be retrieved or after some information (correct or incorrect) has been retrieved, and the rememberer either believes that the target has been reached or has given up. The decision to stop the search is at least partially under the control of the rememberer and is based on such factors as level of confidence in the best candidate answer produced so far, the feeling that one knows the answer even though it has not (yet) been retrieved, the amount of time and effort invested so far, and the incentives for successful performance.

Whereas it is self evident that high confidence in a retrieved answer will induce the rememberer to terminate the memory search, there is also evidence that this decision is affected by the feeling of knowing (FOK) regarding answers that have not yet been retrieved. When FOK is high, participants spend more time searching for the target before giving up than when FOK is low (Nelson and Narens, 1990; Barnes et al., 1999).

The decision to continue the search is also affected by the expected reward for correct retrieval. Loftus and Wickens (1970) found that the larger the reward offered at the time of retrieval, the more time participants spent before terminating the retrieval, although this did not affect their performance. More direct evidence comes from Barnes et al. (1999) in examining the ‘willingness to continue searching’ component of their metacognitive retrieval model. They assumed that the willingness to continue searching depends on two conflicting incentives – the reward for finding the correct answer and the cost of spending additional search time. For example, in most exam situations, continuing to search for an answer to one question is beneficial to the extent that this allows the correct answer to be reached, but it is detrimental to the extent that this takes away from the time that can be spent on other questions. Manipulating the reward for each correct answer and the cost of additional search time on a cued-recall test, Barnes et al. (1999) found that both higher rewards and lower costs induced the participants to take longer before responding. This increased the number of correct responses and decreased the number of omission errors without increasing the number of commission errors – indicating that the additional retrieval effort was not in vain.

### 2.18.6 Controlled Report Processes

#### 2.18.6.1 Deciding Whether or Not to Report an Answer

Much memory research has used forced-report testing procedures, such as forced-choice recognition or forced cued recall, in which the participant is required to select/provide an answer to each and every test probe. In most everyday memory situations, however, as in many laboratory recall tasks, rememberers have the option of *free report;* that is, they are allowed to decide for themselves whether to answer a particular memory query, or instead to respond 'don't know' (or refrain from responding).

The option of free report is particularly crucial in situations, such as courtroom testimony, in which a premium is placed on accurate reporting. Koriat and Goldsmith (1994, 1996b) showed that, when participants are given the option of free report and a moderate incentive for accurate reporting (a penalty for each wrong answer equal to the reward for each correct answer), they are able to boost the accuracy of what they report substantially in comparison to forced-report testing. They do so by withholding best-candidate answers that are likely to be wrong. For example, in one study (Koriat and Goldsmith, 1994, Experiment 1), the option of free report allowed participants to increase their recall accuracy from 47.6% in forced report to 76.6%. Moreover, when given an even stronger accuracy incentive (a 10:1 penalty-to-reward ratio; Koriat and Goldsmith [1996b, Experiment 1], or the loss of all winnings if a single wrong answer is volunteered, Koriat and Goldsmith [1994, Experiment 3]), report accuracy was boosted even further. In each case, however, the increased report accuracy came at the price of a reduction in the quantity of correct information reported – that is, a quantity-accuracy trade-off (see also Barnes et al., 1999; Kelley and Sahakyan, 2003).

The existence of a quantity-accuracy trade-off means that rememberers must strive to find a compromise between these two conflicting aims in regulating their reporting. Consider, for example, a courtroom witness who has sworn "to tell the whole truth and nothing but the truth." Generally, it is not possible to fulfill both endeavors simultaneously. How, then, should the witness proceed?

Koriat and Goldsmith (1996a) proposed a model (for similar models, see Barnes et al., 1999; Higham, 2002), in which one first assesses the likelihood that one's best candidate answer is correct and then compares this assessment to a report criterion. The answer is volunteered if its assessed probability of being correct passes the criterion; otherwise, it is withheld. The setting of the criterion is assumed to depend on the relative incentives for accuracy and quantity; in general, report accuracy should increase, but the quantity of correct answers should decrease as the criterion level is raised.

In line with this model, a very strong relationship was found between the tendency to report an answer under free-report conditions and subjective confidence in the answer (assessed probability that the answer is correct). In one study, for example, the mean within-participant gamma correlation between confidence in the answer and the decision to volunteer it or withhold it on a recall test was .95 (Koriat and Goldsmith, 1996b, Experiment 1; see also Kelley and Sahakyan, 2003). In addition, manipulating the incentives for accurate reporting in the manner described earlier (by manipulating the relative rewards and penalties for correct and incorrect answers, respectively) induced rememberers to adjust their report criterion accordingly; higher levels of confidence were required for reporting answers under a strong accuracy incentive than under a more moderate accuracy incentive (Koriat and Goldsmith, 1996b, Experiment 1; Kelley and Sahakyan, 2003, Experiment 1). Finally, modeling the report decision in terms of a confidence criterion (cutoff), with the level of the criterion for each participant allowed to vary as a free parameter, yielded a very good fit with the data, accounting for about 94% of the participants' actual report decisions under recall testing (Koriat and Goldsmith, 1996b, Experiment 1). Similar levels of fit were found by Kelley and Sahakyan (2003).

The consideration of the role of metacognitive monitoring and control processes in reporting has yielded some interesting insights concerning variables that affect memory accuracy and quantity performance. One, of course, is the effect of accuracy motivation mentioned earlier. A second important variable is monitoring effectiveness, that is, the extent to which the rememberer can distinguish between correct and incorrect answers. On the one hand, as monitoring effectiveness increases, the option of free report allows one to screen out wrong candidate answers without also mistakenly screening out correct candidate answers, thereby reducing the rate of the quantity-accuracy tradeoff. On the other hand, when monitoring effectiveness is impaired, the exercise of the option to withhold answers may yield little or no benefit in terms of report accuracy (Koriat and Goldsmith, 1996b; Rhodes and Kelley, 2005; Kelley and Sahakyan, 2003) and may simply reduce the quantity of correct information that is reported (Higham, 2002), compared with forced report.

A third important variable is test format with – recall versus recognition. This variable has been implicated in both traditional, quantity-oriented research and in more naturalistic, accuracy-oriented research, with opposing implications. Whereas the general finding from decades of laboratory research (e.g., Brown, 1976) is that recognition testing is superior to recall testing in eliciting a greater quantity of correct information from memory, the established wisdom in eyewitness research, for example, is that recall is superior to recognition in eliciting accurate information from rememberers (e.g., Hilgard and Loftus, 1979; Neisser, 1988). Koriat and Goldsmith (1994), however, showed that this recall–recognition paradox actually stems from the common confounding between test format (recall vs. recognition) and report option (free vs. forced). Typically, recognition participants are forced either to choose between several alternatives or to make a yes–no decision regarding each and every item, whereas recall participants have the freedom to withhold information that they are unsure about. Comparing performance on a free-recognition test (in which participants had the option to respond 'don't know' to individual items), to a free-recall test, Koriat and Goldsmith (1994) found that recognition quantity performance was still superior to recall, but now recognition accuracy was as high or even higher than recall accuracy. An examination of the underlying memory and metamemory components of recall and recognition performance (*See* Chapter 2.20; Koriat and Goldsmith, 1996b) indicated that monitoring effectiveness was in fact somewhat lower for recognition than for recall testing, but that this disadvantage was more than compensated for by superior memory access and the adoption of a more conservative report criterion under recognition testing.

The consideration of the role of metacognitive monitoring and control processes in reporting has also yielded interesting insights with regard to other important topics and questions, such as developmental changes in memory accuracy (Koriat et al., 2001; Roebers et al., 2001), memory decline in the elderly (Jacoby, 1999; Pansky et al., 2002; Kelley and Sahakyan, 2003; Rhodes and Kelley, 2005), cognitive and metacognitive impairment in schizophrenia (Danion et al., 2001; Koren et al., 2006), psychometric and scholastic testing (Koriat and Goldsmith, 1998; Higham, 2007), and the classic encoding specificity principle (Higham, 2002; Higham and Tam, 2005). As just one example, there has been a question about the reliability of children's memory, particularly in the area of legal testimony, (e.g., Bruck and Ceci, 1999). Yet, Koriat et al. (2001) showed that children as young as 8 or 9 years old can regulate their memory reporting to produce a more accurate record of past events when they are allowed to screen out wrong answers and when they are explicitly motivated to do so. Furthermore, like adults, they are also sensitive to specific levels of accuracy incentive, increasing the accuracy of their reports further when a higher premium is placed on memory accuracy. However, the children in that study (see also Roebers et al., 2001) and elderly adults in other studies (Pansky et al., 2002; Kelley and Sahakyan, 2003; Rhodes and Kelley, 2005) were found to be less effective than young adults in utilizing the option to withhold answers to enhance their accuracy.

Of course, there may be variables whose influences are not amenable to control by way of report regulation. For example, Payne et al. (2004) observed that when participants were allowed the option of free report, they could enhance their overall memory accuracy, but the withholding of answers did not reduce stereotype bias. Their findings suggest that stereotypes distort memory through an unconscious-accessibility bias to which subjective confidence is insensitive. The implication is that any variable that affects memory performance without affecting subjective confidence (i.e., that cannot be monitored) will not be susceptible to report control.

#### 2.18.6.2 Deciding on the Grain Size of the Reported Answer

In addition to the exercise of report option, another means by which rememberers regulate the accuracy and amount of information that they report is controlling the *grain size* of their report, that is, the precision or coarseness of their answers (Yaniv and Foster, 1995, 1997; Goldsmith and Koriat, 1999; Goldsmith et al., 2002, 2005). For example, when asked to specify what time an event occurred, a rememberer who is unsure might provide a relatively coarse response such as "in the late afternoon" or "between 5.00 and 6.00 p.m.," rather than venture a more precise response. In fact, Neisser (1988) observed that, when answering open-ended questions, participants tended to provide answers at a level of generality at which they were "not likely to be mistaken." Of course, more coarsely grained answers, while more likely to be correct, are also less informative. Thus, Goldsmith et al. (2002) proposed that the control of grain size is guided by an accuracy-informativeness trade-off (see also Yaniv and Foster, 1997), similar to the accuracy-quantity trade-off that guides the exercise of report option. They found that, when participants were allowed to control the grain size of their report, they did so in a strategic manner, sacrificing informativeness (precision) for the sake of accuracy when their subjective confidence in the more precise-informative answer was low. The participants also took into account the relative payoffs for accuracy and informativeness in choosing the grain size of their answers; they tended to provide more precise answers (thus taking a greater risk of being wrong) when the relative payoff for informativeness was high than when it was low. The monitoring and control processes involved in the regulation of memory grain size appear to be similar to those underlying the decision to volunteer or withhold specific items of information, implying perhaps the use of common metacognitive mechanisms.

As in the case of report option, a consideration of the control of grain size in memory reporting has begun to shed light on other memory phenomena and issues. One example is the potential role of control over grain size in modulating the changes that occur in memory over time. Goldsmith et al. (2005) examined the regulation of report grain size over different retention intervals. Starting with the well-known finding that people often remember the gist of an event though they have forgotten its details, they asked whether rememberers might exploit the differential forgetting rates of coarse and precise information in regulating the accuracy of the information that they report over time. The results suggested that, when given control over the grain size of their answers, people attempt to maintain a stable level of report accuracy by providing coarser answers at longer retention intervals.

In this section we focused on the control of grain size that takes place at the reporting stage. There is evidence, however, that rememberers can also control the level of coarseness or precision at which they retrieve information (Anderson et al., 2001; Brainerd et al., 2002; Koutstaal, 2003; Koutstaal and Cavendish, 2006). Koutstaal (2003), for example, showed that rememberers can flexibly alternate between attempts to query memory at a highly specific level and attempts to query memory at a categorical level, and that this flexibility is somewhat impaired in older participants. Moreover, Koutstaal and Cavendish (2006) found that initially inducing participants to adopt and use a gist-based retrieval orientation can impair performance on a subsequent memory task that requires a more precise retrieval orientation.

## 2.18.7 Concluding Remarks

In this chapter, we examined the processes of voluntary remembering that are under the control of the rememberer. Such control is evident throughout the course of remembering, from the initial decision regarding whether and how to begin the memory search, until the final decision regarding how the retrieved information is to be reported. The investigation of self-controlled processes in remembering presents a methodological challenge to students of memory, because such processes are, by definition, less amenable to strict experimental control. Yet, as evidenced by the work reviewed in this chapter, recent years have seen a growing willingness to face this challenge. Clearly, however, much more work needs to be done to illuminate the underlying mechanisms of controlled remembering and clarify the intricate interplay between controlled and automatic memory processes. Ultimately, research should be targeted toward integrating these processes into more general theories of memory and remembering.

# 2.19 Source Monitoring

**D. S. Lindsay**, University of Victoria, Victoria, BC, Canada

People sometimes experience difficulty identifying the origins of their thoughts, images, and feelings. You might, for example, find yourself wondering 'Where did I get the idea that the U.S. Speaker of the House is third in line to the presidency?' or 'Did I turn off the oven before I left the house, or did I only think about turning it off?' Moreover, people sometimes erroneously attribute thoughts, images, and feelings to origins other than the true sources. Victims of cryptomnesia (unconscious plagiarism), for example, experience memory-based thoughts as new ideas (Brown and Murphy, 1989; Marsh et al., 1997; Stark and Perfect, 2006). In déjà vu, in contrast, a person has the subjective experience of recognizing a current situation as familiar without having experienced a directly corresponding prior episode (Brown, 2004).

The source monitoring framework (SMF) is an evolving collection of ideas designed to explain the mechanisms by which people attribute mental events to particular origins (Johnson et al., 1993; Johnson, 2006). It is referred to as a framework, rather than a theory or model, in acknowledgment of the fact that the approach stops far short of fully specifying or formalizing the mechanisms involved in identifying the sources of mental events. The core thesis of the SMF is that thoughts/images/feelings that come to mind do not include abstract tags or labels that name their sources, but rather have qualitative and quantitative characteristics that are more or less diagnostic of source. As elaborated in the following, mental events are said to be attributed to particular sources on the basis of their characteristics in the context of the individual's current orientation.

Source is a multidimensional construct that refers to the various dimensions that collectively specify how one came to have a particular mental experience. Dimensions of the sources of memories include spatial/environmental context, temporal context, modality of apprehension (e.g., whether a remembered sentence was heard or read or merely imagined), and agent (e.g., who said a remembered utterance). Thus the concept of memory for source is similar to what Brown and Kulik (1977), in their exploration of flashbulb memories, termed memory for circumstances of encounter (e.g., your recollections of learning of the 9/11 attacks on the World Trade Center).

The construct of source is also similar to (but more inclusive than) that of memory for context. Some models of memory make a sharp distinction between memory for content and memory for context, characterizing the latter as an abstract tag or label that is associated with but not intrinsic to the memorial representation of content (Anderson and Bower, 1974; Murnane et al., 1999). Such models constrain the range of potential contexts quite narrowly (e.g., List 1 vs. List 2). In the SMF, in contrast, the distinction between content and source is a blurry one, sources are thought to be inferred from multiple aspects of the accessed memorial information itself rather than read off from a tag, and the range of potential sources is unbounded.

## 2.19.1 Underlying Assumptions Regarding Basic Mechanisms of Memory

The SMF is not in itself an account of encoding/retention/revival of memory information, but it rests on certain assumptions about how memory works (see Johnson, 1985). Space constraints prohibit a detailed exegesis here, but it is worthwhile briefly summarizing some key points. One such assumption is that memory traces or records are by-products of the multiple cognitive operations that underlie and give rise to ongoing experience. It follows that memory traces for any given event are distributed across multiple processing subsystems. Reading a word, for example, involves a host of cognitive processes, from relatively low-level, data-driven, automatic, generic processes (e.g., figure/ground separation, identifying letter and word shapes, etc.) to higher-level, more conceptual, abstract, effortful, and instance-specific processes (e.g., noting a conceptual relationship between a study word and an earlier word on the list). All such processes have lasting effects on the processing subsystems that perform them (memory traces), as per connectionist models of memory (McClennand and Rumelhart, 1985; McClelland et al., 2003; see also Kolers and Roediger, 1984).

The SMF assumes that the revival of information from memory follows the transfer-appropriate processing (TAP; Morris et al., 1977) or encoding specificity principle (ESP; Tulving and Thompson, 1973), as in Tulving's ideas about synergistic ecphory (Tulving, 1984). Ongoing processes that are sufficiently and distinctively similar to past processes cue revival of those past processes. Importantly, some aspects or features of the processes that gave rise to and constitute a past episode can be revived without other aspects or features being revived. A cue might bring to mind information about the spatial location of a previously presented stimulus, for example, but not information about its color. Or one might recollect relatively abstract, conceptual aspects of a past experience without remembering surface-level details of that experience (e.g., one might remember that a previously presented word was a taboo word but not remember the exact word) (cf. Brainerd and Reyna, 1990).

Several factors influence which features of a past event are, versus are not, revived by a cue. For one, cognitive processes vary in the extent to which they produce distinctive traces of the sort likely subsequently to be experienced as recollections of a specific prior episode. Highly automatic, low-level, data-driven processes are rarely consciously experienced in ongoing experience, and they tend to be executed in much the same way each time they are engaged. Thus records of any particular instance of such processing cannot readily be cued (cue overload) and in any case their revival would not directly give rise to thoughts or images per se because their initial performance did not give rise to thoughts or images. That is, processes that are tacit and unconscious in ongoing experience are tacit and unconscious when later cued, although the influence of such memory traces can be detected under some conditions, such as in measures of repetition priming involving transformed text or highly unusual fonts (Kolers and Roediger, 1984; Wiggs and Martin, 1994; Westerman et al., 2003).

Another determinant of which aspects of a past experience are versus are not revived by a cue is the nature of the cue, as per TAP/ESP. For example, memories of prior sensory processes are more likely to be revived by representation of the perceptual stimulus than by a more abstract cue. Being oriented toward remembering – what Tulving (1998) called being in retrieval mode – can be described in TAP terms as a matter of configuring aspects of current thought in ways that more effectively act as cues for past thoughts. Finally, which aspects of a past event are revived in response to a cue is influenced by the extent to which different aspects of the initial event were bound together with one another, which in turn reflects attention during and shortly after the event. Aspects of an event that are in the focus of attention and that are reflected upon as or immediately after they occur tend to be bound together in ways that support revival of aspect X in response to a cue that maps on to aspect Y (Johnson et al., 2005). Refreshing newly created memories by reflecting on recently experienced events may also be involved in memory consolidation (Wixted, 2004).

Cues rarely if ever revive only memory information from a single to-be-remembered prior episode. Rather, cues evoke episodic information from multiple past events that are similar in various ways to the cues (cf. Neisser's 1981 concept of "repisodes"), along with more abstract knowledge and beliefs conceptually related to the cues. Thus schema and scripts, biases, expectations, stereotypes, etc., are evoked by cues in parallel with episodic details when we remember the past. The memory system must work in such a way that cues evoke memory information from multiple episodes combined with more general knowledge, because otherwise we could only retrieve memories of event X by way of extremely X-specific cues. If the system gave us only exactly what we were looking for, we would have to be able to specify very precisely what it is we are looking for. Of course, if we knew exactly what information we sought from memory there would be no need to look for it. Thus we need a sophisticated set of source monitoring processes not only to specify the sources of a particular memory record but also to help us differentiate between recollections of the multiple episodes, repisodes, inferences, schemas, etc., that come to mind in response to internally and externally generated cues.

The SMF also assumes that reviving memory information itself leaves traces. That is, when a person recollects a past event she creates memories of that episode of recollection. Cues that are effective for reviving the event itself are also likely to be effective for reviving such memories of remembering (Lane et al., 2001). After multiple instances of recollecting a particular past event, the revival of memories of the prior recollections may come to dominate those of the event itself. Relatedly, the way a person talks about his or her memories of an event can influence subsequent recollections of that event (Higgins and Rholes, 1978; Marsh and Tversky, 2004; Echterhoff et al., in press). Reviving memories also appears to strengthen the binding between different aspects of the remembered event (i.e., those aspects that are revived; Johnson, 1994); again, binding is key to the episodic, autonoetic quality of remembering (i.e., the subjective experience of partially reliving a prior experience in one's personal past).

## 2.19.2 Johnson and Raye's Reality Monitoring Model

The SMF is an outgrowth and elaboration of Johnson and Raye's (1981) reality monitoring (RM) model. The RM model was primarily an account of how individuals differentiate between memories of actual perceptual events versus memories of thoughts, fantasies, or dreams (e.g., 'Did I lock the door, or did I only think about locking the door?'). The RM model emphasized the role of average quantitative differences between memories of actual versus imagined events. The model posited, for example, that memories of actual experiences tend, on average, to be more perceptually detailed than memories of imagined events and hence that amount of perceptual detail serves as a cue to a memory's reality status: Perceptually detailed memories probably really happened, whereas perceptually vague memories were probably merely imagined. As another example, the RM model held that memories of imagined events typically include more traces indicating effortful, internally generated cognitive operations (i.e., the mental processes involved in deliberately imagining the event), and hence that amount of memorial evidence of cognitive operations serves as a cue for differentiating between memories of actual versus imagined events.

According to the RM model, perceptually rich memories with little indication of effortful cognitive operations are likely to be experienced as memories of actual events. Thus, for example, a memory of an unusually vivid and fluently generated fantasy is likely to be misidentified as a memory of an actual event. The RM model also includes a more reflective, systematic process that can be engaged when memories with intermediate quantitative characteristics come to mind. Those more analytical processes use knowledge and beliefs to make deliberative inferences about the reality status of a remembered event based on its content (e.g., 'It must be that I really did give that message to Sara, because if I hadn't she would have called me by now'). Such systematic processes may also be engaged when the qualitative content of a memory contradicts the reality status implied by its quantitative characteristics. A vivid memory of unaided flight, for example, might initially be classified as a memory of a real event by rapid, heuristic processes based on quantitative characteristics, but then be reclassified as a memory of a dream or fantasy based on the rememberer's belief that people cannot fly.

Johnson and her coworkers amassed a considerable body of evidence in support of the RM model. For example, participants rated their memories of past fantasies as less perceptually detailed than their memories of past real events, and when asked why they believed a particular memory was of a real versus imagined event, they often cited such characteristics (Johnson et al., 1988b). As another example, subjects were more likely to confuse memories of seeing line drawings with memories of imagining line drawings if the objects were easily imaged than if they were difficult to image (Finke et al., 1988).

The SMF incorporates the ideas of the RM framework, but as explained below it differs from it in two major ways. First, the SMF assumes that the quantitative characteristics of memories (e.g., amount of perceptual detail) constitute only a small subset of a broad range of memorial characteristics that can be used quickly and automatically to attribute thoughts, images, and feelings to particular sources of past experience. Second, rather than dichotomizing between internally generated and physically instantiated events, the SMF seeks to account for an unbounded range of finer-grained source identifications that, collectively, specify all dimensions of a mental event's origin.

## 2.19.3 Memory Source Monitoring

### 2.19.3.1 Basic Mechanisms

As noted, the key premise of the SMF is that the sources of memories are rarely abstractly specified (named or labeled) in the memorial contents whose revival is prompted by a cue. This follows from the assumption that memory traces are by-products of ongoing cognitive processes, and from the corollary that individuals only occasionally reflect on and label the various dimensions of the source of ongoing events. As you read the preceding paragraph, for example, you probably were not thinking, 'I'm reading Steve Lindsay's chapter in Roddy Roediger's handbook at time X on date Y in place Z.' What is tacit in ongoing experience will be tacit in memory records. Consequently, even if the full wealth of cognitive processes performed during a particular past event could be revived, they would probably not abstractly label or specify many source dimensions.

According to the SMF, the processes by which memories are attributed to sources are analogous to those by which aspects of perceptual events are attributed to particular sources in ongoing experience (see also Payne and Blackwell, 1998). If your friend Kathy calls you on the phone, when she says 'Hello' you recognize her voice; the auditory signal does not include any abstract designation of the speaker's identity, but processing the sounds evokes the information that leads you to hear it as Kathy's voice. In both the perceptual and memorial cases, source attributions are usually made very quickly, with little if any conscious awareness of a decision-making process and with very high levels of accuracy. But various conditions can undermine source attributions, making them more difficult and error prone.

One source of difficulty in memory source attributions is sparse revival of memorial information. This is analogous to the difficulty you might have in recognizing a friend's voice on the phone if the connection was bad. In the memorial case, sparse revival may be due, for example, to poor attention during the event itself or to poor cuing (e.g., cues that only partially map onto the to-be-remembered past event and/or that also map on to numerous other past events (cue overload)). Thus, various manipulations that impair encoding or retrieval of source-specifying aspects of an event tend to lower source monitoring performance. Troyer et al. (1999), for example, showed that performing a finger-tapping task during study substantially lowered SM accuracy (more than it lowered recognition). Similarly, Zaragoza and Lane (1998) showed that subjects who encountered or retrieved misleading suggestions under divided attention were more likely to later make false-memory reports consistent with those suggestions than were subjects who encountered or retrieved them under full attention (see also Lane, 2006).

Memory source attributions are also compromised when two or more sources of prior experience are highly similar to one another. If your friends Kathy and Francine have very similar voices, then you may misidentify a recollected utterance of Kathy's as having been made by Francine, just as you might confuse Kathy's voice with Francine's on the phone. In a breakthrough study by Johnson et al. (1988b), subjects heard an experimenter say some words and imagined other words, and later attempted to remember which words had been spoken and which had been imagined. Subjects who had been instructed to imagine the words in their own voice were substantially more accurate than were those who had been instructed to imagine the words in the experimenter's voice (even though old/new recognition was equivalent in those two conditions). I term this a breakthrough study because, to the best of my knowledge, it was the first in which the sources could only be differentiated on the basis of qualitative content (e.g., remembered sound of voice) as opposed to quantitative characteristics (e.g., amount of sensory detail). As another example along the same lines, participants in a study by Lindsay et al. (1991) watched a video in which two individuals took turns telling a story about going to the circus; subjects were later tested on their ability to identify which of the storytellers had mentioned particular details. Performance was substantially poorer when both storytellers were teenaged girls than when one storyteller was a teenaged girl and the other was an elderly man. Presumably, memories of the appearance and sound of the two speakers were more diagnostic of source when the two storytellers were dissimilar on those dimensions.

Effects of source similarity on subsequent SM are not limited to perceptual similarity; semantic or conceptual similarity can also reduce SM discrimination. For example, in the Lindsay et al. (1991) study, subjects more often failed to remember which storyteller had talked about a particular detail (e.g., that the sword swallower wore black boots) if both storytellers had said something about that circus act than if only one of them had said anything about that act.

As one might expect given the analogy to perception, source monitoring attributions can be influenced by expectations and stereotypes held by the rememberer. For example, Marsh et al. (2006) found that stereotypically masculine statements were more likely to be attributed to a male speaker and stereotypically feminine statements to a female speaker. Similarly, Mather et al. (1999) found that subjects tended to attribute remembered utterances to speakers whose political views fit those utterances. Spaniol and Bayen (2002) found that SM judgments were more likely to be influenced by schemas when memory was relatively poor, just as expectations are more likely to distort perception of vague or ambiguous stimuli than strong and clear ones.

Another sort of bias, termed the it-had-to-be-you effect, is the tendency to attribute false memories to whichever source tends to give rise to weaker memories. In an experiment by Johnson et al. (1981), for example, subjects listened to the experimenter say some words and generated words of their own; on a later test, when they falsely recognized a word, they tended to say that the experimenter, rather than themselves, had generated that word. Presumably, memories of nonpresented words tend to be fairly vague and weak, biasing subjects toward assuming that they came from whichever source tends to give rise to weaker memories. In the first of a clever pair of studies, Hoffman (1997) set up a situation in which recognition memory was better for items that subjects had been asked to imagine in an initial phase than for items they had perceived; when subjects false-alarmed to a nonstudied item, they tended to classify it as having been perceived. In Hoffman's second experiment, phase 1 was changed in ways that led memory to be better for perceived than for imagined items, which in turn reversed the direction of the bias: Now when subjects false-alarmed they tended to attribute those memories to imagination rather than perception. Bink et al. (1999) provided evidence and arguments to the effect that such biases are not necessarily based on strength *per se*: Rather, subjects are biased to attribute false memories to whatever source has characteristics that resemble those of false memories.

In a related phenomenon, people often report phenomenological qualities of false memories that correspond to the characteristics of the source to which the person erroneously attributes those memories. For example, Mather et al. (1997) had subjects listen to audio recordings of Deese/Roediger/McDermott (DRM) lists read by different voices. Such lists consist of words that are all backward associates of a critical word that is not, itself, included in the list (e.g., bed, rest, awake, tired, etc., for the critical word sleep), and subjects very often falsely remember the nonpresented critical lure. If one speaker read all of the words in each list, then when subjects false-alarmed to critical lures they were very likely to attribute their memories of the lure to the associated list (for analogous findings, see Lampinen et al., 1999; Gallo et al., 2001; Roediger et al., 2004).

As noted earlier, variables that impair encoding often compromise SM. But under some conditions superior encoding can promote SM errors. For example, Toglia et al. (1999) found that deep as opposed to shallow processing of DRM items increased correct recall but also increased false recall. Likewise, Gallo and Roediger (2003) found that elderly adults did more poorly than younger adults on remembering the source of studied DRM items, and that this age-related decline in source memory had the salutary effect of reducing the tendency to attribute false memories of critical lures to the associated list. Similarly, Lyle et al. (2006) found that elderly adults were less able to remember the spatial locations in which images had been presented for study and that they were less likely to falsely claim to have studied look-alike foils in those locations. In all of these cases, the processes that promote accurate recollection also tend to promote illusory recollection.

Under some conditions, processes that enhance memory for studied items also serve to differentiate memories of studied versus nonstudied items and hence to lower the incidence of false memories. Dodson and Schacter (2002), for example, had subjects study a list of words or a list of pictures, then tested their recognition memory with words. Some new (nonstudied) test words were repeated on the test with various lags (as per Jennings and Jacoby, 1997). Subjects who had studied items as pictures were substantially less likely to false-alarm to repetitions of new items on the test than were subjects who had studied items as words, presumably because having studied pictures led subjects to expect that they would be able to recollect pictorial information in response to test probes corresponding to studied words.

Instructions to attend to memory sources, or warnings about potential source monitoring confusions, usually reduce the likelihood of such errors. Presumably such instructions encourage individuals to engage more deliberative, systematic source monitoring processes, rather than relying on quick and easy but more error-prone source monitoring heuristics. Under conditions that encourage lax source monitoring, subjects may endorse almost any item that seems familiar, whereas under other conditions subjects may take care to disentangle different sources of familiarity. For example, Lindsay and Johnson (1989) tested subjects in a variant of Loftus's eyewitness misinformation procedure (e.g., Loftus et al., 1978). Subjects viewed an event, were exposed to misleading suggestions regarding some details in that event, and were then tested on memory for the event. Those tested with a yes/no recognition memory test very often falsely responded Yes to test items that referred to details that had been suggested but not witnessed. Subjects tested on a SM test, in contrast, rarely claimed to have seen in the event things that had merely been suggested, presumably because the SM test encouraged subjects explicitly to query their memories of each item to differentiate between different sources of familiarity (cf. Zaragoza and Koshmider, 1989; Echterhoff et al., 2005). Similarly, manipulations that make the source of misleading suggestions more salient and memorable tend to reduce SM errors (e.g., Sharman et al., 2005).

Source attributions can be made at a wide range of degrees of precision or grain size (e.g., Schacter et al., 1984; Dodson et al., 1998). You might, for example, remember that a statement was made by a woman rather than by a man, perhaps even that the statement was made by a woman student in one of your classes last week, without being able to identify the speaker. The specificity of source attributions is partly a matter of the accessible memory information; the information revived about a past event is often sufficient only for a relatively crude level of source monitoring. Also, within the limits of the accessible memorial information, the specificity of source attributions is flexibly tuned to the rememberer's current goals. Oftentimes people are not concerned about precisely specifying the sources of the thoughts and images that come to mind. In telling an anecdote at a social gathering, for example, one may babble along, interweaving recollections of the to-be-related episode with memories of other prior experiences and memories of stories told by others, filling in weak spots in the narrative with inferences, and enlarging the fish that got away without being aware of doing so, because one's objective is to be entertaining rather than to monitor the origins of one's material.

Most SM attributions are made quickly and without conscious reflection (again, just as is the case with most identifications in ongoing perception). But sometimes rapid, heuristic SM processes fail to produce a source attribution at the appropriate grain size, and the rememberer has a subjective experience of being unable to specify a memory's source. In such cases the individual may bring more consciously controlled reflective strategies to bear. One such strategy is deliberatively cuing memory in different ways in an effort to retrieve additional source-specifying details. Another is to retrieve memories that are associated with the memory in question (e.g., memories of what happened before or after the event in question, or memories of other events involving the same agent or context as the memory in question). The use of memories of associated events to guide deliberative SM judgments has not received much study, but there is evidence that subjects report more memories of preceding and succeeding events for memories of actual events than for memories of imagined events (Johnson et al., 1988b). Intuition suggests that memories of associated events play major roles in resolving SM failures. Yet another deliberative SM strategy is reasoning (e.g., inferring when an event occurred on the basis of the idea that causes precede effects).

### 2.19.3.2 Source Monitoring Versus Old/New Recognition

As has long been noted, most laboratory studies of recognition memory are essentially tests of SM, because both studied and nonstudied stimuli are familiar to subjects from extraexperimental sources. Such tests require subjects to discriminate between items encountered extraexperimentally and in the study list versus items encountered extraexperimentally but not in the study list (Anderson and Bower, 1972). Moreover, even when novel stimuli are used, subjects at test must discriminate between reactions to stimuli that stem from having encountered those stimuli on the study list versus those that arise for other reasons (e.g., ease of processing the test probes; Whittlesea, 1993, 2002).

In a typical SM experiment, subjects study items from two sources and are later tested on a mixture of items from Source A, items from Source B, and new items. Thus performance can be assessed in terms of old/new discrimination (i.e., proportion old recognized as old regardless of source-identification accuracy) and in terms of SM accuracy (e.g., proportion of old items recognized as old correctly attributed to source). In most such situations, SM accuracy requires a finer grain of memory specificity than does old/new recognition, simply because Sources A and B are nested within the set of old items. Thus correctly recognizing an item as being from a particular source within the experiment generally requires a finer level of detail than does recognizing an item as having been presented in one source or another in the experiment.

Because of this characteristic difference in grain size, SM is sometimes sensitive to variables that do not significantly affect old/new recognition accuracy. For example, relative to healthy young adults' performance, poorer SM but equivalent old/new recognition may be observed in young children (Foley and Johnson, 1985; Lindsay, 2002), elderly adults (McIntyre and Craik, 1987; Hashtroudi et al., 1999), and amnesics (Shimamura and Squire, 1987). Similarly, under at least some conditions, dividing attention at study has larger effects on SM than on old/new discrimination (e.g., Frost et al., 2002; Castel and Craik, 2003).

It is possible to contrive situations in which conditions that lead to inferior old/new recognition lead to superior SM. Subjects in a study by Lindsay and Johnson (1991), for example, saw a series of words, some presented on the right and others on the left. Half the subjects performed a relatively deep orienting task for words on the right and left, whereas others performed a deep task for words on one side and a shallow orienting task for words on the other side. As one would expect, old/new recognition was poorer among subjects who studied half of the items with a shallow task than among subjects who studied all of the items with a deep task. But because memory for orienting task provided a potent cue for source discrimination among subjects who studied half of the items with a shallow task, those in that condition had higher SM scores than those who studied all of the items with a deep task.

Despite such dissociations, the SMF holds that old/new recognition judgments and SM judgments generally have much in common. In many laboratory tasks, memory information that indicates that an item came from source X also constitutes evidence that the item is old. To the extent that two judgments draw on the same information, performance on them will be correlated (Glanzer et al., 2004; Johnson, 2005).

### 2.19.3.3 Measures of Source Monitoring

In many studies, SM has been indexed as the proportion of old items recognized as old that are also correctly attributed to source (sometimes called an identification of origin or IDO score). For example, given two sources, A and B:

$$(A|A + B|B)/(A|A + B|B + A|B + B|A)$$

where A|A means that the subject responds A when given an item from source A, etc. One limitation of this measure is that it is likely to be inflated by guessing. Another is that it assumes that SM is equivalent for items from sources A and B, which is not necessarily the case. Yet another concern is that the IDO score implies that SM discrimination and old/new recognition are independent; put differently, the IDO score may confound old/new discrimination and source discrimination.

As a solution to these problems, Batchelder and Riefer (1990) introduced a multinomial model of SM that yields measures of sensitivity and bias for both old/new recognition and source attribution. They and others subsequently elaborated on the multinomial approach, offering a variety of multinomial models for old/new discrimination and source discrimination (Batchelder et al., 1994; Bayen and Murname, 1996; Meiser, 2005). Taking a different approach to the same problems, Banks (2000) developed a multidimensional signal detection model to assess sensitivity and bias for both old/new discrimination and source attribution, since built upon and supported by others (Glanzer et al., 2004). Yonelinas (1999) proposed a model in which recognition without source identification (i.e., familiarity) is described as a signal detection parameter, whereas source identification is assumed to rely on a threshold recollection process (see Qin et al., 2001; Parks and Yonelinas, 2007; Wixted, 2007, for comments on the Yonelinas model). My hunch is that source identification or recollection tends to behave like a threshold process when the materials and procedures are such that source discrimination relies on generation of a very narrow range of kinds of memory information (i.e., on any given trial, a subject will either generate that information or not), whereas in situations in which source can be correctly identified on the basis of numerous different kinds of information, source identification will behave more like a signal detection parameter.

There are no theory-free measures of memory for source (nor, for that matter, of memory without source identification; cf Jacoby et al. 1997). Moreover, there is no one true measurement model that applies in all situations (Meiser, 2005). Rather, the best measure will rely on the specifics of the situation, depending on factors such as the extent to which identification of sources A and B relies on the same sorts of memory information. Pending a more complete understanding of memory, it may be that the best approach is to compare a variety of measures; often they converge quite closely, and when they do not, the disparities have the potential to be illuminating. Note that I am not suggesting that researchers try all measures and then report only the one that best supports their biases.

### 2.19.3.4 Time Course of Source Monitoring

On average, coarser source discriminations can be made more quickly than finer ones. When a recognition probe is presented, information that enables the subject to recognize the item as familiar from the experiment typically comes to mind more quickly than information that enables the subject to identify the specific source within the experiment (Johnson et al., 1994). This may simply be due to the fact, noted earlier, that specific within-experiment sources are nested within the larger category of items presented during the experiment, and hence on average require a finer grain size. These time course effects may contribute to the finding that various types of memory errors are more common when subjects are given little time to respond (Dodson and Hege, 2005; Jones, 2006). Such findings have sometimes been described as evidence for a sharp dichotomy between a fast familiarity process and a slow recollection process (McElree et al., 1999), but as noted earlier the SM perspective describes familiarity and recollection as *ad hoc* categories of memory influences rather than as discrete memory systems.

The SMF does not assume an invariant two-stage process in which items are first recognized as old and then attributed to particular sources. It sometimes occurs that an item is initially recognized as old and then attributed to a particular source, but on other occasions an item might first be identified as coming from a particular source (e.g., speaker A) and on that basis experienced as old. Multinomial models appear to imply a two-stage process, but such models are analytic tools, not processing models.

### 2.19.3.5 Temporal Source Monitoring

Among the most common real-world SM failures and confusions are those involved in situating a remembered event in time. 'Was it yesterday or the day before that Justin dropped off the key? Was that before or after Myta called?' 'When I had my tonsils out and stayed home from school eating Jello, was it fall, winter, or spring?' There are literatures on various aspects of memory for temporal information, including a large body of work on serial recall (Anderson and Matessa, 1997), studies of memory for duration (Yarmey, 2000), and research on dating public and personal events (Brown et al., 1986; Burt, 1993; Berntsen and Rubin, 2004; Friedman, 2004; Lee and Brown, 2004). But as far as I know, there has been no empirical work on temporal memory explicitly grounded in a SM perspective.

The SMF suggests that qualitative and quantitative aspects of accessed memory information may provide cues as to when a remembered event occurred. Thus, a recollection of something happening while you were sitting at your breakfast table might be identified as an event that happened in the morning; memories of a snowball fight would likely be attributed to winter. Just as with other attributes of source, such cues can be misleading: perhaps, for example, the snowball fight took place in July in the mountains.

Dating remembered events poses special problems for SM because the contents of event memories usually provide only very indirect cues to the date. If, for example, you once had an accident driving to work, years later you might still be able to recall many details of that experience because of its distinctiveness and salience, and those memories might enable you to specify the location of the accident, the approximate time of day (e.g., driving to vs. from work, in light or darkness), and even perhaps the season (rain or snow), but the memory records probably will not provide direct cues to the date on which the accident occurred. The memories constrain the date (e.g., if you retrieve information about geographical location, and you traveled that route only during a particular period), but such constraints tend to be imprecise (except for memories of events intrinsically associated with particular dates).

Consistent with these ideas, people generally have difficulty dating autobiographical events. For example, Friedman (1987) interviewed people 9 months after a major earthquake: On average, respondents were correct to within 1 h in their judgments of the time of day the earthquake occurred but erred by nearly 2 months in their judgment of the month (see also Thompson et al., 1996; for work on the development of temporal SM, see Friedman and Lyon, 2005).

Repeated experiences of highly similar events increase the difficulty of specifying the date on which a particular instance occurred. On which birthday did you receive that blue sweater? Such a question is likely to cue multiple birthdays, each sharing numerous features and none easily dated, such that they tend to blend together in recollection (into what Neisser, 1981, termed repisodes). Relatedly, Connolly and Lindsay (2001) found that children were more susceptible to misleading suggestions regarding variable details about an event they had experienced on several occasions.

### 2.19.3.6 Affect and Source Monitoring

Emotional arousal tends to enhance memory for occurrence but to impair memory for source. For example, Johnson et al. (1996) showed subjects videos of individuals making emotionally evocative and neutral statements, with instructions that either oriented the subjects to their own affective responses or to those of the speaker. Focusing on one's own emotional responses improved recognition of spoken statements on a subsequent test, but it impaired the ability to remember which speaker had made which statements.

In a more recent study using a short-term source task, Mather et al. (2006) found better item recognition for emotional than for neutral pictures, but better memory for the pictures' spatial locations for neutral than for emotional pictures. Emotionally evocative materials may encourage a narrowing of attention that undermines the binding together of the evocative item and its surrounding context (as per weapon focus; Mitchell et al., 1998).

Orienting toward one's emotions during an event does not always impair subsequent SM. In the Johnson et al. (1996) study just described, for example, shifting the self-focus from how participants felt about the statements to how participants felt about the individual speakers eliminated the self-focus deficit. Although I am not aware of any study testing the hypothesis, it is likely that if a particular emotion was diagnostic of a source, then emotion would be a basis for veridical SM. Nonetheless, in many situations stimuli that evoke strong emotional responses shift attention away from external details that might subsequently be useful for SM.

### 2.19.3.7 Developmental Changes in Children's Source Monitoring

Children as young as 5 years (and probably younger) can do as well as adults on SM tasks in which the sources are quite dissimilar (even when performance for all age groups is below ceiling). But when the sources in a particular situation are highly similar, then younger children do more poorly than adults. For example, seminal studies by Foley and Johnson and coauthors showed that 5-year-olds were as accurate as adults at remembering which of two actors had performed particular actions, but had more difficulty than adults discriminating between memories of actions they had performed versus memories of actions they had imagined themselves performing (Foley et al., 1983; Foley and Johnson, 1985; Foley et al., 1989). Presumably the cognitive processes involved in performing and imagining oneself performing an action are highly similar, and hence memory records of those two types of events are difficult to discriminate. Consistent with this account, Lindsay et al. (1991) found that young children also had more difficulty than older children when discriminating between memories of what they had seen another person do and memories of what they had imagined that person do.

In more recent research, Foley and coauthors found that, after taking turns with the experimenter to add pieces to a collage or model, preschoolers showed a pronounced tendency to remember themselves as having made contributions that were actually made by the experimenter (Foley and Ratner, 1998; Foley et al., 2002). Foley and coauthors proposed that this is at least in part due to children spontaneously anticipating their collaborator's actions; memories of such self-generated anticipations would be highly similar to, and hence easily confused with, memories of having performed actions.

Why do preschoolers make more errors on difficult SM tasks than older children or adults? It is possible that young children imagine events more vividly than do older children, and hence that their memories of imagined and actual events are inherently more confusable than the memories of older children (especially when real and imagined events are performed by the same agent). It is also likely that the memorial information automatically generated in response to test probes becomes more source-specifying with age (i.e., older children recollect more details, including source-specifying ones; e.g., Sluzenski et al., 2006). My hunch, though, is that the primary source of this age difficulty interaction has to do with developmental improvements in strategically controlled SM. Older children and young adults take longer to respond when source discriminations are difficult than when they are easy, whereas my impression is that younger children often respond as quickly under difficult conditions as under easy ones. It may be that older children have better metacognitive insight into when they do versus do not have an adequate basis for making a source attribution and/or are more skilled at deliberately searching for additional source-specifying memory information when needed (Ackerman, 1985; Schacter et al., 1995). Also, preschoolers' memory-test responses seem to be driven largely by the semantic content or gist of the items, rather than recollections of episodic details or verbatim traces (Brainerd and Reyna, 1995). As noted, older children may also place greater reliance on heuristic biases that, while imperfect, often do lead to correct source attributions.

In a series of studies by Poole and Lindsay (1995, 2001, 2002), 3- to 8-year-old children experienced a series of interactive events and subsequently listened to a parent describe some of those events along with nonexperienced events (including an ambiguous instance of touching). Subsequently, when children received an optimal, nonleading interview, many of them reported having experienced events that their parent had described but that they had not really experienced (including a number of reports of the ambiguous touching event). In response to open-ended questions, the oldest children were just as likely as the youngest children to make false reports of suggested events, perhaps reflecting offsetting effects of age-related improvements in ability to remember and talk about the suggestions as well as age-related improvements in the ability to suppress such reports. Late in the interview, children were specifically asked to discriminate between events they remembered experiencing and those that they might merely have heard about. This SM test substantially reduced false reports of suggested events in older children, but had no such effect on younger children.

In Poole and Lindsay's 2002 study, half the children participated in a simple SM-training procedure at the beginning of the interview. In this procedure, the interviewer performed some actions (e.g., wiping off the tape recorder) and talked about performing other actions (e.g., pushing the button to reset the counter on the tape recorder). Immediately thereafter, children were asked whether the experimenter had really performed each action, and they were given explicit corrective feedback (e.g., 'That's right, I really did wipe off the tape recorder; you know that because you saw me do it,' or 'Think hard – Remember when I said that I sometimes push the button to reset the counter on the tape recorder? But you didn't really see me push the button to reset the counter on the tape recorder, did you? No, you didn't, so "No" is the right answer'). This procedure substantially reduced, but did not eliminate, false reports of suggested details in response to direct questions in the main part of the interview for 7- and 8-year-old children; it had no impact on younger children (see also Giles et al., 2002; Bright-Paul et al., 2005; Thierry et al., 2005).

SM is not a single skill that children acquire at a specific age. Rather, SM involves inferences about numerous dimensions of source – remembering who, remembering where, remembering how, remembering when, etc. – and depends upon multiple kinds of mental activities (e.g., perceptual analysis and reflective integration during encoding, revival of memory records, and decision-making processes at test). Thus developmental changes in SM are gradual and situation-specific rather than sudden and global. These considerations also suggest that SM development is correlated with individual differences along a number of dimensions (Lorsbach and Ewing, 1995; Quas et al., 1997; Welch-Ross et al., 1997; Drummey and Newcombe, 2002; Roebers and Schneider, 2005).

### 2.19.3.8 Source Monitoring Performance in Old Age

Henkel et al. (1998) reviewed a wealth of evidence indicating that SM performance generally declines late in life. As with young children, elderly subjects can do well on SM tasks when the sources are highly discriminable, but their performance deteriorates sharply as source similarity increases. Henkel et al. (1998) argued that aging-related SM deficits may be mediated by reductions in the extent to which contextual details are encoded in ways that tightly bind them together with other aspects of an event (see also Lyle et al., 2006). Poorer encoding and integration of features means that older adults are less able to recollect such details later on, leaving them with more vague, abstract memories of experienced events. Such memories are difficult to discriminate from memories of internally generated events.

### 2.19.3.9 The Neuroscience of Source Monitoring

The hippocampus appears to play important roles in episodic memory. Johnson (2006) argued that the hippocampus is particularly important in binding together different aspects or features of an event to create complex, multifaceted memories which, among other things, afford SM attributions. Damage to the hippocampus and surrounding areas has profound debilitating effects on episodic memory (Milner, 2005). Mitchell et al. (2000) used functional magnetic resonance imaging (fMRI) in a short-term memory test in which young and old adults were either required simply to recognize items or to bind together items and locations. They found that younger adults exhibited greater hippocampal activity on binding trials than on item trials, whereas older adults did not (consistent with a selective age effect on performance of SM vs. old/new recognition tests). Johnson (2006) also argued that the prefrontal cortex (PFC) is likely to be involved in noting and reflecting on relationships between features of events, and that such processes, too, play important roles in creating highly source-specific event encodings.

There is also evidence for roles of sensory and motor cortex during encoding in laying the groundwork for subsequent SM performance. In an fMRI study by Gonsalves et al. (2004), for example, subjects saw some items and were asked to imagine seeing others. Activation in visual areas was greater for to-be-imagined items that subjects later erroneously claimed to have seen than for those that they correctly reported imagining, consistent with the idea that vivid and detailed images are more likely to be later mistaken as memories of perceptual events (see Leynes et al., 2006, for a related finding with event-related potential (ERP)).

Earlier, I noted that PFC is thought to be involved in discovering and maintaining attention to relations between different features or aspects of an event in ways that may be important for hippocampal consolidation of complex memories. It is also thought that the PFC plays important SM roles during remembering. Consistent with that claim, Johnson et al. (1997) found greater PFC activity on an SM test than on an old/new test for the same items. Johnson (2006) reviewed a number of ERP and fMRI studies whose findings suggest that the left PFC is particularly important for SM judgments.

## 2.19.4 Related Theoretical Perspectives

### 2.19.4.1 Jacoby's Memory Attribution Approach

Larry Jacoby and his coauthors noted that people sometimes use memory information from specific prior episodes without having the subjective experience of remembering (as in involuntary plagiarism), and that people can have the subjective experience of remembering specific prior episodes that they never in fact experienced (as in various forms of false memories; e.g., Schacter, 2001). Jacoby and coworkers argued that the subjective feeling of remembering arises from an unconscious attribution that is based on the fluency with which an item is processed. Specifically, when cognitive processing is surprisingly fluent one may attribute that fluency to the use of memory, especially if the situation highlights the past (i.e., memory) as a source of influence on current processing (Jacoby and Dallas, 1981; Jacoby and et al., 1989a).

Bruce Whittlesea's SCAPE model can be described as an elaboration of Jacoby et al.'s (1989a) ideas regarding fluency-based attributions to memory. Whittlesea has emphasized that it is unexpected fluency, not fluency *per se*, that leads to memory attributions (a point that was tacit in Jacoby's treatment; e.g., Jacoby and Whitehouse, 1989). Whittlesea and Williams (1998), for example, exposed subjects to words and nonwords and later tested them on a mix of studied and nonstudied words and nonwords. Subjects read each test word aloud before making a recognition judgment to it. Half of the nonwords were regular (e.g., hension), whereas the others were irregular (e.g., stofwus). The key finding was that reading times were fastest on words, but it was the regular nonwords that drew the highest rate of false alarms. Presumably, subjects tended to attribute the fluency with which they read words to their status as words. Regular nonwords may thus have been experienced as surprisingly fluent. It is only when the fluency is discrepant with the person's moment-by-moment impression of how fluent his/her processing should be, and when memory is a plausible source of that fluency, that the person is likely to attribute fluency to memory.

The question of what leads people to attribute thoughts, images, and feelings to memory versus to other sources can be described in terms of the SMF: Thoughts, images, and feelings that come to mind with characteristics typical of memories are likely to be experienced as memories, especially if the person is oriented to the past as a source of current mental events. Similarly, those with the characteristics of perception will tend to be attributed to sensory stimuli (sometimes giving rise to hallucinations; see Johnson, 1988), those with the characteristics of new ideas will be experienced as novel insights, etc. From this perspective, relative fluency is but one cue to source.

### 2.19.4.2 Dual-Process Models of Recognition Memory and the Remember/Know Distinction

Dual-process models of recognition memory hold that items can be correctly recognized as old on either of two independent and qualitatively different bases: (1) Familiarity, a rapid, automatic, undifferentiated feeling of having previously encountered a test item; and (2) recollection, a more deliberative and effortful process of retrieving episodic details regarding the prior encounter with an item (Mandler, 1980; Jacoby, 1991). That contrast is related to the distinction between Remember and Know judgments in the remember/know procedure, in which subjects are asked to indicate whether affirmative recognition judgments are based on episodic recollections of details of encountering the item on the study list or on an undifferentiated feeling of just knowing that the item was on the list.

According to the SMF, processing a test probe sometimes leads to the generation of sufficient source-specifying memory information to enable source identification at a particular grain size, and other times does not (as governed by the principles discussed earlier). The SMF also suggests that certain kinds of memorial information are relatively likely to give rise to a subjective experience of remembering a unique prior episode, whereas others are more likely to give rise to a less-differentiated sense of familiarity. Specifically, source identifications and reports of remembering are likely to arise from access to memories of relatively reflective, elaborative, integrative, distinctive processes. Reports of just knowing, in contrast, are likely to reflect memories of more automatic, data-driven, generic cognitive processes. The recollection/familiarity and remember/know contrasts refer to categorically distinct phenomenological experiences, but from the SMF they are thought to arise from a continuum of memory specificity (Dodson and Johnson, 1996; Gruppuso et al., 1997; Bodner and Lindsay, 2003).

#### 2.19.4.3 Constrained Retrieval

Can you recall an event that occurred when you were in high school that is somehow associated with fire? To generate such a memory, you might in principle first retrieve lots of fire-related memories and then check to see if any of them occurred in high school, but in practice we seem to constrain retrieval such that memories are more likely to come to mind if they are from the to-be-recalled source than if they are from other sources (although of course the constraint is imperfect). Jacoby et al. (2005) proposed that such constrained retrieval plays a central role in enabling individuals to remember material from the appropriate source. They also argued that people can constrain the ways they process recognition test probes so as to facilitate retrieval of memory information from the to-be-recognized source as opposed to memory information from other sources. These provocative new ideas valuably complement the SMF's emphasis on monitoring.

### 2.19.5 Empirical Phenomena Illuminated by the Source Monitoring Framework

The study of memory phenomena that can be described as SM failures or confusions far predates the development of the SMF itself. In this section, I provide brief reviews of a number of such phenomena; for a wider-range review, see Schacter (2001).

#### 2.19.5.1 Verbal Learning Effects

Prior to the development of the SMF, phenomena involving SM had been investigated for many years in the verbal learning tradition. For example, studies of list differentiation assessed subjects' ability to attribute studied words to different study lists (Winograd, 1968; Abra, 1972). This research demonstrated the importance of factors such as semantic similarity and temporal separation of the lists. Such findings informed efforts to understand retroactive and proactive interference effects (Postman, 1975).

#### 2.19.5.2 The Eyewitness Misinformation Effect

Studies of eyewitness memory, and of the effects of suggestive influences on eyewitnesses' reports, have featured prominently if sporadically in the history of psychology (for reviews of early psychological research and speculation on this topic, see Brigham and Grisso, 2003; Goodman, 2006). In the mid-1970s, Beth Loftus and coauthors reported studies that inspired interest in this domain that continues to the date of this writing. Loftus et al. (1978) introduced a three-phase procedure in which subjects first viewed a series of slides depicting an event, then were exposed to verbal information that included misleading suggestions regarding some details in that event, and later were tested on memory for the initially witnessed details. Their key finding was that subjects' answers were often based on the misinformation, rather than on what they had actually witnessed. For example, having seen a slide in which a traffic intersection was marked with a yield sign and then later being exposed to the suggestion that the intersection was marked with a stop sign, subjects quite often reported at test that the intersection had been marked with a stop sign.

Throughout most of the 1980s, debate on this eyewitness misinformation effect focused on the question of whether or not misleading suggestions regarding a witnessed detail impaired witnesses' ability to recall or recognize the witnessed detail (e.g., whether the stop sign suggestion impaired memory for the yield sign). McCloskey and Zaragoza (1985) considerably enlivened that debate with an article providing a cogent logical analysis of the various reasons that suggestions could lower accuracy even if they had zero effect on ability to remember the witnessed details (e.g., compared to control subjects who had never encoded the event detail, misled subjects who also had failed to encode the event detail would be less likely to guess correctly on the test), and six experiments whose results provided no support for any event-detail memory impairment phenomenon (but see Payne et al., 1994; Chandler et al., 2001; Eakin et al., 2003, for evidence that modest memory-impairment effects are obtained under some conditions).

In the late 1980s and throughout the 1990s, attention shifted from this memory-impairment issue to the question of whether or not misled subjects believe that they remembere witnessing details that had in fact merely been suggested to them. This question falls squarely in the purview of the SMF, and the answer (as with any psychological question) is, it depends. As previously mentioned, under some conditions, misinformation effects obtained on a yes/no recognition test (i.e., subjects falsely responding Yes to items that were merely suggested to them) vanish when subjects are given a SM test that orients them toward scrutinizing the sources of their memories (Lindsay and Johsnon, 1989; Zaragoza and Koshmider, 1989). That might be because on the yes/no test subjects sometimes endorse items that they believe they remember from the misinformation (e.g., because they assume the misinformation was accurate). Alternatively, it might be that the SM test leads subjects to use more systematic SM procedures to avoid SM confusions that they would make using more heuristic processes on a yes/no test. Importantly, it has been amply demonstrated that misinformation effects can be obtained on SM tests if the conditions make SM difficult (the sources are highly similar and there is a delay between them and the test, the subjects are young children or elderly adults, etc.; see Lindsay, 1994; Zaragoza and Lane, 1998; Poole and Lindsay, 2001; Mitchell et al., 2003).

Even positive responses on an SM test are not definitive evidence that subjects genuinely believe that they remember witnessing suggested details. If subjects trust the source of the suggestions, they might be tempted to claim that they both remember encountering details in that source and witnessing those details. As a stronger test of the hypothesis that subjects are sometimes genuinely unaware of the source of their memories of suggested details, Lindsay (1991) applied Jacoby's opposition procedure (Jacoby et al., 1989b) in a misinformation paradigm. Subjects witnessed a theft depicted in a series of slides, and were later exposed to a narrative description of the theft that presented misleading suggestions regarding some details and control information about other details. In the difficult condition, the event and narrative were presented in immediate succession, with the test given 2 days later; for subjects in the easy condition, the event was presented on the first day and the narrative was presented 2 days later, immediately followed by the test. This latter condition was easy both in that it should be easy at test to remember the suggestions (which had just been presented minutes before) and it should be easy to differentiate memories of the suggestions from memories of the event (due to the large separation between the two sources). At test, subjects were given cued recall questions along the lines of, 'Under what sort of tool did the handyman hide the stolen calculator in his toolbox?' with half of the questions pertaining to items for which subjects had received misleading suggestions (e.g., hammer in event, wrench in narrative) and others pertaining to items for which no suggestions were given (e.g., see a can of Coca-Cola in the event, read it described as a can of soda in the narrative). Crucially, before taking the test subjects were emphatically told that if they remembered having heard something in the narrative that might be used as an answer to a question on the test they could know for certain that it was a false suggestion, and that they should therefore not report anything they remembered from the narrative. Subjects in the easy condition showed no tendency to report suggested details; given that these subjects were in a good position to remember those details, this indicates that subjects understood and followed the instruction not to report details from the narrative. Subjects in the difficult condition, in contrast, quite often reported suggested details. Significant suggestibility effects under opposition instructions provide powerful evidence that subjects are sometimes genuinely misled about the sources of their memories (see also Holliday and Hayes, 2002; Eakin et al., 2003; Price and Connolly, 2004).

### 2.19.5.3 False Memories Induced by Schemas, Scripts, and Associations

The SMF fits well with earlier research on schema-based memory errors, in which individuals' knowledge and beliefs were shown to distort their memory reports (Bartlett, 1932; Brewer and Treyens, 1981). That is, schemas support the fluent generation of inferences that may have many of the characteristics of memories. As a recent example consistent with this idea, Gerrie et al. (2006) found that subjects who had viewed slides depicting highly scripted events (e.g., making a peanut butter and jelly sandwich) very often falsely recognized script-typical slides that had been omitted from the studied series.

### 2.19.5.4 Other Fluency-Based False Memories

Similar to knowledge and beliefs, other variables that facilitate processing of recognition test probes can increase endorsement rates. For example, Jacoby and Whitehouse (1989) preceded recognition test probes with briefly presented primes that either matched or mismatched the probe. When prime duration was very short, such that subjects were not consciously aware of the presentation of the prime, Yes rates to both old and new probes were higher when preceded by matching primes. Presumably, the brief prime facilitated processing of the test probe and that fluency was attributed to prior exposure on the study list. Of critical importance, when primes were presented for a slightly longer period, so that subjects were consciously aware of them, the data pattern reversed as subjects evidently overattributed the fluency with which they processed test probes to the preceding matching prime. Similarly, Whittlesea (1993) found that a variety of manipulations of the fluency with which test probes were processed affected recognition responses. Lindsay and Kelley (1996) demonstrated analogous effects in cued recall: A manipulation that enhanced the ease with which words popped to mind in response to recall cues increased both accurate and erroneous cued recall reports.

### 2.19.5.5 Veridical and Illusory Recovered Memories of Childhood Sexual Abuse

The 1990s saw a heated controversy regarding cases in which individuals reported that they had recovered long-forgotten histories of childhood sexual abuse. The debate focused on cases in which reports of recovered memories arose in the context of psychotherapy oriented toward fostering memory recovery. Critics of such therapies argued that they were dangerously suggestive and that they sometimes led clients to develop false beliefs or false memories of abuse that never really occurred (Loftus, 1993). Some proponents of trauma-memory-oriented therapies countered that such criticisms were anti-feminist, pro-perpetrator backlash against victims of childhood sexual abuse.

This is a tremendously complex, multifaceted, and emotionally explosive topic, with valid concerns on both sides (Read and Lindsay, 1997). Fortunately, although strenuous contentions still arise in this area (Wade et al., 2007), my perception is that a middle-ground position that acknowledges the likelihood that both essentially accurate and essentially illusory recovered memories occur has come to dominance (Lindsay and Briere, 1997).

In any case, the point for present purposes is that the SMF was of considerable value in understanding how a prolonged, socially influenced, multipronged (albeit well-intentioned) effort to foster the recovery of suspected hidden memories of abuse could, instead, lead individuals to develop false beliefs and memories of abuse (Lindsay and Read, 1994, 2006). There is, for example, some evidence that individuals who report recovered memories are more susceptible to SM confusions on laboratory tasks (McNally et al., 2005) and that they are more prone to forget prior instances of remembering events (Geraerts et al., 2006).

### 2.19.5.6 The Knew-It-All-Along Effect

The knew-it-all-along (KIA) effect, or hindsight bias, is observed when persons report that they possessed knowledge at a previous point of time that they in fact acquired subsequent to that time (Fischhoff, 1975; Wood, 1978; Hasher et al., 1981). Of particular interest here is the memory version of the KIA effect, in which subjects answer a set of questions in phase 1, are then exposed to the correct answers to some of those questions in phase 2, and in phase 3 are asked to re-answer the questions exactly as they did in the first phase. The standard finding in this procedure is that subjects' re-answers to items for which they had been shown the correct answers are often shifted in the direction of the correct answers.

When subjects demonstrate a KIA effect, do they have an (illusory) subjective experience of remembering themselves giving newly learned correct answers on the initial test? Or is their experience merely one of guessing or inferring their prior responses? There is evidence that, under at least some conditions, subjects fail to appreciate the extent to which their re-answers are influenced by the experimental exposure phase in KIA procedures (Begg et al., 1996) and in closely related procedures (e.g., Prentice and Gerrig, 1999; Marsh et al., 2003), but do subjects remember giving correct answers that they did not really give?

To explore this question, Michelle Arnold and I (Arnold and Lindsay, in press) conducted KIA experiments in which subjects were asked to report, for each re-answer, whether they: (1) remembered giving that answer initially, (2) knew they had given that answer without being able to recollect having done so, or (3) felt that they were merely guessing or inferring that they had given that answer. Under standard KIA procedures (passive exposure to the correct answers to trivia questions), when subjects showed a KIA effect they almost always reported guessing or inferring their prior answers. But when the materials were insight problems and the second phase involved providing subjects with sufficient cues to solve the problems, then they quite often subsequently reported false memories of answering questions correctly in the first phase. Presumably in the latter procedure, memories of having been led to figure out a problem in Phase 2 were highly confusable with memories of having spontaneously solved that problem in phase 1.

#### 2.19.5.7 The Forgot-It-All-Along Effect

Schooler et al. (1997) sought out cases in which adults reported having recovered long-forgotten memories of childhood sexual abuse for which there was evidence that the abuse had occurred. They reported two cases in which individuals had apparently told others about the abuse during the period of alleged amnesia. Schooler et al. speculated that these women had recalled the abuse in a qualitatively different way that was accompanied by strong emotions, and that they made an unconscious attribution along the lines of 'I must not have known about this before, lest I wouldn't be so emotionally affected by these recollections.' Schooler et al. termed this hypothetical phenomenon the forgot-it-all-along (FIA) effect, in reference to the aforementioned KIA effect.

Arnold and Lindsay (2002, 2005) developed a laboratory analogy designed to capture some aspects of this hypothesized FIA effect. Subjects were cued to remember items on two different occasions; for half of the items the cues were varied on the two occasions so as to shift the way the subjects thought about the recalled item. On the second test, after each item was recalled, we asked subjects whether they had also recalled that item in the first test. We found that when subjects had recalled the same item on each of the two tests, they were more likely to fail to remember their test-1 recall of the item if they had been cued to think of the item in different ways on the two tests (i.e., a FIA effect). Geraerts et al. (2006, Experiment 2) extended the procedure to memories of autobiographical events and, as mentioned earlier, found larger FIA effects among subjects who reported having recovered repressed memories of childhood sexual abuse than among control subjects.

#### 2.19.5.8 Cryptomnesia

Cryptomnesia, also known as unconscious or inadvertent plagiarism, occurs when an individual mistakes memories of another's ideas as new ideas of his or her own. Brown and Murphy (1989) introduced a three-phase procedure for studying cryptomnesia. In an initial phase, subjects took turns (with one another or with the experimenter or computer) generating items that fit a specified constraint (e.g., names of musical instruments). In the second phase, subjects were asked to recall their own phase-1 contributions. In phase 3, subjects were asked to generate new items not previously generated by them or anyone else in the experiment. Cryptomnesia was often observed in phases 2 and 3, with subjects tending to claim that they recalled themselves generating items that others had in fact generated, and including in their 'new' phase 3 generations items that they or others had generated in phase 1.

As the SMF would lead one to expect, manipulations that increase the similarity between self-generated and other-generated ideas increase rates of cryptomnesia. For example, subjects tested in same-sex pairs show higher rates of cryptomnesia than those tested in different-sex pairs (Macrae et al., 1999), a finding that also emerged in a retrospective self-report survey of everyday cases of cryptomnesia by Defeldre (2005). Marsh et al. (1997) reported converging evidence for the idea that failures in SM processes underlie cryptomnesia. More recently, Stark and Perfect (2006) found that elaborating on another's idea substantially increased subsequent plagiarism, perhaps because the processes performed when elaborating an idea are very similar to and hence highly confusable with those involved in hatching the idea.

#### 2.19.5.9 The Mere Exposure Effect

In a classic paper, Kunst-Wilson and Zajonc (1980) demonstrated that very briefly presented neutral stimuli were subsequently preferred over novel neutral stimuli in two-alternative forced-choice judgments, even though subjects were at chance when explicitly asked to discriminate between previously exposed and new stimuli on the same test pairs. Anecdotal reports (and my own experience) indicate that it is not easy to obtain above-chance preference coupled with at-chance recognition, but that pattern has been reported sufficiently often to compel the conclusion that it is a real albeit delicate phenomenon (Seamon et al., 1983a,b). Both aspects of this effect are interesting. First, it is interesting that influences of prior exposure can be experienced as preference. This is an SM failure of a sort, perhaps reflecting an inherent tendency to prefer stimuli that are easily processed (Winkielman et al., 2006). It is perhaps noteworthy that to the best of my knowledge, the effect on preference in the absence of recognition has only been reported with stimuli that afford little in the way of strong preferences (e.g., random polygons). It is also intriguing that subjects at chance on recognition have been shown to select previously exposed items at above-chance levels on certain other kinds of judgments (e.g., brightness or darkness judgments in Mandler et al., 1987; see Seamon et al., 1998, for evidence that it is easier to obtain the dissociation pattern with affective judgments than other sorts of judgments).

Arguably more interesting than the above-chance performance on preference judgments is that, having memories sufficient to generate this preference effect, subjects nonetheless respond on the recognition test as though they had no such memories. Whittlesea and Price (2001) offered arguments and evidence to the effect that this dissociation arises because subjects tend to make preference judgments in a nonanalytic, holistic manner, whereas they tend to make recognition judgments in a more analytic, feature-based manner. Presumably, the latter orientation toward test stimuli reduces the extent to which subjects cue revival of the weak and poorly bound memory records of the prior exposure. This may also account for the evidence of Seamon et al. (1998), mentioned previously, that various judgment tasks are differentially sensitive under conditions that lead to chance-level recognition.

#### 2.19.5.10 Déjà Vu

Most people report that they have had the uncanny experience of being in what they know to be a novel situation and yet feeling that they have previously been in that situation. If the mere exposure effect is tough to get in the lab, déjà vu is nigh unto impossible, so the latter effect has been studied with self-report measures. Brown (2004) summarized that research and offered three accounts of déjà vu: (1) a decoupling of streams of perceptual processing that normally progress in synchrony, such that one stream runs faster than the other with the later stream, then cuing memories of the (milliseconds old) faster stream; (2) a momentary lapse of attention, during which perceptual processes carry on automatically, with memories of those (poorly bound) perceptual processes being cued when attention returns to the ongoing situation; and (3) partial revival of memories of some similar past situation, giving rise to a strong feeling of familiarity without providing sufficient source-specifying information to enable the person to attribute that familiarity to its correct source. The last of these accounts is most amenable with a memory SM perspective, but as discussed in the next section, all three are in keeping with a broader approach to SM.

## 2.19.6 Challenges and Future Directions

### 2.19.6.1 Multidimensional Source Monitoring

Most studies motivated by the SMF have explored rememberers' ability to discriminate between memories from two sources (e.g., two external sources or an external source versus an internal source such as a spontaneous inference or a directed image), typically using forced-choice tests. In everyday life, SM is much less constrained. If, for example, you try to remember how you got the idea that polar bear hair is translucent and hollow, the range of potential sources is very wide. A number of recent studies have tested SM across two pairs of nested sources (e.g., identifying which of four individuals – two women and two men – had said particular words; Dodson et al., 1998). Some studies have involved simultaneous explorations of two different dimensions of source manipulated orthogonally (e.g., font size and location; Marsh et al., 2004; Starns and Hicks, 2005). I suspect that much more can be done to explore SM in situations in which the range of potential sources is broad.

### 2.19.6.2 Interpersonal Source Monitoring

In the course of conversation, auditors sometimes make inferences regarding the sources of their interlocutor's memory reports. You may, for example, have listened to someone relating an anecdote and thought to yourself, 'He's probably making that part up,' or 'I bet she's exaggerating a bit,' or 'I bet he got that from the *National Enquirer*.' The bases for such inferences are likely numerous and complex, particularly in cases in which the auditor has extensive prior experience with the storyteller or has independent knowledge of the content of the tale. Such inferences have as much to do with social and personality psychology as with cognition, but nonetheless the SMF may inspire hypotheses about at least some of the processes involved in making inferences about the accuracy and source of another person's verbal reports.

Even when listening to an unfamiliar person describing a novel event, auditors may make inferences about the accuracy and reliability of those reports. This is especially so when conditions foster concerns about lying (as in police investigations), and there is an extensive and fascinating literature on deception detection (Granhag and Vrij, 2005). Sporer (2004) has developed a deception-detection scale based in part on the SMF, and this approach appears to have substantial potential. Relatedly, jurors weigh the testimony of witnesses, evidently driven largely by the witnesses' apparent confidence (e.g., Brewer and Burke, 2002; Tetterton and Warren, 2005).

It is also interesting to consider interpersonal SM in situations in which lying is not at issue but in which storytellers might nonetheless be mistaken. Schooler et al. (1986) exposed subjects to misleading suggestions regarding a witnessed event, had them write descriptions of the event, and gave those descriptions to new subjects for evaluation; these evaluations were slightly but significantly above chance (see also Johnson and Suengas, 1989). Johnson et al. (1998) found that the more details an account contained, the more believable naive judges found that account to be. Lindsay et al. (2000) found that undergraduates role-playing as police officers were above chance at discriminating between accurate and inaccurate truthful witnesses, but that they did so less well than witnesses' own self-ratings of confidence (see also Dahl et al., 2006). Here again the SMF is a source of hypotheses as to how perceivers make such judgments and how their accuracy might be improved.

### 2.19.6.3 Falsifiability

The SMF has a great many degrees of freedom. For one thing, memory records are described as multifaceted, imperfectly bound constellations of numerous aspects or features, from low-level perceptual primitives to conceptual reflections. Thus, for example, two sources might be highly similar along some dimensions and quite distinct along others (e.g., Marisa and Jim might both have Spanish accents but very different pitches, whereas Marisa and Elke might have similar pitches but different accents). How do multiple dimensions of similarity interact? As another example, compared to generating an image of an item once, generating it several times may increase both (1) records of cognitive operations associated with generating an image of that item (which could be taken as evidence that the item was generated) and (2) the fluency and vividness with which the latter images were generated (which could be taken as evidence that the item was perceived). Without a theory to specify which aspects will be more or less accessible and more or less heavily weighted in a particular situation, it is not always obvious which conditions will lead to more or fewer SM failures.

Moreover, SM performance is said to depend not only on the characteristics of memory records but also on the rememberer's expectations, biases, stereotypes, current orientation, and goals. Variations along these higher-level dimensions can interact with variations in the characteristics of memory records. As an example, consider an eyewitness misinformation study by Bonto and Payne (1991), in which some subjects were exposed to the witnessed event and the postevent information in the same context, whereas others were exposed to the two sources in a different context. The SMF would predict that source discriminations would be more difficult in the same-context condition than in the different-context condition, but Bonto and Payne found equivalent (and substantial) influences of misinformation in both conditions. One possible account has to do with the fact that Bonto and Payne's procedure likely encouraged subjects to rely on memories from both sources. There was no warning about misinformation, so subjects may have assumed that the postevent information was a legitimate and reliable source of answers to test questions and hence not been concerned about discriminating memories from the two sources.

Some of the most clever SM research in recent years has come out of the labs of Rich Marsh and his coauthors, including several studies that further illustrate the difficulty of using the SMF to make specific predictions. In a study by Marsh et al. (2002), for example, subjects were presented with compound words (e.g., deadbolt, neckline) in two sources and were later tested on either a yes/no recognition test or on a SM test. Of central interest was the rate of falsely claiming to have studied conjunctions (e.g., deadline). One might expect that the SM test would lead subjects to scrutinize their recollections more carefully before responding and thereby lower the rate of such errors. Instead, Marsh et al. found that when the two sources were sharply dissimilar and when the 'parents' of a conjunction had both been presented in the same source, then subjects tested with the SM test were more likely to make conjunction errors than were subjects tested with the recognition test (for related results, see Hicks and Marsh, 2001). Marsh, Hicks, and their colleagues have discussed these and similar results in terms consistent with the SMF, but the point for present purposes is that the framework does not always provide a clear and firm framework for predicting behavior in complex situations.

In many well-controlled and simple experiments, the SMF is falsifiable, but in more complex, less controlled situations it is often possible to fashion accounts consistent with the SMF for a variety of different empirical outcomes. Some theorists (e.g., Reyna and Lloyd, 1997) have strongly criticized the SMF for this limited falsifiability. This may partly be a matter of taste, with some theorists putting a premium on falsifiability and others esteeming the extent to which a theory serves to organize and inspire nuanced hypotheses regarding a wide range of phenomena. Of course, in the long run, proponents of the SMF hope to more precisely specify the interactions among the numerous variables involved in attributing mental events to particular sources.

## 2.19.7 Conclusion

Some theories describe remembering as a matter of using the episodic memory system, knowing as a matter of using the semantic memory system, skilled performance as a matter of using the procedural memory system, etc. Indubitably there are functional brain systems specialized for the sorts of cognitive processes that typically support remembering, knowing, doing, etc. But just as surely those brain systems do not operate in isolation from one another, and the thoughts, images, and feelings to which they give rise are products of multiple subsystems interacting. Because the implications of mental contents vary greatly as a function of their sources (e.g., remembering that one previously encountered a tiger near this water hole is more consequential than remembering that one previously dreamed of such an encounter and less consequential than currently sighting a tiger), we routinely monitor the sources of our thoughts, images, and feelings. The SMF provides a productive way of thinking about the processes by which such attributions are made.

## Acknowledgments

Work on this chapter was supported by the Natural Sciences and Engineering Research Council of Canada. I thank Keith Lyle for several insightful suggestions for improving a draft of this chapter.

# 2.20 Metamemory

**J. Metcalfe**, Columbia University, New York, NY, USA

**J. Dunlosky**, Kent State University, Kent, OH, USA

Metamemory refers to the processes and structures whereby people are able to examine the content of their memories, either prospectively or retrospectively, and make judgments or commentaries about them. Thus, metamemory is not memory itself, although it may depend critically upon memory. Rather it is the judgments, assessments, or commentaries that are made about memories or learning. These kinds of self-reflective judgments have a long and controversial history. Presumably, for example, when Descartes was engaged in his famous doubting meditation – musing about how his memories or perceptions could have been different than they were, or how he could have been mistaken about them – he was engaging in metacognition. This kind of reflection was taken by him as the basis of all knowledge and the core of our phenomenological selves. Similarly, the introspectionists (with whom behaviorists later took such exception) were, presumably, engaging in what we would now call metacognition. The lack of reliability of their findings was a shortcoming that proved devastating for their method by opening the door for the behaviorists to oust the study of consciousness, at least temporarily, from the domain of respectable topics in psychology. However, the judgmental biases that were the bane of early twentieth century introspectionism are now being studied under the guise of the biases and framing effects that are both systematic and rampant in metacognitive judgments.

That these metamemory judgments can be studied objectively, and reliably, is now apparent, with many hundreds of studies having been directed at issues of human metacognition. Indeed, growing interest and research from a metacognitive perspective – with its emphasis on people's memory-based attributions – can be considered one of the most significant developments in the science of psychology in this new century. Both the processes that underlie the judgments themselves and the implications that these judgments have for self-guided control of learning are yielding to investigation. Current methods promise both enhanced understanding of impairments in metacognition and also the possibility of remedying certain biases to enable people to better assess and control their own learning.

How these judgments are made has been the focus of much research, and some of these processes are detailed shortly. Classically, three types of judgments have formed the core of metamemory research: Feeling-of-knowing judgments, tip-of-the-tongue judgments, and judgments of learning. Although there may be some differences between feeling-of-knowing and tip-of-the-tongue judgments (see Schwartz, 2006), their similarities outweigh their differences, and we treat them together. However, the restriction to these so-called classic judgments is arbitrary, because metamemory refers to any judgment that is about a memory. The reflective quality is what is important in the definition. Thus, other judgments such as confidence judgments, source judgments, recognition judgments, and remember/know judgments are also properly considered to be metamemory. Indeed, any attribution about memory is properly considered to be metamemory, and one may even argue that all memory output relies at least partially on metamemory. For instance, if you covertly recall that the word needle was on a list of words that you just tried to memorize or that Dr. Case told me that the medication would have no side effect, you would likely not report the word needle or recommend the medication to a friend if you were not sufficiently confident in your memory (Koriat and Goldsmith, 1996). Accordingly, we also briefly discuss other memory judgments – in particular, source judgments and remember/know judgments – in the same context as the classical metamemory judgments.

**Figure 1** provides an illustration of what is meant by metamemory. Nelson and Narens (1990), in a highly influential paper, argued that metacognition entailed two mental levels: an object level and a

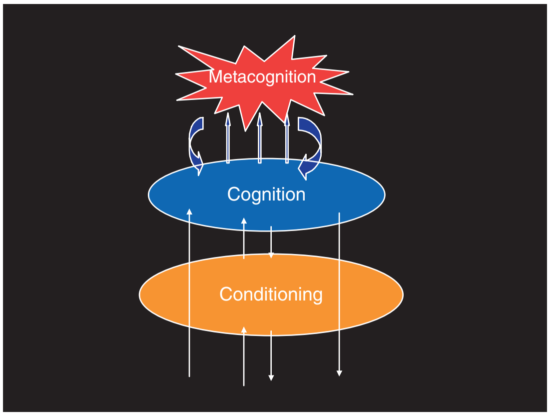

**Figure 1** A model of the relations among metacognition, cognition, and conditioning. The model shows that the metacognitive level both monitors (up arrows) and controls (down, thick arrows) the contents of the cognitive level.

metalevel. The object level consists of the memories themselves. The metalevel involves monitoring the object level, such as reflecting upon memories and ongoing learning. When the object level is memory, such monitoring is measured by feeling-of-knowing judgments, judgments of learning, source judgments, or judgments about whether the individual remembers the event explicitly or only knows that it must have happened. The requirement is that the object of the judgment be a mental event, rather than something that is present in the environment. Many animals can make judgments about the world, but few are capable of reflecting on the objects of their minds, such as their memories (see Terrace and Metcalfe, 2005). The ability to so reflect indicates a fundamentally different kind of mental life for the animals that have it.

As can also be seen from the figure (arrows flowing from metacognition to cognition), metacognition is presumably necessary for high-level control of one's own mental processes and memories. Without knowledge of what one does not know, one could not be expected to take action to remedy the situation by, say, allocating differential study opportunities, rehearsal, or time. The metacognitive individual can choose to mould his or her own mind by self-initiated study processes, thereby learning things under self-control rather than only under stimulus control. To regulate effectively, such self-guided learning requires accurate metacognitions, of course, but it also depends on their appropriate use. If one's metacognitive judgments are inaccurate, self-regulated study could be suboptimal because the person does not know what he or she does not know. Such metacognitive failure could result because of immature metacognition capabilities or because of an impairment due to illness, stroke, or head injury. Distortions in metacognition also occur, even in normal and unimpaired people, because they are blinded by some illusion of metacognition due to the circumstances of the task at hand. Many metacognitive illusions – or biases – have now been documented by researchers (Bjork, 1994), and understanding and finding methods to debias them is fundamental if self-guided study is to succeed (Thiede et al., 2003). However, self-controlled learning and memory processing can also go awry even when a person's metacognitions themselves are excellent, if those metacognitions are not converted into optimal control strategies. One could know what one knows, but still do the wrong thing. Finally, even if one knows what one knows, and one knows what to do about it, the actual implementation of the control knowledge could be faulty – leaving a fully metacognitive person still unable to effectively control their own learning and memory.

Whereas early research on metacognition and control focused almost exclusively on people's judgments about their memories, with the often-stated hope that this would lead to enhanced learning, recent research is increasingly aimed at the control aspect of meta-level awareness. In the section that follows, we focus on the judgments themselves, first, and on theories about how those judgments are made. We then turn to how those judgments are put to use in controlling learning and memory.

## 2.20.1 Metamemory Paradigms

### 2.20.1.1 Feeling-of-Knowing Judgments

The feeling-of-knowing judgment was the first to be systematically explored experimentally, by Joseph Hart, in 1965. Hart gave people a variety of general information questions to answer. When they could not answer a question, he asked them whether they felt they knew the answer anyway. The feeling that they knew it corresponded to their later choosing the correct answer on a recognition memory test. This paradigm posed a puzzle: How is it that people could ostensibly not know, as evidenced by their failure to produce the answer, and yet still be able to predict accurately whether they would know in the future, as evidenced by the correlations that were well above chance between their predictions and subsequent performance?

This finding of above-chance predictive accuracy has been replicated hundreds of times, so there is no doubt as to its reliability. The research in recent years has been directed not at establishing the predictive accuracy of feeling-of-knowing judgments but, rather, at understanding what cues people are using that give rise to it. Several theories have addressed this puzzle of seemingly not knowing and knowing at the same time, that is, how people are able to correctly predict what they will know in the future, when at the moment they are unable to retrieve the correct answer.

#### *2.20.1.1.1 Theories*

Whereas some early theories suggested that the person might have direct access to subliminal traces, all modern theories are basically heuristic in nature; that is, they assume that people have explicit access to some information that notably may be correct or incorrect, diagnostic or nondiagnostic, and that their feeling-of-knowing judgments are based on this information. Thus, while all current theories of this metamemory paradigm (and, indeed, of all metamemory paradigms) are heuristic theories, they differ in the exact heuristic that they propose people are using to make metamemory judgments.

***2.20.1.1.1.(i) Domain and cue familiarity*** A logical possibility for the basis of feeling-of-knowing judgments is that people assess the familiarity of the cue (i.e., the question itself) or the domain of the question. Greater familiarity leads to higher judgments, that is, more confidence that a currently unretrieved answer will later be recognized. Concerning domain familiarity, even though people may be unable to immediately answer a question such as "Who painted *The Sunflowers*?," they may be able to assess how much they know about art and make a reasonable judgment on that basis. If they know something about art, they may be able to narrow down the field in a recognition test and eliminate incorrect alternatives. Thus, this kind of familiarity with the domain of the question may both be used to make a feeling-of-knowing judgment and be diagnostic, because, in general, strategic multiple-choice decision making will be better in well-known than in little-known domains. Thus, the person may not know who painted a particular painting but may nevertheless have a quite good idea of who did not do so, and such knowledge will help them on the test.

Glenberg and Epstein (1987) conducted an experiment in which people were selected for participation based on their expertise in various domains. They were then presented with texts to read that were either in their own domain or not. They found that people made higher judgments of knowing on those passages that were within their own area of expertise, thereby indicating that this kind of knowledge about the domain is one of the cues or heuristics that people use in making their judgments. Surprisingly, however, in this particular case, experts were not well calibrated when making judgments within their own domain. The mystery of this unexpected result remains unresolved even today. Finally, because many studies of feeling of knowing have been conducted with general information questions, and there are several domains of knowledge implicated in these questions (e.g., American history, old movies, sports, geology, capitals of various countries, etc.), knowledge of the types of general knowledge one knows most about could be quite predictive of recognizing the correct answers.

Concerning cue familiarity, Reder and her colleagues (e.g., Reder, 1987; Reder and Ritter, 1992; Miner and Reder, 1994) conducted a series of experiments in which they showed that the familiarity of the cue influenced feeling-of-knowing judgments. For instance, Reder and Ritter (1992) presented participants with math problems (e.g., 113 + 29 = ?) and had them quickly decide whether they wanted to retrieve or compute answers to each one. Prior to making a decision, the cue item was primed, without altering the target answer. Thus, in a math problem such as 113 + 29, they would prime the cue by giving another problem such as 113 * 29. When 113 + 29 = ? was presented, people then hit a button if they wanted to retrieve the answer as compared to compute the answer. If they already knew the answer, it would behoove them (because they would gain a greater reward) to hit the retrieve button, indicating that they could quickly retrieve the answer from memory. The interesting finding, from the perspective of the cue-familiarity heuristic, is that when the cues had been primed, people were more likely to indicate that they could retrieve the answer, even though such priming might even have hurt the retrieval of the correct answer. In a similar manner, Metcalfe et al. (1993) found that cue priming of verbal pairs influenced the feeling of knowing without altering target retrievability. In particular, they showed that the crucial factor influencing the magnitude of feeling-of-knowing judgments was the number of repetitions of the cue (which presumably would boost cue familiarity), rather than the retrievability of the sought-after target.

Whereas these and other studies (e.g., Maki, 1999; Eakin, 2005) clearly implicate the familiarity of the cue as one heuristic that people use in making metamemory judgments, evidence also suggests that partial information retrieved about the target is important.

***2.20.1.1.1.(ii) Partial target accessibility*** The other main source of information for making feeling-of-knowing judgments is partial knowledge about the target. Perhaps one recalls that the answer to the sunflower question given earlier is an impressionist, and maybe even that there is a 'G' in the name. Even with this information, the person may be unable to give the answer. However, such partial target information may be sufficient that he or she will assign the item a high feeling of knowing. Such partial information, which is about the target itself, may be insufficient to allow the person to express the target item but may, nevertheless, indicate (often correctly) that he or she will be able to select the target in a multiple-choice test. (The only problem the person might experience in the present case could be in distinguishing Gauguin from Van Gogh, should both be present in the list). Thus, if partial or fragmentary target information is retrieved, it may be used to indicate that people will know the answer (and hence be related to high feeling-of-knowing judgments).

Koriat (1993) conducted experiments in which the to-be-remembered items were four-letter nonword strings. He showed a positive correlation between the number of letters the person could recall and their feeling of knowing rating. Of course, having three letters rather than just one was highly predictive of whether they would be able to pick the right answer from the set of alternatives offered, and so the predictive accuracy of this particular information-based metacognition was extremely high. The experiment was designed such that a 20-questions strategy was highly diagnostic, because one could eliminate half of the multiple-choice test alternatives with every letter correctly remembered. Playing 20 questions, and deliberatively assigning feeling-of-knowing judgments on the basis of the knowledge that partial information would allow them to eliminate alternatives in the test, is a logical possibility, and one that should work fairly well in the world. Phenomenologically, the judgments often feel more intuitive and less deliberative; however, even if people are less analytic about making these judgments than Koriat's experiments would suggest, if one has partial information, such as the first letter of the target, such information may give rise to a diffuse feeling that one knows more than nothing, and in many cases, one would be correct to inflate one's feeling of knowing.

It seems likely that the two mechanisms – cue familiarity and partial target information – account for most of the variability in feeling-of-knowing judgments. If so, hybrid models that describe how both cues combine (e.g., Leibert and Nelson, 1998; Koriat and Levy-Sadot, 2001) will likely fare well and are worthy of further exploration.

### 2.20.1.2 Tip-of-the-Tongue States

While overlapping in many respects with feeling-of-knowing judgments, tip-of-the-tongue judgments focus more directly on highly accessible partial information, and they appear less inferential in nature (for a general review, *See* Chapter 2.22). Nevertheless, even if tip-of-the-tongue states merely represent very strong feelings of knowing, tip-of-the-tongue judgments have been investigated extensively (and separately from feeling-of-knowing judgments) because they occur so commonly in everyone's lives (Schwartz, 1999). In fact, well before the term 'metamemory' was coined, and before other metamemory judgments were scrutinized, the tip-of-the-tongue state captured the attention of William James (1890/1981). In his now-famous quote, James wrote: "Suppose we try to recall a forgotten name. The state of our consciousness is peculiar. There is a gap therein; but no mere gap. It is a gap that is intensely active. A sort of wraith of the name is in it, beckoning us in a given direction, making us at moments tingle with the sense of our closeness.… The rhythm of a lost word may be there without a sound to clothe it; or the evanescence sense of something which is the initial vowel or consonant may mock us fitfully, without growing more distinct" (James, 1890/1981: 243–244).

Schwartz (1999) has conducted a survey of 51 language groups and found that in the majority of them, there is an expression for what, in English, is called the tip-of-the-tongue state, though the exact expression varies slightly. In Korean, for example, this state is provocatively called "sparkling at the end of the tongue." This state seems to be almost universally experienced.

#### 2.20.1.2.1 Theories

**2.20.1.2.1.(i) Partial target access** In a manner that is similar to the target access view of feelings of knowing, the dominant theory of tip of the tongues is that they reflect partial target access. In support of this view, a number of studies have shown that people are able to report the number of syllables in the to-be-retrieved word, some aspects of semantic content, or its first letter (for a review, see Schwartz, 2002).

**2.20.1.2.1.(ii) Lexical access without phonological access** Burke et al. (1991; see James and Burke, 2000) have proposed that a semantic level of representation of a sought-after word feeds to an articulatory/phonological level, which is necessary for word retrieval and output, and that the two representations can be dissociated. One dissociation is reflected by a tip-of-the-tongue state when the individual has complete or partial access at the semantic or lexical level, without being able to translate that activation into a phonological form that allows retrieval – or output – of the sought-after word. According to this model, the individual really can know an answer without being able to articulate it. Older adults seem to exhibit this phenomenon whereby an impairment occurs in phonological translation, which results in more tip-of-the-tongue states (for a recent review, see Schwartz and Frazier, 2005).

A prediction of this model is also supported by evidence from Metcalfe et al. (1995), who described an anomic patient who had difficulties retrieving words. In particular, this patient (HW), after experiencing a severe stroke, was able to converse intelligently but was unable to articulate the words for nearly all specific nouns, verbs, or adjectives when so requested. Thus, if asked to fill in the correct answer "One ______ the Thanksgiving turkey by brushing butter on while it is roasting," "The precious gem that is red is the _____," "The name of people who explore caves is ______," or even "Sirius is the ________ star in the sky excluding the sun," HW could not say bastes, ruby, spelunker, or brightest. However, he expressed a strong tip-of-the-tongue for these words. When he was later given a recognition test, he was able to pick the correct alternative with an accuracy better than that of Dartmouth College students, indicating that he knew the words he was seeking (i.e., he had semantic knowledge or lexical access) but could not articulate them. Burke et al.'s model eloquently explains HW's deficit.

**2.20.1.2.1.(iii) Blocking** One phenomenon seen in conjunction with tip-of-the-tongue states is that people often report that an incorrect response persistently comes to mind. This persistent alternative is usually called a blocker. We suspect that what makes tip of the tongues frustrating at times is that people in a blocked tip-of-the-tongue state know perfectly well that what keeps persistently coming to mind is wrong. Blocked tip of the tongues differ from nonblocked tip of the tongues insofar as people's phenomenology is different. In addition, it has been shown that blocked tip of the tongues tend to be more difficult to resolve than tip of the tongues without a blocker (Burke et al., 1991; Reason and Lucas, 1984). Researchers have thought that blockers actively keep people from accessing the correct answer. However, recent research by Kornell and Metcalfe (2007) indicates that this active blocking role of the so-called blockers is incorrect. In particular, they conducted an experiment to investigate the idea that blockers impaired performance, as is assumed both in the tip-of-the-tongue literature (Jones, 1989) and in the insight literature, where a similar phenomenon is thought to occur (Mayer, 1995). Theorists have stated that people need to incubate (e.g., take a break to think about something unrelated to the problem) in both a problem-solving attempt or when attempting to retrieve a sought-after answer when in tip-of-the-tongue state. If a persistent alternative came to mind originally (which is supposed to be actively interfering with the generation of the correct solution), this break may allow one to forget it. If so, the off time will allow the problem-solver to overcome the harmful blocker and retrieve a correct solution.

To test this idea, Kornell and Metcalfe (2007) asked people to state whether their tip-of-the-tongue states included a blocker or not. The subjects then either continued to try to solve the problem or waited until the end of the experimental session for the additional minutes that they were assigned to attempt to solve the problem. As in the past literature, blocked tip of the tongues were resolved with a frequency that was lower than that of nonblocked tip of the tongues. Furthermore, consistent with the reminiscence literature, people answered more questions correctly at a delay than immediately. However, the delay interval did not particularly help the blocked tip of the tongues, as compared to the nonblocked tip of the tongues, as should have been the case had the blockers themselves kept the correct answer from appearing. Also, the blockers were forgotten over the delay interval. Thus, the delay interval did, effectively, get the blockers out of mind (as presumably should have been necessary to obviate their deleterious effect). But that made no difference for the rate of resolution, indicating that the so-called blockers do not really block. Kornell and Metcalfe (2007) favored a road sign view of blockers; they are in the person's semantic network, and the person might well articulate them in their quest for the correct answer, but they do not actively participate in the process. Whether they are accessed or not has no effect on the probability of retrieving the target.

#### *2.20.1.2.2 Function of feeling-of-knowing and tip-of-the-tongue states*

Little emphasis has been placed on the question of why people have feeling-of-knowing states or tip of the tongues. Perhaps the nagging emotional quality of the tip of the tongues is motivational and keeps people seeking an answer that otherwise they would not try to find. Similarly, Reder and Ritter (1992) have suggested that people's feelings of knowing indicate to them that there is something in memory to be found, and hence these feeling states – especially the fast feelings of knowing – provide information that people use to determine whether they will or will not attempt retrieval. Systematic research on whether and how feelings of knowing and tip of the tongues guide decision making and retrieval is needed.

### 2.20.1.3 Judgments of Learning

Judgments of learning are assessments that people make, either while in the course of learning, or afterwards, about how well they have learned the particular target materials under question. These judgments are thought to be of fundamental importance because the monitoring of study tapped by them is presumably used by a person to determine whether or not to study (e.g., Thiede and Dunlosky, 1999; Son and Metcalfe, 2000). Thus, if the judgments are faulty, so too will be people's subsequent study behavior. It is thought that with biased judgments, ultimately people's learning will be less than optimal.

Judgments of learning can be made in a cumulative manner, whereby the participant is asked to assess the degree of learning over an entire list or session, or they can be made on an item-by-item basis. For instance, when studying a list of 20 paired associates (e.g., dog–spoon), participants may be asked to predict how many out of 20 they will correctly recall when later tested (e.g., dog–?). While studying, they may make item-by-item judgments of learning, where participants are shown either only the cue (e.g., dog–?) or both the cue and response (e.g., dog–spoon) and are asked to predict the likelihood that the correct response (i.e., spoon) will be recalled. Item-by-item judgments of learning can be made either immediately while the person is learning or directly following that learning, or they can be made at a delay. As compared to aggregate judgments, the item-by-item judgments of learning currently have received the most empirical and theoretical attention in the field (for a comparison of the two judgments, see Dunlosky and Hertzog, 2000), so we shall largely restrict our review to them.

Two major findings have held up extremely well over the course of the last decade of research and have become the target of much further investigation. First, delayed, cue-only judgments of learning are highly accurate. The gamma correlations relating people's judgment-of-learning ratings to their later performance are often in the 0.90 range. In contrast, immediate judgments of learning and delayed judgments of learning when the cue and target are also given are often rather inaccurate, and it is not uncommon to see the analogous gamma correlations being around +0.30. The reasons for these differences, which are tightly related to theories of how people make judgments of learning in these different conditions, are outlined below. The second major finding is that whereas first-trial immediate judgments of learning (and aggregated judgments) are often overconfident (i.e., their mean value is higher than the mean performance that people exhibit when they are tested), judgments of learning made on a second study-test trial over the same items are nearly always underconfident. Again, we discuss the explanations researchers have isolated (and those potential reasons that they have discredited) in the theoretical section that follows, titled 'Theories of the delayed-judgment-of-learning effect.'

#### 2.20.1.3.1 Theories of the delayed judgment-of-learning effect

Four theories have been directed at the issue of why accuracy (as measured by resolution or the correlation relating judgments of learning to subsequent performance) is substantially greater for delayed than immediate judgments of learning, which has been dubbed the delayed judgment-of-learning effect (Nelson and Dunlosky, 1991). The first was the monitoring dual memories hypothesis, and the second is the transfer-appropriate processing framework. The third is the self-fulfilling prophecy hypothesis, whereby the judgment itself alters memory, and this alteration is responsible for the boost in accuracy for delayed judgments of learning. The fourth is a stochastic drift model.

***2.20.1.3.1.(i) Monitoring-dual-memories hypothesis*** Nelson and Dunlosky's (1991) monitoring-dual-memories hypothesis assumes that judgments of learning are made by retrieving information from both short-term memory (STM) and long-term memory (LTM). In the immediate-judgment-of-learning condition, STM information is highly accessible, but it is transient and does not reflect what information will be available at final test. The presence of this STM information during the judgment, therefore, adds nondiagnostic information to the judgment, thereby reducing the accuracy of the judgments of learning. In the delayed-judgment-of-learning case, people are thought to base their judgments primarily on the retrieval of information from LTM. This retrieved information is more accurate in predicting final test performance, which is also based on LTM alone. This first explanation has a basic similarity to the second explanation – the transfer-appropriate processing explanation – insofar as both posit that the information that the person bases the judgment on is more similar to the information at time of test for the delayed than immediate judgments of learning.

***2.20.1.3.1.(ii) Transfer-appropriate monitoring hypothesis*** The second explanation – a transfer-appropriate processing view – proposes that the delayed-judgment-of-learning effect occurs because of differences between the two judgment-of-learning conditions in the degree of contextual match from the time of the judgment to the time of the test (Begg et al., 1989; Dunlosky and Nelson, 1997). Making a judgment of learning in a situation that is as similar as possible to that of the test should maximize its accuracy. Insofar as the retrieval attempt, which is thought to be the critical information on which the judgment of learning is based, is more similar between a delayed test and a delayed judgment of learning than between a delayed test and an immediate judgment of learning, the delayed judgments are predicted to be more accurate.

***2.20.1.3.1.(iii) Self-fulfilling prophecy hypothesis*** The third explanation locates the increase in gamma accuracy between immediate and delayed judgments of learning in a differential change in memory with immediate and delayed judgments of learning that comes with making the judgment itself (Spellman and Bjork, 1992; Kimball and Metcalfe, 2003). This third theory has been called a Heisenberg explanation or the self-fulfilling prophecy hypothesis. An assumption here is that people attempt retrieval to make their judgments of learning but, in the delayed-judgment-of-learning condition, are successful with only some of those attempts. The practice elicited by cue-only delayed judgments of learning enhances memory for retrieved items, but only some items are retrieved at the delay. Moreover, the items that receive this memory boost are not distributed randomly across the judgment of learning range, but rather are those given high judgments of learning, because the basis of the judgment is whether or not the person is able to retrieve. Those items that people fail to retrieve are given low judgments of learning and get no boost in study. Thus, the high-judgment-of-learning items benefit from an extra (spaced) study trial, while the low-judgment-of-learning items receive no additional practice and get no memory boost. This differential study has an effect on memory that bolsters the predictive value of the ratings only in the delayed-judgment-of-learning condition. In the immediate-judgment-of-learning condition, virtually all items are recalled during the judgment (e.g., Nelson et al., 2004), which occurs immediately after study and has little memorial effect. In addition, being uniform across the entire judgment-of-learning range, this immediate retrieval does not make the high judgments of learning more memorable or the low judgments of learning less memorable.

***2.20.1.3.1.(iv) Stochastic drift model*** Finally, Sikstrom and Jonsson (2005) propose (in a manner related to the monitoring dual memories hypothesis) that the accuracy difference is because memory strength for any given item can be decomposed into exponential functions with slow and fast components. The drift from these decay processes from time of judgments to time of test is large for immediate judgments of learning, resulting in low predictability, but is smaller for the delayed judgments, resulting in high predictability. This model is most welcome in the field for two reasons: First, because it is a much needed formal model of the processes thought to underlie the judgments and their consequences, and second, because it makes new predictions about outcomes.

***2.20.1.3.1.(v) Status of theories for the delayed-judgment-of-learning effect*** Although considerable empirical work has been conducted to evaluate these theories (either in isolation or in competition), it is currently premature to declare one as a clear winner. Nevertheless, albeit intuitive, the transfer-appropriate monitoring hypothesis has been repeatedly disconfirmed (e.g., see Weaver and Kelemen, 2003; Dunlosky et al., 2005b). Moreover, recent modeling of the delayed-judgment-of-learning effect suggests that both a monitoring-dual-memories component and a Heisenberg-style component may be required to fully account for the effect (Jang et al., 2006).

All four of the theories explain the delayed judgment-of-learning effect by assuming that people make their judgments by using the heuristic of trying to retrieve the target, at least in the delayed case. None of these models take into account the possibility that other cues may be used to make the delayed judgments of learning. However, Son and Metcalfe (2005) have shown that people sometimes make very fast delayed judgments of learning and that these fast judgments of learning are probably not based on retrieval or attempted retrieval of the target. They showed that there were notable differences in the results when people were simply asked to make delayed judgments of learning as compared to when they were asked to attempt to retrieve the target immediately prior to making each judgment of learning (e.g., for detailed application of this method, see Nelson et al., 2004). In particular, the very fast judgments of learning drop out in the latter case, suggesting that normally people are doing something to produce these fast judgments of learning that they are not doing when they explicitly try to retrieve the target. They suggested that people are basing these fast low judgments of learning on a lack of familiarity with the cue, and that when the cue is unfamiliar, people do not bother to try to retrieve the target. In this way, they proposed a two-factor hypothesis in which familiarity and retrieval interact to influence people's judgments of learning.

Benjamin (2005) provided support for a two-factor hypothesis by showing that when people are time pressured, factors that affect cue familiarity come into play in their judgments of learning. When they are not time pressured, factors affecting the retrievability of the target are influential. Note that these are the same two cues that people use in making feeling-of-knowing judgments. With delayed judgments of learning, these cues appear to be used in a specific order. First, people assess the familiarity of the cue. If it is unfamiliar, they give a low judgment of learning. If it is familiar, they go on to the second stage, in which they attempt retrieval of the target. If they cannot do so, they give the item a relatively low judgment of learning; if they can do so, they give it a high judgment of learning. Given the evidence for the second factor in delayed judgments of learning, it appears that none of the four theories can fully account for the judgments. Regardless of its ultimate explanation, however, there is general agreement that delayed judgments of learning may be quite valuable in helping people both accurately monitor and effectively control their learning (Bjork, 1994).

The heuristics used when people make immediate judgments of learning are less straightforward than those used in making delayed judgments of learning. Data indicate that a variety of cues may play a role, such as the fluency of processing words during study (Begg et al., 1989), the fluency of generating study strategies (Hertzog et al., 2003), the relatedness of words within paired associates and across individual words (e.g., Koriat, 1997; Dunlosky and Matvey, 2001; Matvey et al., 2006), and memory for the outcome of previous tests (Finn and Metcalfe, 2007, 2008), among many others (for a review, see Koriat, 1997). Whereas some of these cues, clearly, must have some predictive value – the gamma correlations are nearly always greater than zero – they are typically less diagnostic than the cues used in delayed judgments.

#### *2.20.1.3.2 Theories of the underconfidence-with-practice effect*

The second major finding within the judgment-of-learning literature is that although people's judgments of learning tend to be overconfident on the first trial, by the second trial, there is a shift to underconfidence that persists on subsequent trials. Much research has focused on this underconfidence-with-practice effect, and a number of efforts to explain it, based on exactly how people make judgments of learning, have been proposed (as shown in **Figure 2**, from Koriat et al., 2002). Besides drawing attention to the underconfidence-with-practice effect, Koriat et al. (2002) demonstrated that it persisted despite a variety of experimental manipulations that might otherwise provide explanations of it. For example, feedback about performance on a prior trial had no effect. Both incorrectly and correctly recalled Trial 1 items showed underconfidence on Trial 2. Although this finding suggests that past test performance may not drive the effect, Finn and Metcalfe (2007) have shown that the underconfidence is significantly larger for items that were incorrect on Trial 1 than for items that were correct on Trial 1, qualifying the earlier conclusion that Trial 1 performance was irrelevant.

One possible explanation for the underconfidence-with-practice effect is that people are underconfident because they have insufficient control over their own study to learn because the duration of study for each item is typically under experimental control. In contrast to this possibility, the underconfidence-with-practice effect was found when the study time allowed for each item was fixed or when it was self-paced (Koriat et al., 2002). Perhaps people just do not care and make the judgments without due consideration. However, even with incentives given for making accurate judgments – a manipulation that increases Trial 1 judgment of learning accuracy – the underconfidence-with-practice effect persisted. Thus, mere laziness on the part of participants does not appear to be the answer.

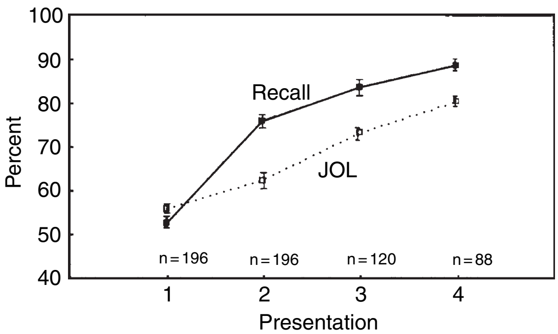

**Figure 2** Illustration of the underconfidence-with-practice effect, with judgments of learning (JOL) showing overconfidence on an initial study trial and underconfidence on subsequent trials. From Koriat A, Sheffer L, and Ma'ayan H (2002) Comparing objective and subjective learning curves: Judgments of learning exhibit increased underconfidence with practice. *J. Exp. Psychol. Gen.* 131(2): 147–162.

Numerous studies have shown that easy materials tend to result in less overconfidence than difficult materials (Lichtenstein and Fischhoff, 1977), so perhaps the underconfidence-with-practice effect is just another manifestation of item effects described in the confidence literature. Although possible, Koriat et al. (2002) reported that both easy and difficult items showed the underconfidence-with-practice effect. And it does not appear to be attributable to the undue effects of retrieval fluency from the first test trials (Serra and Dunlosky, 2005). Their idea was that people might assign low judgments of learning to items that were recalled on Trial 1, slowly or with great difficulty. The data, however, did not support this hypothesis.

One hint about the underconfidence-with-practice effect comes from the finding that immediate judgments of learning show the effect, whereas delayed judgments of learning do not (e.g., Meeter and Nelson, 2003; Koriat and Ma'ayan, 2005; Scheck and Nelson, 2005; Koriat et al., 2006; Finn and Metcalfe, 2007). In fact, early evidence relevant to the underconfidence-with-practice effect involved delayed judgments of learning and did not demonstrate the effect (Dunlosky and Connor, 1997). Meeter and Nelson (2003) showed only a 1% difference between delayed judgments and recall performance on Trial 2. Serra and Dunlosky (2005) showed underconfidence for both delayed and immediate judgments but a much greater shift toward underconfidence across trials for immediate judgments. Koriat et al.'s (2006) data showed overconfidence with delayed judgments of learning, though the difference from calibration was slight. Taken together, these reports suggest that delayed judgments of learning are not underconfident but, rather, are very close to being perfectly calibrated. Immediate judgments of learning, however, are nearly always underconfident after the first study-test trial.

As discussed, one difference between immediate judgments of learning and delayed judgments of learning is that people are very likely to rely on different heuristics in making the two different judgments. In the former case, as described earlier, they rely primarily on retrieval of the target item (with some reliance on familiarity of the cue). In the latter case, though, the heuristics are less clear. Finn and Metcalfe (2007) have proposed that use of the Memory for Past Test heuristic selectively in the immediate judgment of learning case, could account for much of the underconfidence-with-practice effect. The idea is that when people make second-trial judgments of learning they think back to whether they remembered that particular item in the past test. If they did, they give it a high judgment of learning. If they did not, they give it a low judgment of learning. If people were using this heuristic, they would tend to underestimate current trial performance insofar as it ignores the new learning in which the person has just engaged. Thus, they would be underconfident. The relationship between second-trial judgments of learning and Trial 1 performance would be expected to be stronger than the relationship between second-trial judgments of learning and Trial 2 performance, which it is (King et al., 1980). Furthermore, when Trial 1 test was manipulated independently of Trial 2 test, people's judgments of learning gravitated toward their manipulated first trial test performance (Finn and Metcalfe, 2008). And finally, when people were asked to simply report what they did to make the judgment, reliance on first trial test performance was a frequently given reason for the judgment given (Dunlosky and Serra, 2006). Thus, the use of this heuristic appears to be a viable candidate for explanation of the underconfidence-with-practice effect, though there are no doubt other factors that contribute to people's second-trial immediate judgments of learning (e.g., Kelley and Muller, 2006).

#### *2.20.1.3.3 Function of judgments of learning*

It is commonly believed that judgments of learning are of critical importance in learning insofar as they determine what people will choose to study and for how long they will persist (e.g., Nelson and Narens, 1990; Nelson and Dunlosky, 1991; Mazzoni and Cornoldi, 1993; Nelson and Narens, 1994; Benjamin et al., 1998; Koriat, 2000; Metcalfe, 2000). If these judgments of learning are accurate, then people will be in a position to choose to study the items that will result in optimal learning. If they are biased, or inaccurate, however, they will be unable to make such optimal choices.

Although the available evidence suggests that judgments of learning in part drive the allocation of study time, this evidence has been largely correlational, so direct experimental evidence is needed to more definitively establish that when metacognitions are manipulated people's study choice follows. Nevertheless, some demonstrations show that when people with inadequate metacognitions have been induced to make more accurate metacognitive judgments, their learning is improved. For instance, Thiede et al. (2003) had students study paragraphs and make a judgment of learning for each. Before making a judgment for a paragraph, participants were asked to generate five keywords about the paragraph that captured its essence. One group generated keywords (and made judgments) immediately after reading each paragraph, whereas another group did so after all the paragraphs were read. After reading and judging the paragraphs, (1) a test was administered about the content for each of the paragraphs, (2) participants were allowed to select paragraphs for restudy, (3) they restudied chosen texts, and (4) a final test was administered.

Several outcomes are notable. First, judgment-of-learning accuracy for predicting first-test performance was substantially greater for the delayed judgment ($+0.70$) than for the immediate group ($<+0.30$). Second, whereas first-test performance did not differ for the groups (both had a mean value a bit greater than $+0.45$ questions correct), the final test performance was much better for the delayed group (approximately 0.65 correct) than for the immediate group (approximately 0.50). Why such a difference? Fine-grained analyses showed that the delayed group, who had much better judgment accuracy, was more likely to choose paragraphs for restudy that they did not know well, and hence they made the greatest gains in learning during restudy. Without the ability to isolate these less well-known items, students' metacognitive judgments simply did not help them effectively regulate their learning. Thus, preliminary evidence is suggestive that people's metacognitions are used to allocate restudy and, more important, that at least one condition that boosts accuracy can also support more effective learning (for other relevant evidence, see Dunlosky et al., 2005a).

### 2.20.1.4 Source Judgments

Source judgments refer to attributions about the origins of our thoughts and memories (Johnson and Mitchell, 2002; for a review, *See* Chapter 2.19). As such, these judgments are metacognitive, being judgments about other cognitions. Such judgments are targeted when a person is asked who said a particular statement, where they heard something, whether they said something or someone else did, whether they saw the defendant rob the store or only saw him on the sidewalk afterwards, and so on.

Failures of source memory can have profound consequences. One such consequence is unconscious plagiarism. Another is a breakdown in reality monitoring, such as may be seen in psychiatric syndromes such as schizophrenia, in which a person cannot monitor whether the source is internal or external, and in which reality breaks down. Accurate source monitoring is critical for the eyewitness to a crime, but unfortunately, this kind of metacognition can be highly inaccurate.

#### *2.20.1.4.1 Theories of source monitoring*

Johnson and Raye (1981; Johnson, 1983; Johnson et al., 1993) have formulated a model, called MEM (for multiple-entry modular memory system framework), which brings together many of the findings from the source literature in a coherent and elegant form. The consensus view, articulated in the MEM model, of the mechanisms underlying source judgments is that they, like other metacognitive judgments, are based on heuristics. When asked to assess a source, people use what information comes to mind to make the judgments, and this information itself can vary radically depending upon a number of factors. For example, if two potential sources are highly similar to one another, the memory will be highly confusable and the resultant judgment will be more difficult and error prone. If they are quite different from one another, the task is easier. So, if one has to say whether Mary or Lynn said a particular sentence, if Mary is female and Lynn is male, the task is much easier than if both are female (Ferguson et al., 1992). If the two sources are spatially discrete, once again the task is easier than if they are overlapping (Ferguson et al., 1992). Physical differences of this sort have been well documented, are systematic, and conform very nicely to one's intuitions.

Interestingly, though, it is not only the conditions in the world that determine how confusable the sources of different events will be but also the individual's mental capabilities and mental operations that play a part. If a person is readily able to construct vivid images – being able to mentally see a turkey when the word turkey is read – and if he or she automatically encodes concrete nouns as images, then the source distinction of whether a word or a picture was presented will be more difficult than for a different person whose imagery capabilities are less well developed (Johnson et al., 1979). If a person is told to imagine words being spoken in a particular person's voice, which is similar to the speaker's, as opposed to imaging in a voice less similar, the source judgments will be affected (Johnson et al., 1979). The vividness of a person's imagination, then, can have a dramatic effect on whether things that actually happened are confused with those that were only imagined.

Since Johnson's seminal research in the field, the literature has grown extensively, with research involving everything from basic cognitive theory to the neurological underpinnings of source memory. Certainly, this literature is too broad to cover here (for a review, see Johnson et al., 1993; Mitchell and Johnson, 2000; Johnson and Mitchell, 2002), but in contrast to many other coverages of metamemory, we wanted to draw some attention here to this very important, and pervasive monitoring skill.

### 2.20.1.5 Remember/Know Judgments

People can distinguish between events or items that they remember (i.e., for which they have a clear and distinct recollection not only for the target material itself but also for the circumstances of having learned it) versus those that they only know. For example, one might remember one's first iPod, including the circumstances under which one obtained it, and so on, but only have a feeling that they know they saw such-and-such a person some time ago without being able to recall the specific episode. In typical experiments, participants will study a list of words (e.g., pencil, table, football, etc.). After study, the words are presented again mixed with new words, and participants are asked whether each item was originally presented (i.e., a standard recognition judgment), and then whether they recollect that it was presented or merely know that it was presented. In this example, you may state that you recognize that both pencil and football had been presented, but when asked for a remember/know judgment, you may recollect seeing football because you recollected that when it was originally presented you thought of your favorite football team (e.g., the Denver Broncos), whereas you have no recollections about pencil but just have a diffuse feeling, knowing that it was presented.

Being able to tell the difference between remembering and knowing, that is, the ability to make this particular judgment about a memory, is a category of metacognition that is thought to have significance for our understanding of human consciousness (for a general review on remember-know judgments, *See* Chapter 2.17). Events that are recollected are thought to be true memories and to exemplify a special form of memory and consciousness called autonoetic consciousness (Tulving, 2005) or explicit memory (Graf and Schacter, 1985). Facts that are judged to be only known are thought to require only semantic knowledge or mere familiarity and are thought to require only primed noetic consciousness or implicit memory.

There have been many debates over the past decade about this distinction. People question whether it means that there are different systems of memory, or whether it might be due only to differences in the amount of information stored (e.g., with better-stored memories being judged as remembered and less well-stored memories being judged as merely known). One larger issue here is to whether the phenomenology of recollecting actually contributes to one's recognizing something as being previously studied versus whether this phenomenology is merely epiphenomenal; you have the experience of recollecting (e.g., that you recalled Denver Broncos when football had been presented), but this experience does not contribute to your ability to correctly recognize an item as previously studied. Advocates of dual-process models of recognition – which indicate that both familiarity and recollection influence recognition decisions – state that recollection has a causal influence on our recognition performance, whereas strength theorists claim that a single underlying memory dimension (e.g., familiarity alone) can adequately explain recognition. For the latter group, recollections merely arise from having strong memories, but the phenomenology itself is not important for understanding recognition *per se* (for competing views, see Yonelinas, 1994; Rottello et al., 2005).

Paradigms involving this distinction purportedly allow us to ascertain whether people are consciously aware of the memories. This particular metacognitive judgment, then, is one that has been extensively researched and debated. A detailed discussion of the remember/know literature is given in a separate chapter of this handbook, and so we do not elaborate further on it here. We include this section only to note that this particular judgment, like all of those outlined above, is a kind of metacognition because it involves an attribution about a memory, though one that may have considerable consequence for understanding human memory and consciousness.

## 2.20.2 Conclusion

Much progress has been made in understanding the mechanisms that underlie the judgments that people can make about their memories. There is considerable agreement that metacognitive judgments are heuristically based. People seem to rely on the information that they have at hand, and usually on a fairly shallow assessment of that information, to make these judgments. Because these judgments are heuristically based, systematic biases are observed. Under some circumstances, people will be underconfident or overconfident; in other situations, they can be misled. However, insofar as research is untangling those systematic biases and the reasons for them, we are increasingly in a position to help students improve their metacognitions, and hence base their learning on a firmer foundation.

# 2.21 Déjà Vu

**A. S. Brown**, Southern Methodist University, Dallas, TX, USA

The déjà vu phenomenon is one of the most intriguing illusions of memory. We automatically monitor the familiarity of experiences and surroundings. Nearly always, our subjective sense of familiarity corresponds to objective reality, but on rare occasions these clash, giving rise to a feeling of familiarity in the absence of objective evidence.

> We are in a strange place, perhaps on holiday for the first time at a hotel. Suddenly, without warning, a certain feeling of familiarity seems to create itself. At once we seem to know the whole scene, windows, doors, pictures, and view from the windows. We recognize the person with whom we are speaking, although . . . we have never seen him to this minute. We even recognize the words he is saying, though it is impossible to know what he is going to say. We have the feeling of having been through everything before! Then, in a flash, the illusion vanishes. (Humphrey, 1923: 137)

The standard definition for déjà vu, presented by Neppe (1983b: 3), is "any subjectively inappropriate impression of familiarity of a present experience with an undefined past" and a more recent reformulation that incorporates cognitive terminology is "an objective assessment of unfamiliarity juxtaposed with a subjective evaluation of familiarity" (Brown, 2003: 2).

## 2.21.1 Challenges of Déjà Vu Research

The literature on déjà vu extends back over 150 years, and interest in the phenomenon encompasses a wide range of disciplines from medicine to philosophy to psychology (Brown, 2004). Despite this plethora of attention, the phenomenon of déjà vu has struggled to make a solid connection with empirical research in psychology. Although some twentieth-century researchers studied memory errors (e.g., Bartlett, 1932), most followed the lead of Ebbinghaus (1885), where memory errors were ignored or controlled rather than examined as worthy phenomena in their own right (cf. Roediger, 1996). There has been a change over the past few decades, and cognitive scientists have begun to explore the relationship of the déjà vu experience to phenomena such as repetition priming (Schacter, 1996), source attribution (Hoffman, 1997), perceptual fluency (Jacoby and Whitehouse, 1989; Bernstein and Welch, 1991; Joordens and

Merikle, 1992; Roediger, 1996), and subliminal mere exposure (Seamon et al., 1983).

What makes research on déjà vu problematic is the lack of any clearly identifiable eliciting stimulus and objective behaviors. Not only have the causes been elusive; an objective observer may find it impossible to determine whether someone is experiencing déjà vu. Other cognitive phenomena, such as the tip-of-the-tongue experience (Brown, 1991; also *see* Chapter 2.22), have a clear stimulus (John Kerry's vice presidential running mate in 2000) and behavioral resolution (John Edwards). However, reports of déjà vu experiences rely on one's sensitivity to, and awareness of, their own cognitive functioning.

## 2.21.2 Defining Déjà Vu

Through the mid-1900s, researchers used over 30 different words and phrases to describe déjà vu (see Brown, 2004), including such colorful expressions as paramnesia (Burnham, 1889), diplopia (Taylor, 1931), perplexity psychosis (MacCurdy, 1925), promnesia (Myers, 1895), and prescience (Crichton-Browne, 1895). This diversity of terms reflects several things about the experience. First, it is inexplicable and difficult to construct a word or short phrase to appropriately label it. Second, developing a reasonable definition of the subjective experience has been problematic. Brown (2004) assembled over 50 different definitions that reflect this hegemony. Third, there is a lack of consensus among researchers and writers on the cause: Is it a physiological, memory, or perceptual problem? This diversity hampered early research, and settling on the common French language term was accompanied by considerable struggle and debate (Marková and Berrios, 2000).

## 2.21.3 Methods of Investigating Déjà Vu

The primary method for studying déjà vu has been retrospective questionnaire, usually involving either a brief inquiry about the incidence of déjà vu or a more extensive assessment of multiple dimensions of the déjà vu experience (setting, duration, etc.). The most significant problem with retrospective surveys of déjà vu stems from the rarity of the experience (Adachi et al., 2003). Given that most people who do have déjà vu only experience it one to two times per year, it poses a serious challenge to remember the details of an experience that probably happened many months ago, and in ordinary circumstances that may not be very memorable. Thus, survey data provide a conservative estimate, at best, of the actual frequency of déjà vu. Biases also exist in the sampling of respondents (cf. Brown, 2004), with many surveys based on a selection of individuals that are conveniently available (college students for research professors; hospital patients for research physicians).

### 2.21.3.1 Unfortunate Association with the Paranormal and Abnormal

A serious problem with déjà vu assessments is that about one-third of surveys imbed their déjà vu item among items inquiring about paranormal (extrasensory perception, haunting, poltergeist, unidentified flying object) phenomena (cf. Brown, 2004). Other questionnaires imply a relationship between déjà vu and dimensions of psychopathology such as agoraphobia, depersonalization, and derealization (Buck and Geers, 1967; Harper, 1969; Harper and Roth, 1962; Brauer et al., 1970; Buck, 1970; Myers and Grant, 1972). Thus, respondents are given the message that déjà vu is inherently abnormal, which may reduce the willingness of individuals to admit to having such experiences.

### 2.21.3.2 Prospective Surveys

A prospective survey can solve the memory problem inherent in retrospective surveys. However, only Heymans (1904, 1906; translated by Sno and Draaisma, 1993) has employed such a technique, and the lack of methodological clarity coupled with the disparity of incidence estimates in two separate samples (14% vs. 62%; see Brown, 2004) make these data difficult to interpret. One other published prospective report is a case study. Leeds (1944) experienced an extraordinarily high rate of déjà vu (once every 2–3 days), which motivated him to keep a remarkably detailed record of 144 of his own déjà vu experiences, including date, time, intensity, duration, physical setting, and his behaviors, as well as his psychological and physical state at the time. He discovered that the intensity and duration of the experiences were directly related, that longer inter-episode intervals resulted in more intense and longer experiences. Leeds further observed that déjà vu experiences come in clusters and occasionally occur in dreams. His record is fascinating in its remarkable detail, although these experiences may reflect pathological rather than normal déjà vu.

## 2.21.4 Incidence of Déjà Vu

Based on numerous surveys, déjà vu may not be a universal experience. Given this, it is important to separately examine two different dimensions – the incidence of the illusion and how often it occurs among those who have ever experienced it (experients). Across 57 outcomes from 42 published studies, Brown (2004) found that déjà vu is experienced by about two-thirds of those surveyed. The incidence varies considerably across surveys – ranging from 10–100% – and several factors account for this extreme variability. The item context within which the query is placed probably has a substantial impact. As noted earlier, when the déjà vu item accompanies items on paranormal phenomena, this most likely suppresses the reported incidence. The cultural acceptability and understanding of the experience has increased across time (cf. Brown, 2004), so more recent surveys tend to show a higher incidence. Finally, the age of the sample influences the incidence, and samples of older participants tend to show a lower incidence (cf. Brown, 2003).

How often does déjà vu occur among experients? Surveys suggest that it is not a singular event, with the vast majority of experients having more than one lifetime déjà vu (Palmer 1979; Kohr, 1980). About half of experients have had seven or more occurrences in their lifetime (Kohr, 1980). Using a Likert scale, around half of respondents rate déjà vu occurrences as 'seldom' (Leeds, 1944; NORC, 1984, 1988, 1989; McCready and Greeley, 1976), with a relatively small percentage (between 9% and 18%) rating it as 'frequent.' Data derived from more recent surveys indicate that déjà vu appears to occur at least once a month for most experients (Ardilla et al., 1993; Brown et al., 1994; Roberts et al., 1990).

## 2.21.5 Nature of the Déjà Vu Experience

### 2.21.5.1 What Triggers Déjà Vu?

Brown et al. (1994) discovered that the most important element in eliciting déjà vu is the general physical setting, with over half (54%) of experients claiming that this was always the cause (see Neppe, 1983b). Spoken words, actions, and objects are also noted as contributing to the déjà vu experience, although to a far lesser extent. Stress is mentioned in many anecdotal reports as a causative factor in déjà vu (see Brown, 2004), although Brown et al. (1994) found that only a small fraction of open-ended survey responses (about 20%) contained any such reference. The vast majority (three-quarters) of déjà vu experiences occur indoors, about evenly distributed between private and public buildings. Furthermore, about half of déjà vu experiences occur when one is engaged in recreational activities. Déjà vu rarely happens when one is alone and most typically occurs while in the company of one other person (usually a friend).

The déjà vu experience is relatively brief, with about half of survey respondents reporting that it lasts less than 5 s. Déjà vu is more likely to occur during the afternoon or evening (Heymans, 1904; Leeds, 1944) and late in the week (Thursday through Saturday) (Brown, 2004), and the sense of time seems to be momentarily slowed for many experients. It is difficult to precisely identify the emotional reaction accompanying déjà vu. Some characterize this as an essential part of the experience, but the most predominant reactions appear to have more of cognitive than emotional flavor (Brown, 2004), with those surveyed most often describing it as eerie, surprising, odd, confusing, exciting, and curious.

## 2.21.6 Physical and Psychological Variables Related to Déjà Vu

The most consistent finding in the déjà vu literature is that the incidence systematically decreases with age from the 20s through the 80s (Brown, 2003, 2004), although teenagers tend to experience déjà vu less often than those in their 20s. Data on changes across broad age ranges are found in two studies with hospital patients (Chapman and Mensh, 1951; Richardson and Winokur, 1968). A larger sample with a more representative cross section of individuals was conducted by the National Opinion Research Center (NORC) in their General Social Surveys conducted in 1984, 1988, and 1989. The data from these sources are summarized in **Figure 1**, and all three sources confirm the systematic decline in the incidence of déjà vu with age. In addition, significant negative correlations have been found between age and déjà vu experience, ranging from −.22 to −.38 (Chapman and Mensh, 1951; Kohr, 1980; NORC, 1984, 1988, 1989; Sno et al., 1994; Adachi et al., 2003). Given that older adults used to be young, the lifetime incidence of déjà vu should either remain steady or increase, rather than drop. However, this logically impossible age change is probably due to an increase

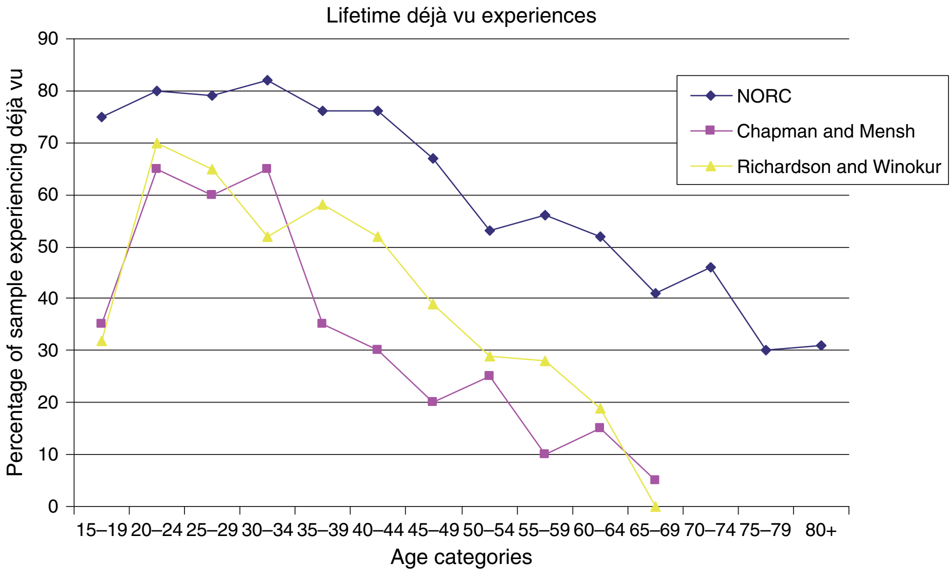

**Figure 1** Percent of respondents experiencing déjà vu across age groups (from three surveys).

in the cultural awareness and acceptability of the experience across the past four or five decades (Brown, 2004).

Among experients, the incidence of déjà vu drops off dramatically across the adult age span (Chapman and Mensh, 1951; Richardson and Winokur, 1968), as reflected in **Figure 2**. Why do older experients report fewer incidents of déjà vu? Perhaps they are less in touch with the subtle qualities of their own cognitive experiences (Brown et al., 1995), are more settled in their physical routine and less likely to encounter new experiences to trigger déjà vu, or have a greater acceptance of incongruent memory experiences (Adachi et al., 2003). There has been no extensive survey on the minimum age at which déjà vu first occurs, although Neppe (1983b) discovered that some adults claim to have had their first déjà vu sometime in the teens or 20s. Fukuda (2002) found a

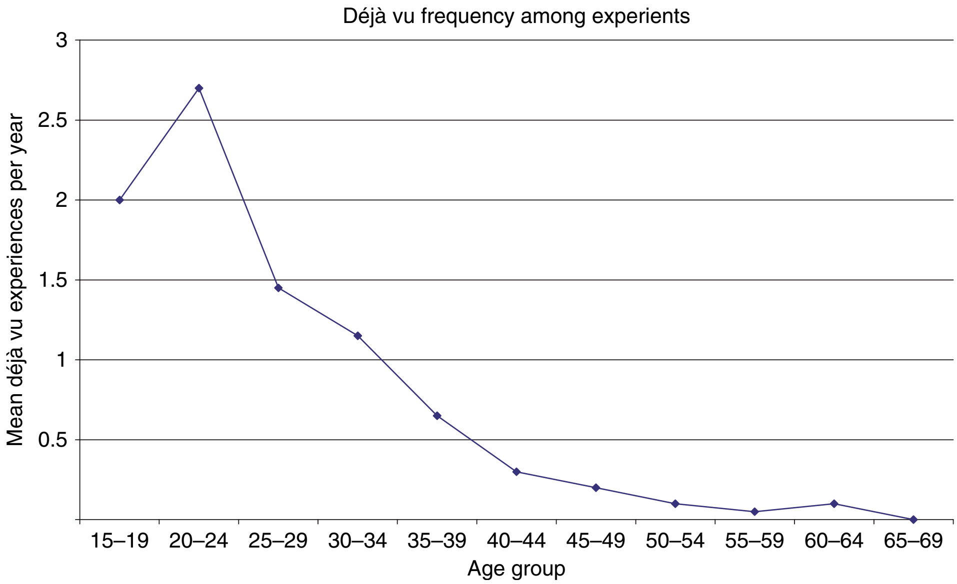

**Figure 2** Yearly frequency of déjà vu across age groups among those who have the experience.

somewhat earlier estimate in a retrospective survey of college students, with most claiming a first experience between ages 6 and 10 (49%) or between ages 11 and 15 (33%).

There is a positive relationship between déjà vu incidence and education (Chapman and Mensh, 1951; Richardson and Winokur, 1967, 1968; Harper, 1969; Palmer, 1979; Kohr, 1980; Neppe, 1983b; NORC, 1984, 1988, 1989; Gallup and Newport, 1991; Adachi et al., 2003) and between déjà vu and travel frequency (Brown, 2004). Déjà vu incidence appears to be directly related to socioeconomic status (SES) (Crichton-Browne, 1895; Chapman and Mensh, 1951; Richardson and Winokur, 1967, 1968; Harper, 1969; Palmer, 1979; Gallup and Newport, 1991). Because socioeconomic status and academic achievement are closely intertwined, Brown (2004) attempted to extricate the separate contributions of each variable by comparing low versus high SES within each of four education levels within the NORC survey database. Déjà vu incidence was higher for low than for high SES within each education level, although the incidence systematically increased with each level of education. Thus, SES and education level are associated with déjà vu experience in opposite ways: Déjà vu is inversely related to SES but directly related to education level. Travel also appears to be associated with déjà vu. Those who do any travel are more likely to report déjà vu than those who don't, with little difference across various numbers of trips (Brown, 2004). Déjà vu incidence is unrelated to gender, race (black vs. white), religious preferences, or political affiliation (Brown, 2003, 2004), although there is a clear tendency for déjà vu incidence to be higher among those with a liberal versus conservative orientation.

There is some evidence that various prescription and nonprescription drugs have the potential to either trigger (amphetamines, Ellinwood, 1968; carbamazepine and clonazepam, Garbutt and Gillette, 1988; toluene, Takaoka et al., 2001; amantadine hydrochloride and phenylpropanolamine hydrochloride, Taiminen and Jääskeläinen, 2001) or reduce (clonazepam, Ide et al., 2000) déjà vu experiences, but this is based on selective data from case reports. There appears to be a tendency for déjà vu to be elevated in alcoholics (Turner, 1910), and NORC data reveal a positive association between alcohol consumption and déjà vu, with those who drink experiencing it more frequently than those who don't.

## 2.21.7 Physiopathology and Déjà Vu

Some of the early explorations of déjà vu were motivated by an apparent association between temporal lobe epilepsy (TLE) and déjà vu (Quaerens, 1870; Jackson, 1888; Maudsley, 1889; Crichton-Browne, 1895). A small percentage of TLEs experience déjà vu in the aura that immediately precedes their seizure, and one physician documented his personal experiences in a published report, claiming that his first epileptic attack was preceded by a series of increasingly frequent and intense déjà vu experiences (Quaerens, 1870). This issue has been debated for many decades, but most evidence suggests that déjà vu is not symptom or cause specific to epilepsy (Richardson and Winocur, 1967; Harper, 1969). However, research conducted on TLEs has contributed to our understanding of the experience. An examination of cortical activity in TLEs with both electrical stimulation and recording procedures (Mullan and Penfield, 1959; Cole and Zangwill, 1963; Penfield and Perot, 1963; Penfield and Mathieson, 1974; Gupta et al., 1983; Cutting and Silzer, 1990; Gloor, 1991; Palmini and Gloor, 1992; Fish et al., 1993; Weinand et al., 1994; Sengoku et al., 1997; Adachi et al., 1999) suggests that déjà vu is associated with activity in the right temporal lobe, specifically involving the hippocampus and areas immediately surrounding it (e.g., amygdala, parahippocampal gyrus, temporal isocortex) (although see Brown, 2004, for cautions in interpreting these data).

Some evidence suggests that déjà vu may be more common in those who have suffered head trauma, especially accompanied by amnesia (Weinstein et al., 1962) or disturbance/loss of consciousness (Harper, 1969; Weinstein, 1969). It has been suggested that déjà vu is associated with various moderate to severe psychological disturbances (Calkins, 1916; Pickford, 1944) such as schizophrenia (Neppe, 1983b; Sno et al., 1992; Sno, 2000), but there has been no definitive verification that déjà vu is associated with any form of psychopathology (Brown, 2004). There is, however, modest evidence that déjà vu may be associated with depersonalization and derealization (Roth, 1959; Buck and Geers, 1967; Harper, 1969; Myers and Grant, 1972), but others have failed to find support for such an association (Brauer et al., 1970; Dixon, 1971; Adachi et al., 2003). Some have argued that déjà vu should be included in the *Diagnostic and Statistical Manual* (DSM) of the American Psychiatric Association as a form of psychopathology (Sno and Linszen, 1990; Sno et al., 1992), although this change has not garnered broad support (cf. Pagliaro, 1991).

## 2.21.8 Interpretations of Déjà Vu

Researchers have proposed over 40 different explanations for déjà vu (Brown, 2004), and Neppe (1983a: 33) cogently suggests that " . . . one single explanation for déjà vu is probably as untrue as one single cause for headache." Belief in the existence of parapsychological phenomena (mental telepathy, precognition, reincarnation) may have roots in déjà vu (Stern, 1938; Carmichael, 1957), given that it is a common experience that can easily feel supernatural. There has also been a considerable amount of published speculation about the psychodynamic underpinnings of déjà vu, suggesting that an individual attempts to subconsciously reduce situational anxiety by labeling it as 'familiar' (see Arlow, 1959). These two classes of interpretations will not be covered in this chapter, but the interested reader is directed to summaries found in Brown (2004).

## 2.21.9 Dual-Processing Explanations

Four different categories of scientifically oriented explanations of déjà vu are described in Brown (2004). Of these, the dual-processing explanations are perhaps more philosophical than scientific, yet draw on established cognitive phenomena. Each variety of explanation in this category assumes that two routine cognitive processes are momentarily out of normal synchrony with each other. For instance, retrieval and familiarity usually work jointly and in close coordination – when one recalls information it is accompanied by an assessment of familiarity. However, if familiarity assessment becomes activated spuriously and independently of recall, a situation may be incorrectly assessed as previously experienced when it was not (Claparède, 1951; Gloor, 1991). Similarly, if encoding and retrieval, which normally operate separately, are activated simultaneously, this could result in a misimpression that the present (new) experience has been retrieved from memory (de Nayer, 1979). Along similar lines, déjà vu has been interpreted as involving the merging of perception and encoding processes (Carrington, 1931), perception and retrieval (Ellis, 1911), implicit and explicit information processing (Wigan, 1844; Myers, 1895), and different states of conscious awareness (Jackson, 1888). Although all of these are logically engaging and theoretically possible, they do not readily lend themselves to empirical evaluation. In the following sections are three categories of déjà vu explanations that provide a more solid scientific foundation on which to evaluate the possible cause(s) of déjà vu.

## 2.21.10 Neurological Explanations

Déjà vu may result from a minimal biological dysfunction involving cortical information processing. This interpretation has its roots in the observation that some TLEs experience déjà vu prior to their seizure (see earlier section titled 'Physiopathology and déjà vu'). If a minor neurological misfiring, or small seizure, occurs in individuals without brain pathology, then this could possibly trigger déjà vu (Halgren et al., 1978; Bancaud et al., 1994). Elaborating on this concept, Spatt (2002) speculated that spontaneous activity in the parahippocampal area of the cerebral cortex, a region routinely involved in encoding and retrieval activities, could create a brief sense of inordinate familiarity that is disconnected from one's present objective experience.

A second variety of neurological explanation assumes that a brief and minimal change in the speed of neural transmission could create an illusion of 'pastness.' Our nervous system transmits the perceptual information we receive in a highly reliable and consistent fashion. Imagine, however, that this tightly formatted neural transmission is momentarily altered by an aberrant event – say, a deficiency or excess of a neurotransmitter at a particular synaptic juncture. This retarding (Grasset, 1904) or acceleration (Allin, 1896) of the message may be misinterpreted as inordinate familiarity (cf. Jacoby, 1988; Jacoby et al., 1988) with an objectively new experience (Burnham, 1889; Ellis, 1911; Schacter, 2001).

Extending this speculation, if two perceptual pathways are involved, any temporal disparity would be even more pronounced. It has been demonstrated that perceptual information is transmitted to cortical processing centers via multiple pathways (Schneider, 1969; Goodale and Milner, 1992; Milner and Goodale, 1995). Imagine that a slight interruption occurs to one of these two messages, but not the other. An additional separation of only a few extra milliseconds between the duplicate messages may create a perceptual echo sufficient to flummox the interpretive centers of the cortex and lead to a misimpression that the second (delayed) perceptual event duplicates the first (leading) message. This possibility was proposed over a century ago and has been elaborated on and extended by many others since (Wigan, 1844; Osborn, 1884; Maudsley, 1889; Myers, 1895; Humphrey, 1923; Efron, 1963; Weinand et al., 1994). Some of the early versions of this dual-message interpretation were grounded in a communication problem between hemispheres and disparities regarding the timing of this information exchange (Wigan, 1844; Myers, 1895; Humphrey, 1923).

A frequently reported feature accompanying personal reports of déjà vu is a sense of precognition (cf. Brown, 2004), with an individual believing that they know exactly what is going to happen moments before it does. On the surface, this appears to challenge any scientific explanation of déjà vu. However, a neurological interpretation involving dual pathways may help explicate this unusual subjective experience. When an inordinate separation occurs between two neural messages, the brain could theoretically focus primarily on either the leading or the trailing version. If the trailing perception is central, then a sense of déjà vu results because the first message already arrived. In contrast, if the brain invests in the leading message, then a sense of precognition could result because the individual can literally foresee what will happen moments later via this brief preview (Efron, 1963; Kohn, 1983).

## 2.21.11 Implicit Memory Explanations

A déjà vu experience may result from an implicit memory for one or more aspects of the present situation (Schacter, 1987; Richardson-Klavehn and Bjork, 1988; Roediger and McDermott, 1993). When the present setting cues an implicit memory that is missing an associated episodic component, one could experience a sense of familiarity that is missing the recollective dimension. The simplest form of this interpretation is that our entire present experience duplicates something encountered earlier (Chapman and Mensh, 1951). Abercrombie (1836) and Osborn (1884) present case reports of déjà vu experiences in adulthood that were later traced to actual childhood events. Abercrombie (1836) described a woman who had a déjà vu experience when escorted to the room where her mother had died. She had no conscious recollection of having been there before, but found out later that as an infant she had been taken to visit her dying mother there. Osborn (1884) discussed a similar incident, where a man experienced a déjà vu at a castle entrance, only to find out later that he had visited that very location with his parents when he was one and a half years old.

Literary works also have the capacity to implant in memory detailed descriptions of scenes or settings that subsequently provide a striking fit to real experience (Hawthorne, 1863; Knight, 1895). Media exposure (television, movies, magazines) also has the potential to paint vivid mental images that can connect to subsequent real experiences, without a recollection of the source. Ellis (1897, 1911) described a déjà vu in a particular setting that he later traced back to a stereoscope picture that he had seen of that exact location. The Internet now provides a particularly rich set of images of real locations. In fact, a television ad by Hotels.com humorously highlights this possibility: A man walks into a room and breathlessly exclaims, 'I've been here before,' to which his partner replies that he saw it in a Web video preview prior to reserving the room online.

Rather than duplicating the entire previous experience, Osborn (1884) speculated that déjà vu may result if the manner in which the information is processed duplicates the way that a previous experience was processed (Kolers, 1973; Morris et al., 1977; Kolers and Roediger, 1984). Although more difficult to test, this processing duplication could allow a much broader generalization of familiarity from one setting to another. Also, the duplication could involve the general perceptual form of some visual or auditory event from our past (Grasset, 1904; Reed, 1974). This gestalt familiarity interpretation is deftly illustrated by Dashiell (1937) in his textbook on psychology (see **Figure 3**). He suggested that if an individual encounters setting A that is new, this may evoke a déjà vu due to its resemblance to the general form of setting B that is familiar. None of the individual elements are identical across settings, but the overall form of the new street scene strongly resembles the familiar scene – large building close on the right side of the street, a church with steeple down the left side of the street, and so forth.

Rather than duplicating the entire prior experience or its general form, perhaps one element in the present experience is old but not identified as such. This element elicits a strong familiarity response that we fail to attach to it, and so we

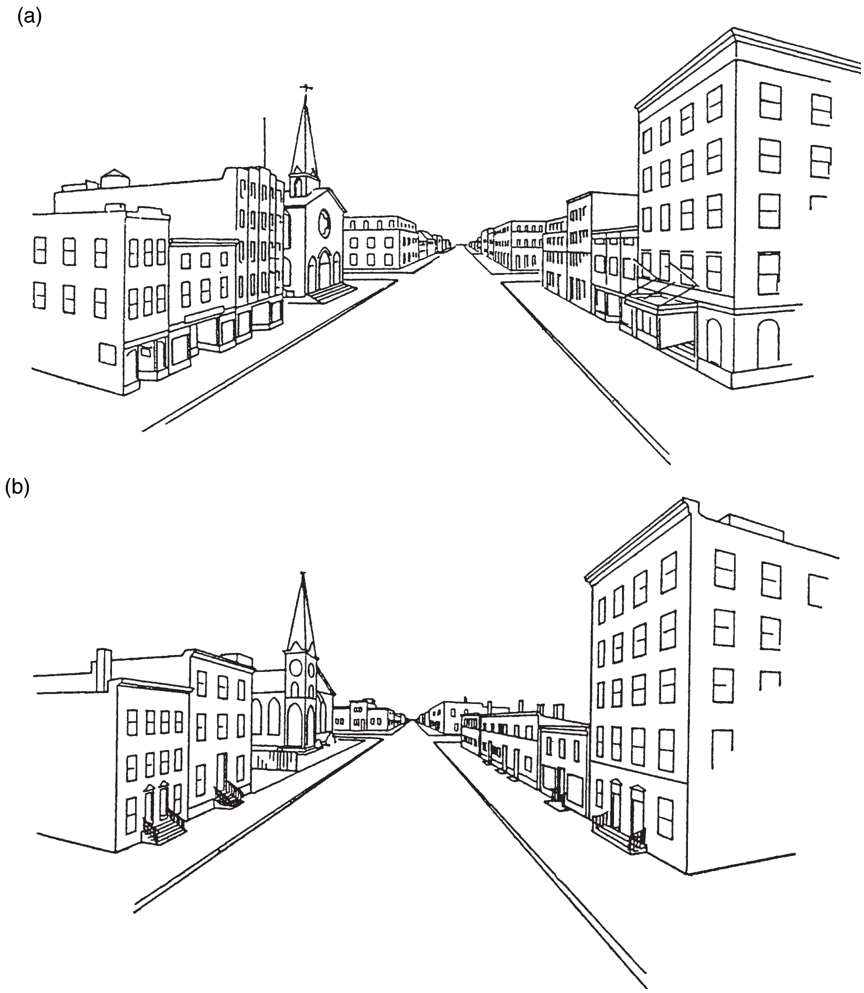

**Figure 3** Illustration of gestalt familiarity explanation of déjà vu (from Dashiell, 1937).

misattribute the sense of familiarity to the entire setting:

> Suppose . . . that after I have visited the picture gallery I go to the next city where there is another gallery. Perhaps in some corner of a room there is some insignificant detail, such as a gilded cornice, that is the same as in the last gallery. This will be seen and recognized, but the feeling of recognition, instead of being confined to the one detail, may be spread over the whole room. (Humphrey, 1923: 140)

The familiar element may not be from objective experience but implanted via imagination or fantasy. MacCurdy (1925) described a déjà vu that he traced to memory fragments from a previous dream. This could also happen with daydreams (Chapman and Mensh, 1951), and Titchener (1928) asserted that our imaginings may leave an even stronger memory trace than real experiences. Sully (1887) also suggested that exquisite prose descriptions may paint a vivid mental picture of a single element – face, object, building façade – and this may have the power to elicit a later déjà vu when a real object resembles it. Multiple familiar elements in combination may have the same effect (Wohlgemuth, 1924; Fleminger, 1991; Findler, 1998; Lampinen, 2002) and may actually increase the probability of déjà vu by summating familiarity while simultaneously interfering with the retrieval of contextual elements necessary for explicit recall (Hintzman, 1988).

Whereas the aforementioned speculation revolves around familiarity associated with unrecognized and embedded stimulus element(s), déjà vu could also result from an affective response (positive or negative) misinterpreted as familiarity (Baldwin, 1889; Allin 1896; Zeidenberg, 1973; Fleminger, 1991; Pagliaro, 1991). Perhaps the strange visceral reaction associated with déjà vu in personal descriptions is not a result, but rather a cause, of the experience (Angell, 1908; Reed, 1974). Seamon et al. (1983) specifically proposed that the type of positive affective response (liking) that is enhanced by mere exposure may underlie déjà vu, and that this may be especially likely with a subliminal exposure which precludes explicit recollection:

> The experience of déjà vu . . . is an expression of the familiarity of a similar stimulus without the retrieval of that earlier event or its context into conscious awareness . . . . Essentially, the same outcome was observed in this study: people liked familiar stimuli without recognizing the basis for their familiarity. In this respect, the finding of target selection by affect in the absence of recognition is similar to the well-known, but poorly understood, phenomenon. (Seamon et al., 1983: 188)

Brown and Marsh (2005) have experimentally evaluated the implicit memory interpretation of déjà vu. They had students superficially process briefly presented scenes of an unfamiliar college campus, and then presented both old and new scenes in a second session (1 or 3 weeks later). In order to model déjà vu, they asked students whether they had actually visited each pictured scene, not just whether it looked familiar. Brown and Marsh (2005) found that the previous presentation of a scene significantly increased mean visit ratings, thus demonstrating that a prior laboratory encounter with a stimulus has the capacity to influence the likelihood of a reaction similar to déjà vu in autobiographical memory.

Hypnosis may also hold promise in modeling déjà vu in the laboratory. Marcuse et al. (1945) reported that a sense of déjà vu accompanies some recollections of stimuli encountered previously under hypnosis. Banister and Zangwill (1941a,b) explored this technique more directly by presenting pictures and odors to hypnotized participants followed by a suggestion to forget. Later, participants were asked to evaluate these same stimuli during full consciousness awareness. Although they were able to elicit a sense of déjà vu in some individuals, they were only moderately successful. O'Connor et al. (2006) have recently applied a similar procedure. Hypnotized participants were told that they would later experience a sense of specific (episodic) familiarity for words with green borders and a sense of unspecified (déjà vu) familiarity for words with red borders. This technique precipitated a déjà-vu-like experience in some participants (5 of 18), although others interpreted the sensation as a tip-of-the-tongue experience (*See* Chapter 2.22). O'Connor et al. noted substantial individual differences in susceptibility to déjà vu, and this should be examined more carefully in future research.

## 2.21.12 Double Perception Explanations

The double perception interpretation of déjà vu rests on the possibility that when an ongoing stream of perception is momentarily dissected or disrupted, this creates the impression of duplicate events:

> . . . you are about to cross a crowded street, and you take a hasty glance in both directions to make sure of a safe passage. Now your eye is caught . . . by the contents of a shop window; and you pause . . . to survey the window before you actually cross the street . . . the preliminary glance up and down, that ordinarily connects with the crossing in a single attentive experience, is disjointed from the crossing; the look at the window, casual as it was, has been able to disrupt the associative tendencies. As you cross, then, you think 'Why, I crossed this street just now'; your nervous system has severed two phases of a single experience, both of which are familiar, and the latter of which appears accordingly as a repetition of the earlier. (Titchener, 1928: 187–188)

Similar speculation is more than a century old (Burnham, 1889; Grasset, 1904) and numerous versions of this explanation have been put forth. One variety proposes that the perceptual experiences both preceding and following the gap are at full awareness, with the ongoing stream of perception being fractured by distraction from either the environment (Conklin, 1935; Leeds, 1944; Tiffin et al., 1946) or our mental activities (Lalande, 1893; Allin, 1896). Allin (1896) suggested that this attentional break between the perception and the reperception moments later is made especially compelling because the reprocessing is faster due to enhanced perceptual fluency (Jacoby and Dallas, 1981).

A second version of the double perception explanation involves a diminished first perception (glance) followed by a second perception at full awareness. The initial perception may be subpar because one's attention is momentarily degraded (1) due to fatigue or distraction (Allin, 1896; Dugas, 1902; West, 1948), (2) because a particular feature is first perceived peripherally and then focally, or (3) from inhibition by other elements in the perceptual array (Dixon, 1971). This diminished-to-full version of the double perception interpretation is lent credibility by several lines of cognitive research. Jacoby and Whitehouse (1989) conducted an investigation inspired by Titchener's (1928) description (see preceding quote). After studying a word list, participants took a recognition test where each word was preceded by a briefly flashed (subliminal) stimulus consisting of the word itself (match), an unrelated word (nonmatch), or a series of symbols (control). Jacoby and Whitehouse (1989) discovered that a new word preceded by itself (match) is more likely to be incorrectly evaluated as old, compared to a new word preceded by a nonmatch or control stimulus. They likened this outcome to déjà vu, and their findings have been replicated by Joordens and Merikle (1992) as well as by Bernstein and Welch (1991), who further suggested that the prime presentation does not have to be subthreshold to elicit this illusion of familiarity.

A second line of research lending credibility to this interpretation is inattentional blindness. Mack and Rock (1998) demonstrated that when searching for a target (+) in a visual display, if a distractor object is inserted along with the target cross after a number of simple trials, most participants will fail to report noticing it, even though the display is well above threshold. Interestingly, this obliviscence is greater when the distracting stimulus appears in the center of the display with the target off to one side. Participants who claim not to have noticed the distracting stimulus show evidence that it was perceived and stored in memory because priming for that distractor stimulus is enhanced on a subsequent indirect test of memory. This processing of unnoticed visual stimuli has also been found in research on cell phone use when driving (Strayer and Johnson, 2001; Strayer et al., 2003).

## 2.21.13 Summary and Future Directions

Déjà vu is a recognition illusion experienced by about two-thirds of individuals, and the incidence generally decreases with age. Most experients have had déjà vu multiple times, generally once every 1 to 6 months in a younger sample (cf. Brown, 2004). Déjà vu experiences are generally brief (several seconds long), triggered by the entire setting, and are more likely to occur indoors, while relaxing, and in the company of friends. The illusion is more likely to occur in individuals with more education, travel experience, and liberal attitudes. Given the rarity of déjà vu, the enigmatic nature of the causative factors, and amorphous response, eliciting a déjà vu experience in the lab may be problematic. However, attempts to model different aspects of the illusion may provide a creative source of research ideas on cognition in general (Seamon et al., 1983; Jacoby and Whitehouse, 1989; Bernstein and Welch, 1991; Joordens and Merikle, 1992; Brown and Marsh, 2005; O'Conner et al., 2006).

There is probably no single cause for déjà vu any more than there is one cause for headaches (Neppe, 1983a). Implicit memory and double perception hold explanatory promise, and evolving research technologies in brain recording and stimulation, psychopharmacology, and virtual reality may also prove useful in clarifying the external (stimuli) and internal (cognitive processing mechanisms) factors that have the capacity to elicit déjà vu (cf. Brown, 2004). Several issues require explication before any complete understanding of the phenomenon can occur, including (1) why déjà vu is less likely with older adults, (2) why déjà vu occurs in both mundane and unique settings, (3) why déjà vu is rarely reported by those with serious memory problems, and (4) why the illusion so often involves a sense of precognition or prior dream.

# 2.22 Tip of the Tongue Experience

**A. S. Brown**, Southern Methodist University, Dallas, TX, USA

Routine word retrieval is a remarkable accomplishment when it goes smoothly. We fluidly access and emit tens of thousands of words with hardly a ripple of conscious awareness. On rare occasions, this transition from word knowledge to word output fails and immediately grabs our attention. This tip-of-the-tongue (TOT) experience is common to us all – we are positive that we know the missing word, but are unable to produce it at the moment. William James (1893) provided a colorful and oft-quoted characterization of the TOT experience:

> Suppose we try to recall a forgotten name. The state of our consciousness is peculiar. There is a gap therein; but no mere gap. It is a gap that is intensively active. A sort of wraith of the name is in it, beckoning us in a given direction, making us at moments tingle with the sense of our closeness, and then letting us sink back without the longed-for term. If wrong names are proposed to us, this singularly definite gap acts immediately so as to negate them. They do not fit into its mould. And the gap of one word does not feel like the gap of another, all empty of content as both might seem necessarily to be when described as gaps. . . . The rhythm of a lost word may be there without a sound to clothe it; or the evanescent sense of something which is the initial vowel or consonant may mock us fitfully, without growing more distinct. (James, 1893: 163–164)

One of the primary goals of empirical research on TOTs is to provide a unique picture of an otherwise incredibly rapid and automatic behavior "... similar to how slow-motion photography clarifies the dimensions of a hummingbird's flight" (Brown, 1991: 204). Brown and McNeill (1966) were the first to apply a scientific approach to study this phenomenon. Their research was methodologically and analytically comprehensive and served as a prototype for subsequent investigations on this topic. They presented definitions of relatively rare words ("one who collects stamps" for philatelist; "a secretion of the sperm whale used in the manufacture of perfume" for ambergris) and elicited TOTs on 13% of such trials. Most surprising was how often information about the missing target word (first letter, number of syllables) was available during this experience, suggesting to Brown and McNeill (1966) the concept of generic recall, where the first stage in word retrieval involves accessing abstract (syllables, syllabic stress) and partial (letter) information about the target word. Their investigation set the stage for a steady growth in research on this topic, with the number of articles approximately doubling every decade since their original publication (see summaries by Brown, 1991; Smith, 1994; Schwartz, 2002b). Whereas most investigators use TOTs as a springboard to address mechanisms of memory storage and retrieval, the TOT experience has also been applied to theories of language production (e.g., Caramazza and Miozzo, 1997; Faust et al., 1997; Askari, 1999; Beattie and Coughlan, 1999; Faust et al., 2003; Faust and Sharfstein-Friedman, 2003; Gollan and Acenas, 2004; Golan et al., 2005) and metamemory (Koriat, 1993; Metcalfe et al., 1993; Schwartz, 1998, 1999, 2001a, 2002b; Schwartz and Frazier, 2005; Schwartz and Smith, 1997).

## 2.22.1 Eliciting and Measuring TOTs

TOTs are a universal experience. In both laboratory and diary investigations, it is the rare individual who fails to experience a TOT, and the concept is universally recognized across individuals and cultures. In fact, the "tongue" metaphor characterizes this word generation difficulty across a wide range of languages (45 of 51 sampled by Schwartz, 1999) and is most likely attributable to the subjective impression that the problem is localized in the late stages of oral language production. People report that between one and two TOTs occur per week in everyday life, as reflected in diary studies of naturally occurring TOTs (Cohen and Faulkner, 1986; Reason and Lucas, 1984; Burke et al., 1991; Ecke, 1997; Heine et al., 1999; Schwartz, 2001b; Gollan et al., 2005), as well as in retrospective assessments of TOT incidence (Burke et al., 1991; Sunderland et al., 1986).

Most laboratory studies on TOTs use definitions as target word cues, following Brown and McNeill's (1966) lead. Others have successfully elicited TOTs using faces (Maylor, 1990; Burke et al., 2004; Cross and Burke, 2004), line drawings and pictures (Brown and Nix, 1996; Gollan and Acenas, 2004; Gollan and Brown, 2006), theme songs (Riefer et al., 1995), smells (Jönsson and Olsson, 2003), learned paired associates (Ryan et al., 1982; Metcalfe et al., 1993), and artificially constructed materials (Smith et al., 1991; Schwartz and Smith, 1997; Schwartz, 1998). TOTs elicited in the laboratory are similar to those that occur naturally (Ryan et al., 1982; Burke et al., 1991; Schwartz, 2001b), but the incidence varies considerably depending on the type of cue materials, procedures, and individuals. A summary of 188 outcomes from 72 published articles in **Figure 1** indicates that the incidence of TOTs is generally between 6% and 15% of items (cf. Brown, 1991).

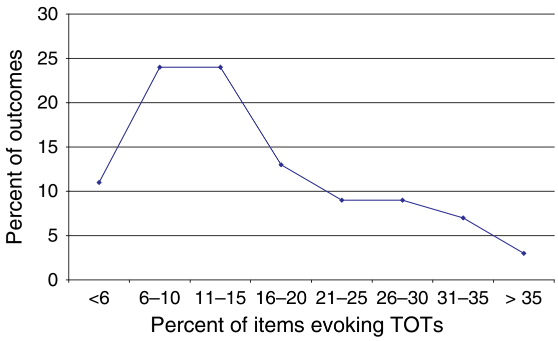

**Figure 1** TOT rate in lab investigations.

Given that TOTs are relatively rare and depend on self-report, there are several measurement issues to consider in this research. First is the distinction between TOT and feeling-of-knowing (FOK) assessments (cf. Yaniv and Meyer, 1987). Typically, an FOK relates to whether one believes that they can later recognize the missing target word, whereas TOTs are triggered by a sense of imminent recall (Maril et al., 2001; Maril et al., 2005). In addition, FOK assessments are requested for all missing target words, whereas TOTs occur spontaneously on only select target words. Researchers also separate positive TOTs (TOT+), where the sought-after target word is the one intended by the experimenter, and negative TOTs (TOT−), where the elusive word differs from the intended target, a distinction made through a recognition test (Brown and McNeill, 1966; Burke et al., 1991). One could argue that a TOT− is a genuine TOT experience, but most exclude these items from analyses (Burke et al., 1991; Rastle and Burke, 1996; Harley and Bown, 1998). There is also the 'fragmentary data problem,' first identified by Brown and McNeill (1966), related to the considerable variation in TOT probability across both participants and stimuli. With each participant's TOTs elicited by a different subset of target words, standard statistical procedures are not well suited to analyzing such data sets.

Finally, there is the phenomenology of TOTs. Informal descriptions of TOTs include such information as James' (1893) observation of a 'tingling' sensation during TOTs and Brown and McNeill's (1966) suggestion that we are 'seized' by, and fall 'under the spell' of, a TOT. Such subjective aspects of experience have received only cursory attention (Schwartz et al., 2000; Schwartz, 2002b), although there seems to be some validity to the sense of imminence, emotionality, and strength associated with TOTs.

## 2.22.2 Influencing TOT Probability

There have been a number of efforts to influence TOT probability through instructions, as well as with primes preceding, and cues following, the target word probe. These manipulations are motivated by efforts to evaluate the mechanisms underlying TOTs. If TOTs are based on a subjective sense of impending or imminent recall of the target word (inferential position), it seems logical that the incidence of TOTs could be manipulated through instructions or motivation. In line with this, Widner et al. (1996) told one group of participants that target words were relatively easy to retrieve, whereas another group was told that they were difficult (the same set of targets were used with both groups). The easy instructions elicited significantly more TOTs, either due to increased motivation to show retrieval competence or greater stress from the struggle to retrieve 'easy' targets (cf. Schwartz, 2002b). In either case, Widner et al. (1996) suggested that an important component of TOTs may be personal expectations about our knowledge base and retrieval competence.

Given that TOTs are sometimes accompanied by related words, it is natural to wonder whether presenting such words influences TOTs in either a positive or negative direction. These experimental manipulations have involved inserting related words either immediately following (cueing) or prior to (priming) the presentation of the target word probe. These efforts have been aimed primarily at differentiating two memory access interpretations of TOTs: blocking and incomplete activation (see discussion later in this chapter).

### 2.22.2.1 Cueing

Jones and Langford (1987) presented cue words that were either (a) phonetically related ('axial' for target 'alchemy'), (b) semantically related ('incubus' for target 'banshee'), (c) both phonetically and semantically related ('abnormality' for target 'anachronism'), or (d) unrelated ('opinionated' for 'cherubic') to the accompanying target word. Phonetically related cue words increased TOTs, whereas semantically related cue words did not, an effect replicated by both Jones (1989) and Maylor (1990a) (cf. Askari, 1999). Unfortunately, cues were not counterbalanced across definitions, and subsequent research suggests that this apparent difference was most likely due to the specific definitions and/or cue words used (Meyer and Bock, 1992; Perfect and Hanley, 1992). Thus, it appears that there is no clear evidence for a related cue word influencing TOT probability. However, this procedure is based on the unlikely assumption that retrieval is not initiated until the definition is completely processed. Rather, it seems more reasonable that retrieval starts well before the entire definition is read. Other investigations have also presented semantic and phonological information related to the target word following the target word probe (Heine et al., 1999; James and Burke, 2000; Abrams et al., 2004), but these generally are designed to influence the resolution rather than the incidence of TOTs, and this research will be covered later in this chapter.

### 2.22.2.2 Priming

A less ambiguous way to influence TOT probability is by presenting related words prior to the target word probe. Although this solves the previously noted problem, it creates another: Participants may become aware of the prime-target relationship and develop strategies to search for target words based on the prime words (cf. Jones, 1989). Rastle and Burke (1996) addressed this problem by embedding target words in an apparently unrelated task preceding the TOT probe session. Participants rated the pronunciation difficulty of a set of words, half of which were targets in the subsequent TOT task. Rastle and Burke (1996) found that there were significantly fewer TOTs on words appearing in the prior prime list, compared to targets that had not been previewed. They further discovered that both shallow (syllable count) and deep (pleasantness) processing of the targets reduced subsequent TOTs.

Several additional investigations have examined the effects of priming with related words, rather than with the target word itself. Burke et al. (2004) presented primes that were either phonologically related (cherry pit) or unrelated (cane) to a celebrity's name (Brad Pitt). Phonologically related primes significantly reduced TOTs relative to unrelated primes, an outcome found with both younger and older adults. Some participants noticed the correspondence between prime and target (see preceding point), and analyses including only unaware subjects yielded a significant prime-related decrease in TOTs for older but not younger participants. Thus, phonological activation can reduce TOTs, but this effect appears to be more pronounced for older adults.

In a similar investigation, Cross and Burke (2004) used semantically (rather than phonologically) related prime words in a proper name retrieval task. Participants were primed with a famous name, either related (Eliza Doolittle) or unrelated (Scarlett O'Hara), to the subsequent target actor (Audrey Hepburn). In the related condition, the actor had actually portrayed the character whose name was primed earlier. There was a slight elevation in TOT rate following a semantically related versus unrelated prime, but this difference was nonsignificant.

Rather than priming the entire target word, James and Burke (2000) exposed participants to various phonological fragments from the target word embedded in a set of 10 prime words preceding the target word cue. With related prime sets, half (5) of the words shared some phonological component ('in*di*gent, *ab*stract, trun*cate*') with the target word ('abdicate'). This type of phonological priming reduced TOTs, relative to unrelated prime sets, where none of the 10 words shared a phonological relation with the target.

#### 2.22.2.3 Target Word Characteristics

Brown and McNeill (1966) originally proclaimed that TOTs occur primarily with rarely used (low-frequency) words, and this assumption has permeated most subsequent research (Naito and Komatsu, 1989; Burke et al., 1991; Askari, 1999; James and Burke, 2000; Lesk and Womble, 2004). Significantly more TOTs have been found with low- versus high-frequency target words (Harley and Bown, 1998; Vitevitch and Sommers, 2003), and target word frequency and TOT probability have been shown to be negatively correlated (Gollan and Silverberg, 2001). Furthermore, Burke et al. (1991) found that about half of naturally occurring TOT target words were so rare that they did not appear in word-frequency norms, and those that did were substantially below the average frequency of occurrence. Smith et al. (1991) experimentally manipulated target word frequency by varying the number of study trials. They found that TOTs were reduced for words with greater frequency, although this difference was significant in only one of two outcomes. In contrast to this, participants rate their naturally occurring TOT targets (diary studies) as relatively familiar (Cohen and Faulkner, 1982; Reason and Lucas, 1984), although data are based on subjective impression rather than objective data.

Another dimension that appears to influence TOT rate is neighborhood density, or the number of words that are phonologically or orthographically similar to the target. More TOTs occur with targets from sparse compared to dense neighborhoods (Harley and Bown, 1998; Vitevitch and Sommers, 2003), suggesting that dense networks may facilitate retrieval. This intriguing finding is based on small and highly selective subsets of words, but this topic certainly warrants additional research. Finally, TOT incidence is considerably higher for proper names compared to other types of target words (common nouns, objects, verbs) in both diary (Burke et al., 1991; Cohen and Faulkner, 1986; Schwartz, 2001b; Gollan et al., 2005) and experimental (Rastle and Burke, 1996; Evrard, 2002) investigations. Interestingly, Gruneberg et al. (1973) found that when individuals are asked to generate their own TOTs ('prospect') they are most likely to search through sets of proper names.

### 2.22.3 Partial Target Word Information

One of the more striking aspects of the TOT experience is that while hanging in linguistic limbo, unable to pull up the elusive target, various aspects of this word often come to mind. In fact, this anecdotal observation was a primary motivation for Brown and McNeill's (1966) original investigation. The meaning of partial target information availability is limited by the fact that it accompanies only some TOTs, and there is considerable variability across studies in how this information is requested, recorded, and reported. Although Brown and McNeill (1966) reported that first letter guesses regarding the target word were correct over half of the time during TOTs, they did not indicate how often such guesses were made. Harley and Bown (1998) found that first letter guess were made on an unimpressive 5% of TOTs, and others don't even provide such information about the missing target word because it is volunteered too infrequently (Schwartz and Smith, 1997; Vitevitch and Sommers, 2003). Thus, one must be careful not to overinterpret the significance of such findings based on low response rates for select items.

For naturally occurring TOTs, approximately two pieces of peripheral information are typically reported, and this rate is lower in lab studies, at less than one piece of information per TOT (Burke et al., 1991; Rastle and Burke, 1996). More than half of naturally occurring TOTs may be accompanied by peripheral information (Cohen and Faulkner, 1986), but this incidence appears to be substantially lower with lab-induced TOTs (Heine et al., 1999). The most salient type of partial target word information is the first letter. Brown and McNeill (1966) originally found that participants correctly guessed the first letter on 57% of attempts, and that 49% of similar sounding (SS) words accompanying TOTs share a common first letter with the intended target. Although subsequent research has yielded a wide range of correct guess accuracy (63%, Yarmey, 1973; 71%, Koriat and Lieblich, 1974; 68%, Rubin, 1975; 40%, Brown and Nix, 1996; 28%, Caramazza and Miozzo, 1997; 54%, Harley and Bown, 1998; 56%, Dahlgren, 1998), the average appears to be around 50% and definitely above chance levels. There is also evidence that individuals can correctly identify the final letter(s) or phoneme during TOTs (Koriat and Lieblich, 1974; Brown and Nix, 1996; Caramazza and Miozzo, 1997), although the accuracy is considerably lower.

The number of syllables in the missing target word also appears to be available on some occasions. Brown and McNeill's (1966) participants were correct 60% of the time guessing number of syllables (from 1 to 5), and later research has yielded somewhat lower rates, averaging around 50% (80%, Koriat and Lieblich, 1974; 35%, Brown and Nix, 1996; 37%, Caramazza and Miozzo, 1997; 54%, Dahlgren, 1998; 55%, Vigliocco et al., 1997; 45%, Gollan and Silverberg, 2001). Although less compelling than first letter guesses, given that the majority of English words are two or three syllables long, these data still suggest that individuals have access to word-form information at greater than chance levels.

Finally, target word gender (masculine, feminine) appears to be accessible during TOTs above chance levels in Italian (71%, Caramazza and Miozzo, 1997; 72%, Miozzo and Caramazza, 1997; 84%, Vigliocco et al., 1997) and French (85%, Ferrand, 2001), although not Hebrew (55%, Gollan and Silverberg, 2001). Thus, most evidence indicates that syntax (gender) as well as orthography (first letter) and general word form (syllables) is accessible during TOTs.

## 2.22.4 Words Related to the Target Word

Individuals often report that nontarget words come to mind when foundering in a TOT experience. These interlopers (Jones, 1989) are immediately identified as incorrect, yet persist in consciousness. They have been variously referred to as relatives (Astell and Harley, 1996), blocking intermediates (Reason and Lucas, 1984), intruders (Schwartz, 1994), candidates (Cohen and Faulkner, 1986), persistent alternatives (Burke et al., 1991; Heine et al., 1999), and ugly stepsisters (Reason and Lucas, 1984). The significance of these interlopers is the subject of a continuing debate that is primarily related to the etiology of TOTs (covered later in this chapter).

Some view interlopers as a byproduct of the TOT experience (cf. Cross and Burke, 2004), reflecting how close one is to the missing target word (Brown and McNeill, 1966). Others see interlopers as causing TOTs: Phonetically or semantically related words are inadvertently retrieved, and their presence hinders successful access to the target word (Jones and Langford, 1987; Jones, 1989; Brown, 1991). Finally, some speculate that these interlopers actually facilitate TOT resolution by sharpening the target word specification (Cohen and Faulkner, 1986).

The majority of naturally occurring (diary) TOTs are accompanied by related words (Reason and Lucas, 1984; Cohen and Faulkner, 1986; Burke et al., 1991; Heine et al., 1999), and their incidence in laboratory-induced TOTs is lower at approximately one-third of TOTs (Burke et al., 1991; Riefer et al., 1995; Brown and Nix, 1996; Harley and Bown, 1998; Riefer, 2002). Most find that semantically related interlopers are more common than phonologically (orthographically) related interlopers (Brown and McNeill, 1966; Riefer et al., 1995; Ecke, 1997; Harley and Bown, 1998), and most are from the same syntactic class as the target word (Burke et al., 1991; Harley and Bown, 1998; Ecke, 2001). It is also common for the interloper and target to share the same initial phoneme and number of syllables (Burke et al., 1991).

## 2.22.5 Resolving TOTs

### 2.22.5.1 Resolution Probability

The vast majority of naturally occurring TOTs are eventually resolved (92%, Burke et al., 1991; 78%, Cohen and Faulkner, 1986; 95%, Heine et al., 1999; 89%, Schwartz, 2001b). About half are resolved within a minute, with most resolved within 1 h (Burke et al., 1991; Schwartz, 2002a). In laboratory research, resolution probability is more difficult to assess because the trial by trial procedure often limits opportunity. Given that most studies allow a maximum of 1 min per trial, any resolutions not occurring within this time frame may not be captured in the procedure. Thus, resolution rates are lower (and highly variable) in laboratory investigations, with an average at around half of TOTs (66%, Gruneberg et al., 1973; 48%, Finley and Sharp, 1989; 38%, Riefer et al., 1995; 22%, Brown and Nix, 1996; 54%, Brédart and Valentine, 1998; 90%, Dahlgren, 1998; 44%, Harley and Bown, 1998; 66%, Beattie and Coughlin, 1999; 50%, Gollan and Silverberg, 2001; 43%, Vitevitch and Sommers, 2003).

### 2.22.5.2 Resolution Process

There are several ways in which the target word can be recovered: mental search, where the individual continues an active memory search; external research, where reference sources or individuals are consulted; and pop-ups, where the word seems to come to mind spontaneously. The incidence of each resolution process varies widely (Read and Bruce, 1982; Reason and Lucas, 1984; Burke et al., 1991; Heine et al., 1999; Schwartz, 2002a) and may partially reflect variations in one's motivation to pursue the inaccessible target word, especially in laboratory TOTs, where one has little personal investment in recovering the elusive word (cf. Brown, 1991). Some controversy surrounds pop-ups because this superficially appears to rely on 'unconscious' mental processes. Whereas some find the incidence quite high, accounting for the majority of resolutions (Finley and Sharp, 1989; Burke et al., 1991; Heine et al., 1999; Schwartz, 2001b), others find the incidence trivial. More specifically, Read and Bruce (1982) found that 3% of TOTs were resolved through 'spontaneous retrieval' and suggested that the incidence in other studies is inflated because pop-ups are striking and hence selectively memorable. Others note that semantic or phonetic cues that one encounters in the environment may trigger the missing target word without conscious awareness of the connection between cue and missing target (Abrams et al., 2003).

Related to pop-ups is the possibility of persistent subthreshold activation of the target word immediately following the TOT. Yaniv and Meyer (1987) suggested that "...the memory trace of a currently inaccessible item may be at least partially primed for a period of time after information is processed from an initial probe question..." (p. 188). In support of such speculation, Yaniv and Meyer (1987) found that immediately after an unresolved TOT, lexical decision latencies were faster for TOT targets than for unrelated words, suggesting a heightened activation level. However, Connor et al. (1992) replicated Yaniv and Meyer (1987) with a 1-week separation between the TOT and lexical decision task, an interval that logically exceeds any continuing activation. Connor et al. (1992) suggested that rather than continuing subthreshold activation, words from well-known categories of information are more likely to lead to both higher TOT incidence and faster lexical decisions (cf. Naito and Komatsu, 1989).

### 2.22.5.3 Resolution through Cueing

Different procedures have been used to aid TOT resolution. Re-presenting the same target-word cue after a delay has been moderately successful (15%, Brown and Nix, 1996; 12%, Schwartz, 1998), as well as providing the first letter of the missing target word (Freedman and Landauer, 1966; Brennen et al., 1990; Heine et al., 1999). Others have used a more subtle manipulation: burying phonetic fragments of the target word in a set of words processed immediately following the TOT. This procedure is similar to one used to manipulate TOT probability (see earlier discussion). James and Burke (2000) found that processing five words sharing phonological components with the target word (embedded in a 10-word set) while in a TOT improved resolution probability, compared to an unrelated set of words. In a more focused effort to specify which phonological element(s) are important, White and Abrams (2002) found that only the first, but not the middle or last, syllable can enhance TOT resolution. Refining this even further, Abrams et al. (2004) discovered that the first letter alone is insufficient, but that the entire first syllable is needed. Finally, Abrams and Rodriguez (2005) found that the first phoneme facilitated TOT resolution only if the target ('rosary') is cued with a word from a different syntactic category ('robust') from the target. When cue word shares the same syntactic class ('robot') with the target, a common initial phoneme is of no assistance in TOT resolution. Thus, phonological activation has the capacity to add activation to the unavailable TOT target word, facilitating resolution of the TOT, but this occurs only if the cue word differs in syntax from the target.

## 2.22.6 Etiology of TOTs

### 2.22.6.1 Direct Access Explanations

Perhaps the liveliest issue in TOT research in the past decade involves identifying the cause of the experience. As noted earlier, Brown and McNeill (1966) originally proposed that TOTs reflect generic recall, where access to specific words involves first sorting through word sets with similar meaning or phonology and then narrowing this down to the particular target. Their ideas did not capture the imagination of researchers in the field, but other interpretations emerged based on the presumption that the TOT reflects a partial activation of the target word. These direct access interpretations fall into two different categories: blocking and incomplete activation. The blocking explanations assume that access to the missing target word is hindered by the presence of other words related to the target (interlopers) (Woodworth, 1938). This perspective motivated some to use related words in an attempt to precipitate TOTs (Reason and Lucas, 1984; Jones and Langford, 1987; Jones, 1989). However, this theory has not received clear empirical support (Meyer and Bock, 1992; Perfect and Hanley, 1992) and cannot easily account for the absence of interlopers for many TOT experiences.

A more likely cause of TOTs is incomplete activation, posited by Burke et al. (1991) and derived from research on language production. Under this interpretation, word production occurs in sequential stages, where activation is passed from a semantic to a phonological representation of the word (Node Structure Theory, or NST). On most occasions, sufficient activation is transmitted from the semantic to the phonological nodes, but on rare occasions the activation conveyed to the phonological nodes is inadequate for complete word production (Burke et al., 1991). Burke et al.'s (1991) version of NST is the transmission deficit hypothesis (TDH). This is the most prominent of incomplete activation theories applied to TOT research, and Burke et al. (1991) speculated that the three most important factors affecting the transmission of activation are (a) recency of word experience, (b) frequency of word experience, and (c) age of the individual. More specifically, a TOT is less likely if the target word has been recently experienced, the word is frequently experienced, and the individual is younger.

Several lines of evidence support TDH. First, individuals can access some aspects of the missing target word (e.g., first letter) because the activation passed along to the lexical nodes is sufficient to make accessible some aspects of the word form without activating the entire lexical entry. The occurrence of interlopers can also be accounted for by TDH. Phonological nodes are shared across multiple words (e.g., 'cha' is shared by 'charity' and 'chastity'), and the activation of a shared node can transmit priming backwards to the semantic level and supply sufficient activation to another word structurally related to the target. TDH is also supported by an age-related decrease in partial target word information (Burke et al., 1991; Rastle and Burke, 1996) and interlopers (Burke et al., 1991). The age-related decline in transmission of activation reduces phonological activation, making elements of the target word (first letter, etc.) less available and reducing the amount of backward activation to related words.

Experimental efforts to increase phonological activation of target word components appear to influence TOTs in a manner congruent with TDH. As described earlier in this chapter, James and Burke (2000) found that phonological components of the target not only reduce TOTs when presented as primes preceding the definition, but also increase TOT resolution when presented as cues following the definition. Rastle and Burke (1996) further found that presenting target words in a prior prime list decreases the number of TOTs, suggesting that recent encounter facilitates the transmission of activation, congruent with TDH (Heine et al., 1999; White and Abrams, 2002; Abrams et al., 2001, 2004).

### 2.22.6.2 Inferential Explanations

In contrast to direct access, an alternative interpretation is that TOTs reflect an individual's inference about their personal knowledge (cf. Schwartz and Smith, 1997), rather than conveying information concerning the partial activation of the target word. The most thoroughly detailed inferential interpretation is the metacognitive control theory of Schwartz (1999, 2001a, 2002b), which suggests that TOTs arise from an individual's inference about retrieval probability for that particular word. When retrieval fails, we evaluate how accessible a target word should be. If higher than a certain threshold, we experience a TOT. If lower, we have a 'don't know' (DK) response. This evaluation of word accessibility serves to maintain our retrieval effort longer, compared to words not so assessed, yielding higher recall rates following TOT versus DK states and more time spent in the retrieval effort (Schwartz, 2001a). Koriat (1993) also suggested that a TOT does not reflect special access to the unavailable target word, but is based on partial information retrieved when searching for the word, whether or not these fragmentary data are related to the missing target. Thus, our sense of imminent recall derives not from how close we are to the target word, but how much partial information comes to mind.

Inferential theorists point to the fact that TOTs can occur for artificially constructed stimuli (TOTimals, or made-up animals) that have not been given a name (Schwartz, 1998), and that the likelihood of a TOT is directly related to the amount of target word information provided in the retrieval cue (Schwartz and Smith, 1997). Schwartz (1998) also argued that inferential theories receive support from the fact that we can experience TOTs for nonexistent target words. 'Illusory' TOTs for a fictitious fact ("What is the name of the legendary floating island in ancient Greece?"; "What is the capital of Bormea?") cannot be based on partial target word information because none exists. However, one difficulty with such a conclusion is that these stimulus materials were ineffective in eliciting TOTs with older adults because they universally recognized that the questions had no answer (Schwartz, 2002b). Others argue that illusory TOTs may actually be negative TOTs (TOT−) for real target words, with participants making perceptual or interpretative errors in reading the 'definitions' (Taylor and MacKay, 2002).

In summary, it is possible that both direct access and inferential components contribute to the TOT experience (Schwartz, 1994). Direct access is supported by our ability to correctly access parts of the missing word. And because every TOT relies, to some extent, on our personal cognitive evaluations of our knowledge store and retrieval capability, inferential theories have some place in the explanatory picture.

## 2.22.7 Individual Differences

### 2.22.7.1 Age

A ubiquitous finding in TOT research is that older adults experience more TOTs than younger adults. This difference has been found in both diary studies (Cohen and Faulkner, 1986; Burke et al., 1991; Heine et al., 1999) and laboratory investigations (Burke et al., 1991; Brown and Nix, 1996; Rastle and Burke, 1996; Dahlgren, 1998; Heine et al., 1999; James and Burke, 2000; Gollan and Silverberg, 2001; White and Abrams, 2002; Vitevitch and Sommers, 2003; Cross and Burke, 2004; Gollan and Brown, 2006). What is less clear is to what extent this reflects a verbal deficit (decrement theory) or a verbal surplus (incremental-knowledge theory) (Schwartz and Frazier, 2005), keeping in mind that these two positions are not necessarily mutually exclusive (Schwartz and Frazier, 2005; Gollan and Brown, 2006). Burke et al. (1991) suggested that aging naturally diminishes the amount of semantic to phonological priming that occurs during normal word production, and that an increase in TOTs reflects this growing deficit. Gollan and Brown (2006) argued that older adults also have more opportunities to experience TOTs because they have larger vocabularies than younger adults. When compared using a set of words that both groups know equally well, older and younger adults experienced similar numbers of TOTs. Gollan and Brown (2006) further suggested that the negative effects of aging (NST) are more pronounced on easier words because they are closer to ceiling levels of activation. Regardless of the position, any group comparison using laboratory investigations with a common set of target words is problematic. If TOTs are viewed as deficiency and analyzed relative to all unsuccessful items (cf. Brown, 1991), the more verbal group may show a greater deficit because they have fewer nonrecalled items in their baseline. If TOTs are viewed as a surplus and analyzed relative to correct retrievals, the group differences often disappear (cf. Gollan and Brown, 2006). Given that most lab studies use a fixed set of targets, one may or may not find group differences, depending on one's orientation (cf. Gollan and Brown, 2006). It is likely that both verbal deficit and surplus mechanisms contribute to age-related TOT differences, although it should be noted that proper names always show substantial age differences, even when knowledge levels are equated (Cross and Burke, 2004).

At the other end of the age spectrum, TOTs have also been documented among children, but this area remains relatively unexplored. Apart from informal documentation (Wellman, 1977; Elbers, 1985), there are only three published reports using standard laboratory designs. All involve a comparison of normal and language-disabled (LD) children (Faust et al., 1997; Faust et al., 2003; Faust and Sharfstein-Friedman, 2003) and suggest that the incidence of TOTs in normal children is in the same range as that found in adults (11% in grades 2 to 3; Faust et al., 1997; 19% in grades 3 to 4, Faust et al., 2003; 7% in grades 7 to 8, Faust and Sharfstein-Friedman, 2003). Also similar to adults, partial phonemic and semantic information is often available during TOTs. This research also shows that TOT rates for LD children are twice that of normal children, and that partial information available during their TOTs suggest that LD children suffer deficiencies in phonetic but not semantic access to the target words.

### 2.22.7.2 Language Competence

The relationship between vocabulary ability and TOTs is ambiguous. Whereas Dahlgren (1998) found that those with high verbal ability have significantly more TOTs than those with low verbal ability, Heine et al. (1999) found a nonsignificant correlation between laboratory-induced TOT rate and vocabulary level. Burke et al. (1991) discovered no correlation between TOTs and vocabulary for naturally occurring TOTs. For lab-induced TOTs, Burke et al. (1991) found no correlation for younger adults but a significant negative correlation for older adults. The inconsistency in these outcomes may be due to the restricted range of vocabulary ability in the particular participant samples, or the selective nature of stimulus materials. An evaluation of the relationship of verbal ability to TOTs should be a routine fixture in future research because the interaction of verbal ability level and word frequency may be an important factor affecting TOT rate (cf. Gollan and Brown, 2006).

Another verbal ability difference examined in TOT research involves monolinguals versus bilinguals. This research has consistently shown that bilinguals experience more TOTs than monolinguals (Gollan and Silverberg, 2001; Gollan and Acenas, 2005; Gollan et al., 2005; Gollan and Brown, 2006), a difference most likely due to bilinguals' reduced use of words (on the average) in both languages (Gollan and Silverberg, 2001; Gollan and Acenas, 2005). This outcome is congruent with TDH (Burke et al., 1991) in that the level of phonetic activation for bilinguals' vocabulary words is less than that for monolinguals because the average usage per word is lower.

## 2.22.8 Summary

TOTs are a nearly universal experience across a broad range of cultures. TOTs are elicited in the laboratory for around 10–15% of targets, and such lab-induced TOTs have a reasonable similarity to those occurring naturally in diary studies. Proper names are especially likely to trigger TOTs. The missing target comes to mind on most occasions, although this rate is lower in laboratory than in diary investigations. During a TOT, related words (interlopers) come to mind frequently, and certain features of the missing target word (e.g., first letter, number of syllables) appear accessible even when the target word is not. Phonological information about the missing target word appears to reduce TOT incidence and increase TOT resolution. TOTs are more prevalent among older (versus younger) adults and among bilinguals (versus monolinguals). Although some have suggested that TOTs result from target word blocking caused by interlopers or inferences about target word accessibility, most research supports the idea that TOTs result from insufficient phonological activation of the target word.

# 2.23 Theories of Recognition Memory

**C. M. Parks and A. P. Yonelinas**, University of California at Davis, Davis, CA, USA

## 2.23.1 Introduction

Current theories of recognition memory include quantitative models and detailed neural/computational models. In this chapter we review three general classes of quantitative memory models (i.e., threshold, signal detection, and hybrid models) and assess each model's ability to account for results from a variety of recognition paradigms. Implications of these findings for neural/computational models (e.g., network models of the medial temporal lobes) are then considered.

For each of the models, we first describe the core assumptions, point out the motivations underlying these assumptions, and describe their major predictions. We then evaluate each class of model in light of the empirical literature. In general, the results indicate that pure threshold and pure signal detection models are not consistent with the existing data, whereas several hybrid models (those that include both signal detection and threshold processes) are consistent with a majority of the results.

One of the most direct ways of testing quantitative recognition models is to use a receiver operating characteristic (ROC) analysis, and this method has been applied most extensively in studies of item recognition. Recently, ROC methods have also been applied to other types of recognition, such as relational (e.g., source and associative), remember/know, and exclusion recognition tests. Taken together, these various recognition tasks provide a rich set of data with which to evaluate these models. Neural data, including recent studies of amnesia, event-related potentials (ERPs), and functional magnetic resonance imaging (fMRI), also prove useful in assessing these models. We begin by describing exactly what ROCs are and why they are particularly useful in evaluating models of recognition memory.

### 2.23.1.1 What Is an ROC?

An ROC is a function that relates the proportion of correctly recognized target items (i.e., the hit rate) to the proportion of incorrectly recognized lure items (i.e., the false alarm rate) across variations in response bias (i.e., the propensity to make a positive recognition response). In a test of item recognition memory the hit rate is the probability of correctly accepting an old (studied) item as old, and the false alarm rate is the probability of incorrectly accepting a new (unstudied) item as old. ROCs are based on signal detection theory, which assumes that recognition memory (standard item recognition in this case) can be described as a set of two overlapping distributions, one for old or studied items and one for new or unstudied items. The distributions reflect the variation in 'memory strength' (a term that has been interpreted in many different ways, but is commonly thought to be similar to familiarity) for these two sets of stimuli (see **Figure 1(a)** for an illustration). In order to make a binary old/new recognition decision, an individual is assumed to select some level of memory strength as a criterion; items with strengths greater than the criterion are then accepted as old, and items with strengths less than the criterion are rejected as new. However, ROCs contain multiple points collected under different levels of response bias, rather than just the one point generated in old/new paradigms.

The multiple points in ROCs can be obtained in various ways, but by far the most common is the confidence rating method (for comprehensive discussions of general ROC methods see Wickens, 2002; Macmillan and Creelman, 2005). For example, after studying a list of items, subjects are presented with a mixture of old and new items and are required to indicate how confidently they recognize each item on a confidence scale, such as the commonly used six-point scale, with 1 labeled 'Sure New' and 6 labeled

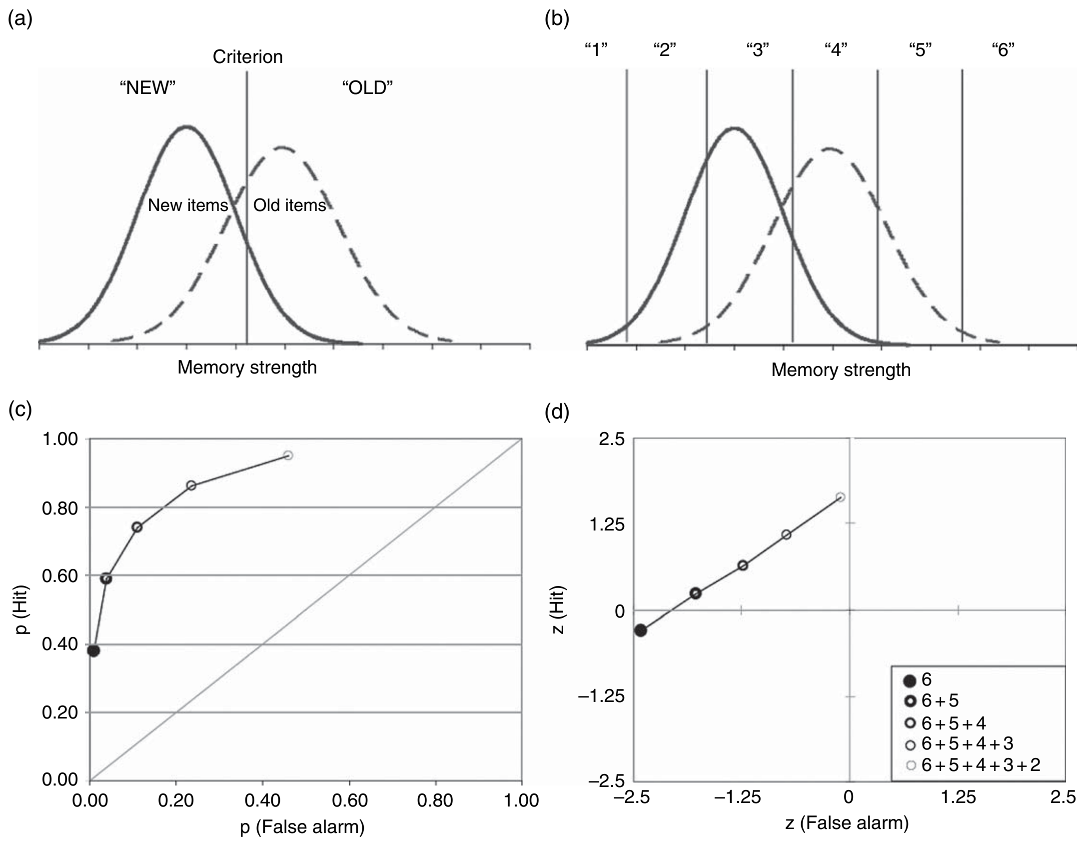

**Figure 1** Example new and old item distributions in (a) a standard binary old/new item recognition paradigm and (b) a confidence rating paradigm for item recognition. Panels (a) and (b) are the same, except for the type of response(s) subjects are required to make. Example ROCs in (c) probability space and (d) z-space. The points in panels (c) and (d) represent pairs of hits and false alarms that are summed across a typical confidence scale ranging from 1 to 6, with 1 labeled 'Sure New' and 6 labeled 'Sure Old.' Thus, the first point represents hits and false alarms for items given a confidence rating of 6 or 'Sure Old.' The next point represents hits and false alarms for items given a confidence rating of 5 and 6, and so on down the confidence scale. Note that the final point (for 1 or 'Sure New') is not plotted because it is constrained to be (1,1).

'Sure Old' (e.g., Sure New 1 2 3 4 5 6 Sure Old). This confidence scale is a way of observing changes in response bias without actually having to manipulate bias experimentally. Thus we can observe how hits and false alarms change as a function of response criteria (i.e., how they change for different ratings on the confidence scale). High confidence ratings correspond to relatively conservative response biases (a low propensity to accept an item as old, or a strict criterion), and low confidence ratings correspond to relatively lax response biases (a high propensity to accept an item as old, or a lax criterion). Thus, subjects are assumed to make decisions by placing n–1 criteria for an n-point confidence along the memory strength axis, as illustrated in **Figure 1(b)** for the standard 6-point confidence scale. An ROC is actually constructed by plotting hit and false alarm pairs (hits on the y-axis, false alarms on the x-axis) beginning with the most confidently recognized items (e.g., hits = P('6'|old), false alarms = P('6'|new)), then repeatedly recalculating the values by including the next most confidently recognized items (e.g., hits = P('6'|old) + P('5'|old), false alarms = P('6'|new) + P('5'|new), etc). Thus, the left-most point on the ROC (**Figure 1(c)**) reflects the hit rate plotted against the false alarm rate when adopting the strictest response criterion (or the least amount of bias). Each subsequent point reflects performance at a more and more relaxed response criterion. Importantly, the function is cumulative, and so both the hits and false alarms are constrained to increase or remain constant as the scoring criterion is relaxed. The example ROC in **Figure 1(c)** shows how each point on the function is calculated from a standard six-point confidence scale. Note that chance performance would be reflected by a function lying on the diagonal (i.e., when hits = false alarms), and increasing accuracy is associated with a function moving toward the upper left, such that the greater the area under the curve, the greater the memory sensitivity or discriminability.

### 2.23.1.2 Why Bother with ROCs?

ROCs have been examined for several reasons. First, given that a subject must adopt some response criterion in order to make an old/new recognition memory judgment, theories of recognition performance must be able to characterize the relationship between accuracy and response criterion, and because ROCs are hit and false alarm rates under different criteria, they provide the opportunity to test a model's characterization of that relationship. Second, ROC results prove to be much more constraining than standard old/new recognition data. That is, memory studies that require subjects to make binary old/new decisions produce an ROC with only one point (a single hit rate and a single false alarm rate). To appreciate the utility of ROC studies, one need only consider how many different theories might account for such a single point – it is difficult to imagine any theory having any difficulty. However, true ROCs – that is, ROCs with multiple points – provide much greater constraint, and thus many fewer theories are able to account for the results. Third, if one can find a theory that adequately accounts for the relationship between accuracy and response bias, then it could be used to derive estimates of accuracy that are not distorted by the particular response criterion that the subject had at a given time. Without such a theory, it may be impossible to determine if an experimental manipulation has influenced accuracy or response bias, or both. So determining which theory can accurately account for ROCs has serious implications not only for theory development, but for measuring recognition memory performance itself.

The shape of an ROC is typically quantified by plotting the z-score (i.e., the inverse of the standard cumulative normal distribution, which assumes a mean of 0 and a standard deviation of 1) of each hit and false alarm rate to produce a zROC (see **Figure 1(d)**). The theoretical motivation for doing so is grounded in signal detection theory as discussed in detail in the sections that follow. Standard linear regression is used to estimate the slope and intercept of the function. If the zROC is linear, then the y-intercept is a rough estimate of recognition accuracy and the slope is an index of the asymmetry of the ROC in probability space. For example, the ROC in **Figure 1(c)** is asymmetrical along the diagonal (it is pushed up on the left side); the slope of the zROC on the right indicates how asymmetrical the ROC on the left is. If the ROC were perfectly symmetrical around the diagonal, the slope of the zROC would be 1.0, but when it is asymmetrical in the way shown in **Figure 1(c)**, the z-slope is less than 1.0. If it were asymmetrical in the other direction it would have a z-slope greater than 1.0, but this is almost never observed in recognition studies. Generally then, the greater the deviation of the slope in z-space from 1.0, the more asymmetrical the ROC is.

Although there are some very stark differences between some of the models reviewed here, and especially between the different classes of models, there are also a few very basic assumptions that they all share. They all assume that recognition decisions require an evaluation of some kind of mnemonic evidence (i.e., memory strength, which may comprise various underlying components depending on the model) that varies for both target and lure items. Thus, all the models are depicted in terms of their probability density distributions of memory strength for target and lure items, such as those shown in **Figures 1(a)** and **1(b)** (which show an unequal-variance signal detection model). The x-axis always represents memory strength (or 'evidence,' more generally), and there will always be at least two probability distributions along that axis corresponding to the lure and target items (although sometimes more axes are introduced, and not all distributions necessarily lie along the same axes).

The models we review in this chapter all make predictions about the shape of zROCs. Therefore, the shape of zROCs found in different types of recognition tests serve as the real tests of the models we consider – that is, the primary question is whether a model is capable of predicting (or at least explaining) the shapes that ROCs and zROCs take on under the experimental conditions devised thus far. First, for each class of models, we review the most prominent models to date and their ROC/zROC predictions, with an eye toward understanding why the models make the predictions that they do. After describing the models and their predictions in each class, we then briefly review the empirical ROC and zROC findings, indicating which models have been best supported by data thus far.

## 2.23.2 Evaluating Theories of Recognition

Theories of recognition fall into three general classes: threshold, signal detection, and hybrid models (i.e., models including both threshold and signal detection assumptions). In the following sections, we describe the core assumptions of these theories, focusing on the most frequently used models within each class, and evaluating their ability to account for recognition data.

## 2.23.3 Threshold Models

Threshold theories are one of the simplest classes of recognition memory models, and they motivate the common practice of estimating memory accuracy by subtracting false alarms from hits. Although their origins are obscure, they can be traced back to the psychophysical work of Fechner (see Boring, 1929), in which it was proposed that there is some minimum sensory signal strength (i.e., the 'threshold' or 'limina') that must be attained before a subject is able to perceive a stimulus. Threshold models treat memory as probabilistic in the sense that only some proportion of the items will exceed the threshold. Thus, for all threshold models, memory is described essentially in terms of success and failure; there is some probability with which memory will succeed (strength exceeds the threshold) and some probability with which memory will fail (strength falls below the threshold).

### 2.23.3.1 High-Threshold Model

The high-threshold model (HT) is perhaps the simplest threshold model (see **Figure 2**) and is the one that is assumed when subtracting false alarms from hits to measure accurate recognition performance. It assumes distributions of old and new items, with old items falling farther to the right along the strength axis than new items. Note that the distributions for HT models are often represented as rectangular for the sake of simplicity, but they can actually take on various different shapes (see Macmillan and Creelman, 2005). The threshold is the point at which the old item distribution exceeds the new item distribution. The new item distribution falls below the threshold, suggesting that new items are never truly remembered in the same sense that old items are. The proportion of old items above the threshold is the probability $R_T$. Memory decisions are made by selecting some level of memory strength as a response criterion and accepting items that exceed that level of strength as having been studied. If the response criterion is set exactly at the threshold, then the hit rate will be equal to $R_T$, and the false alarm rate will be zero. For any given experimental condition the threshold is fixed, but the response criterion is free to vary in either direction of the threshold so the hit rate may exceed $R_T$ (with a lax criterion) or may be less than $R_T$ (with a strict criterion).

Critically, as the response criterion is relaxed (i.e., shifted to the left of the threshold), the hit rate and false alarm rate will increase at a constant rate until they reach 1.00, producing a linear ROC like that seen in **Figure 2**. When a linear ROC is plotted on z-coordinates, the resulting zROC is actually U-shaped. Thus, assessing the linearity of empirical ROCs and z-ROCs provides a direct test of this

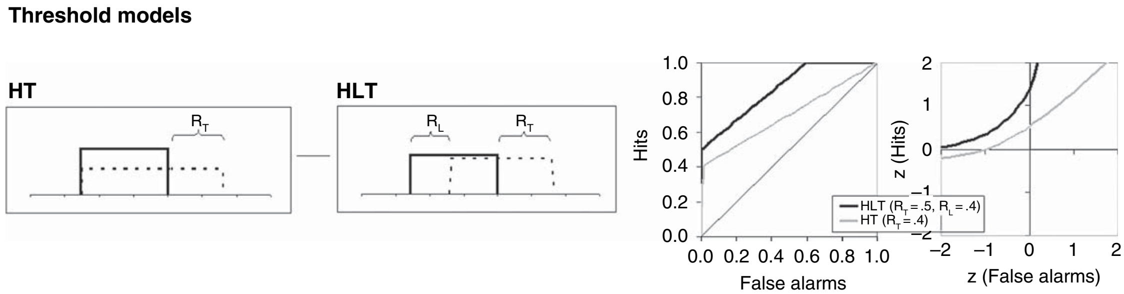

**Figure 2** Strength distributions and predicted ROCs and zROCs for the high threshold (HT) and high-low threshold (HLT) memory models. Predicted ROCs on the left are plotted in probability space, and the ROCs on the right are plotted in z-space. Adapted from Yonelinas AP and Parks CM (2007) Receiving operator characteristics (ROCs) in recognition memory: A review. *Psychol. Bull.* 133: 800–832, with permission.

threshold model. Moreover, the model predicts that as performance increases the ROC should become more asymmetrical. That is, as memory increases, the left y-intercept will increase, and thus the slope of the ROC (and the z-ROC) will decrease.

### 2.23.3.2 High-Low Threshold Model

The high-low threshold (HLT) model is another common threshold model (sometimes referred to as the 'two-high threshold' or the 'double-high threshold' model), in which a second memory component is added to represent the probability that new, or lure, items can be recognized as new ($R_L$, e.g., "I would have remembered my name if it had been in the study list"). The HLT model is identical to the HT model except that the new item distribution extends further to the left than the old item distribution, creating a second threshold, which old, or target, items cannot cross (see **Figure 2**). The low threshold falls at the left-most point of the old item distribution, such that any new item falling below this threshold can be recognized as a new, or lure, item. As with the other threshold, the fact that old items cannot cross the low threshold suggests that they cannot be recognized as new in the same sense that truly new items can be. Although there are two thresholds, a single criterion is used in a typical old/new recognition experiment, just as it would be in the HT model (and in an ROC experiment, there would be the usual n–1 criteria for an n-point scale).

The HLT model generates ROCs very similar to those generated by the HT model, except that the right end of the ROC moves up and intersects the upper x-axis at a point that is $R_L$ from the 1,1 intercept (see **Figure 2**). Thus, like the HT model, the HLT model predicts linear ROCs that are U-shaped in z-space, but it is not constrained to generate an asymmetrical ROC. In fact, the degree of ROC asymmetry can vary independently of overall performance. If $R_T$ is greater than $R_L$, then the ROC will have a slope less than 1; if $R_T$ is less than $R_L$, then it will have a slope greater than 1; and if the two parameters are equal, then the ROC slope will be equal to 1 (i.e., a symmetrical ROC).

Although the HT and HLT models predict linear ROCs, it is possible to produce various nonlinear ROCs by introducing additional parameters or thresholds. For example, Luce (1963) proposed a 'two-state high-threshold' model that produces an ROC made up of two joined linear segments (also see Green, 1960; Norman and Wickelgren, 1965). In fact, by adding multiple steplike thresholds or decision rules, one can produce an ROC that is effectively curvilinear (e.g., Krantz, 1969; Buchner et al., 1995; Malmberg, 2002). However, the latter approach is rarely adopted because it requires an additional free parameter for each new threshold (Hilford et al., 2002). Nonetheless, a consideration of these models is important because it shows that, although ROC experiments may prove useful in testing specific threshold models, results that disconfirm one threshold model may not be problematic for another. Here, we focus on the HT and HLT models because they are the two most commonly adopted threshold models.

There is one important caveat about using tests of linearity to assess the threshold models. Technically, the HT and HLT models (and models in which these theories are nested, such as some of the dual-process models discussed later) predict ROCs that are kinked at their extremes. That is, for both models, the ROC is linear until it intersects the y-axis, at which point it is forced to drop and approach the 0,0 intercept (see **Figure 2**). This occurs when the response criterion moves to the right of the threshold (the high one for HLT), so that false alarms are at zero and the hit rate drops as the criterion becomes more and more strict (i.e., moves further to the right). For the HLT model, the same will also occur as the response criterion becomes very lax (i.e., moves to the left) – that is, the hit rate will reach 1.0 before the false alarm rate, and the false alarms will continue to increase until they reach 1.0 as well. This means that, if the extreme points on an ROC approach floor or ceiling levels, the ROC might appear curvilinear, even if it is perfectly predicted by a threshold model. Thus, when assessing threshold-based models it is important to determine if the extreme points in the average ROC, as well as the individual subject ROCs, are approaching floor or ceiling levels. In these cases, an evaluation of ROC linearity may not provide a valid assessment of threshold models.

Threshold theory, as a general class of models, has one core assumption: there is a sensory limit or threshold. With respect to memory, this means that, although there is a strength continuum, memory can fail. However, additional assumptions have sometimes been adopted by different theorists. Although these auxiliary assumptions do not always alter the predictions that the models make, in some cases they do. One very common assumption is that only old items can exceed the high threshold. This assumption is made in both the HT and HLT models (see **Figure 2**). Thus, the models assume that only items that have been studied can exceed the upper threshold, and that false alarms arise because the response criterion is set to the left of the threshold (likewise, only lures can cross the low threshold in the HLT model). In contrast, however, Luce's (1963) threshold model allows a portion of the new item distribution to exceed the high threshold, and thus it allows for the possibility that false alarms might arise even when the response criterion falls to the right of the threshold.

Second, it is sometimes assumed that the threshold marks a discrete boundary between conscious and nonconscious memory. For example, Fechner suggested that items falling below the threshold are not consciously perceived (i.e., they are subthreshold or subliminal) (as discussed in Boring, 1929). This assumption leads to the expectation that asking subjects to report when they are truly remembering a test item, or if they know it was studied on the basis of familiarity, such as in Tulving's (1985) remember/know (RK) procedure, might provide a way of determining the subject's memory threshold (e.g., Yonelinas and Jacoby, 1995). Thus, the $R_T$ parameter (i.e., the left y-intercept of the ROC) might correspond to the proportion of remembered items. Alternatively, the threshold may correspond to the distinction between know and new responses, if both remember and know responses are treated as forms of conscious memory. In any case, the consciousness assumption has not been widely accepted, and many discussions of threshold theory – particularly those that appeared during the 1960s and 1970s – make no direct mention of conscious experience. Thus, even if a threshold does exist, subjects may not be able to determine exactly what level of memory strength corresponds to this threshold.

Third, it is sometimes assumed that memory strength is all-or-none in the sense that items are either in a discrete and homogeneous 'remembered' state, or they are in a distinct and mutually exclusive 'not remembered' state. Indeed, the typical equations of threshold theory represent memory as a simple probability, which is sometimes interpreted as indicating that all remembered items must be alike because there is no representation of the variance in memory strength. The implication of this assumption is that subjects either remember everything about an event or they remember nothing about the event. If this were true, though, it is not clear how subjects could make meaningful confidence judgments. For instance, if threshold theory is a state theory (the idea the there are mutually exclusive, discrete, homogeneous states of memory), the depiction of threshold theory in **Figure 2** and its description here would be misleading. In the figure, the x-axis would not represent strength, or if it did, then there would be no true distribution of items along that axis. Moreover, memory decisions would not be made by setting criteria based on different strengths, as different strengths would not exist. Instead, subjects would be forced into the awkward situation of randomly responding with different levels of confidence despite their experience of a uniform level of familiarity (and hence confidence) for all remembered items. As Wickelgren put it:

> If a subject truly had only two states in his [memory] system and were faced with the problem of choosing one of six rating responses, the subject would either think the experiment or the experimenter was pretty stupid, or else that there was something wrong with him or his understanding of the task. In either case, it is not clear what his decision rule would be. (Wickelgren, 1968: 129; but see Krantz, 1969, for an alternative view)

Thus, if threshold theory is indeed a state theory, it may not be useful to use confidence-based ROCs as a means of testing it. However, various theorists, including Fechner, have argued that sensation strength can vary continuously and be subject to a threshold (e.g., Fechner as described in Boring, 1929; Swets, 1961; Krantz, 1969), and confidence-based ROCs have been used extensively to test the threshold models (but see Malmberg, 2002, for an argument concerning the usefulness of ROCs in deciding between continuous and state theories). So although the all-or-none assumption is sometimes adopted, it is not a necessary assumption of threshold theory in general.

Fourth, threshold theory is sometimes interpreted as indicating that there is a non-mnemonic process such as 'random guessing' or 'noise' that contributes to performance in addition to a true memory retrieval process (e.g., Batchelder and Riefer, 1990). The idea is that if an item's strength exceeds the threshold, then memory is successful and the item will be remembered, whereas if its strength falls below the threshold, then memory fails and the item will not be remembered. In the latter case, the item might still be accepted as old on the basis of some non-mnemonic process such as a guess or a response error. Although it seems reasonable that subjects might guess or make response errors, the proposal that these errors are due solely to such non-mnemonic processes is not a necessary assumption of threshold theory in general. That is, all responses could be based on memory strength, but because the old and new item distributions can be completely overlapping at points below the threshold, accepting items below the threshold becomes functionally equivalent to guessing or random responding.

### 2.23.3.3 Evaluation

The threshold models provide a poor account of recognition memory. This evaluation is based on their predictions of linear ROCs and U-shaped zROCs. First, in tests of item recognition there is no evidence for the threshold that serves as the core of threshold theory. That is, item ROCs are not linear as predicted by the models, but are instead curvilinear and have an inverted U shape. This pattern was first reported by Egan (1958) (see **Figure 3**) and has now been observed in countless experiments (for earlier discussions of this finding see Egan, 1958; Murdock, 1974; Ratcliff et al., 1992, 1994; Glanzer et al., 1999). Moreover, item recognition ROCs are linear when plotted in z-space, in contrast to the U-shaped zROCs predicted by the threshold models. Although slight deviations from linearity in z-space have been reported in item recognition studies (e.g., Ratcliff et al., 1994; Yonelinas, 1997, 1999a; Heathcote, 2003), the zROCs are almost never as U-shaped as the threshold models predict.

There are, however, some aspects of the ROC data that are consistent with the threshold notion. For example, the HT model predicts that as performance increases the ROCs should become more asymmetrical (z-slopes should drop), and there are variables, such as levels of processing and list length, that do result in this pattern (see **Figure 4**; e.g., Yonelinas et al., 1996; Glanzer et al., 1999). However, other manipulations,

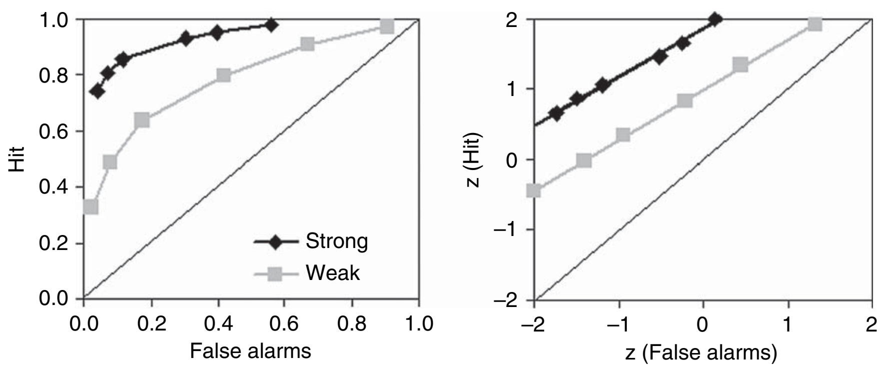

**Figure 3** Item recognition ROCs for weak (one presentation) and strong (two presentations) items plotted in probability space (on the left) and in z-space (on the right). The figure illustrates that item ROCs are (a) curved downward in probability space, (b) linear in z-space, and (c) asymmetrical along the chance diagonal and thus (d) they have a slope in z-space of less than 1.0. Further, the slopes of the two zROCs are the same, but sensitivity differs between conditions. From Experiment 1 (Figure 20) in Egan JP (1958) Recognition memory and the operating characteristic. *USAF Operational Applications Laboratory Technical Note.* No. 58–51: 32. Hearing and Communication Laboratory, Indiana University.

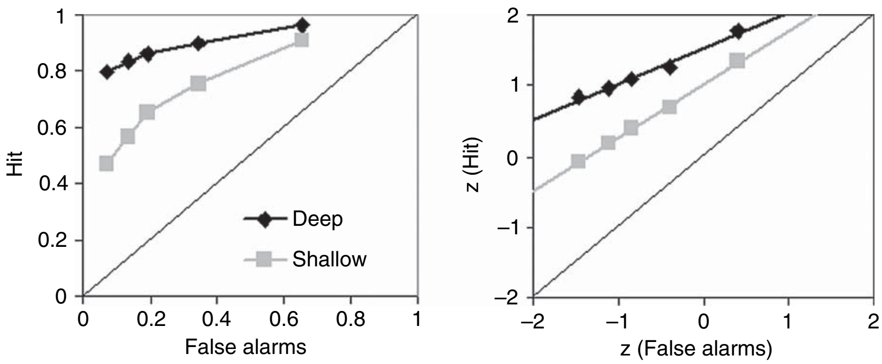

**Figure 4** Item recognition ROCs and z-ROCs for items encoded deeply or shallowly. Both the z-slope and sensitivity differ between conditions. From Experiment 1, Yonelinas AP, Dobbins I, Szymanski MD, Dhaliwal HS, and King L (1996) Signal-detection, threshold, and dual-process models of recognition memory: ROCs and conscious recollection. *Conscious. Cogn.* 5: 418–441.

such as study repetition, increase performance but do not affect symmetry (e.g., Glanzer et al., 1999), which presents problems for the HT model. However, the HLT model, which includes two thresholds and so can vary the degree of asymmetry independently of overall performance, is consistent with these aspects of the recognition results.

In addition, linear ROCs have been reported in several studies of relational recognition tasks, such as test of source or associative recognition (e.g., Glanzer et al., 1999; Yonelinas, 1999a; Rotello et al., 2000; Arndt and Reder, 2002). These linear ROCs are consistent with the threshold predictions and suggest that, at least in relational tests, subjects do sometimes fail to retrieve the relevant information altogether (i.e., items fall below threshold). In direct contradiction to threshold theory predictions, though, curved ROCs have also been reported in other relational recognition experiments (e.g., Yonelinas, 1999a; Qin et al., 2001), and therefore these models do not provide an adequate account of relational recognition performance either.

There are various other ROC results discussed in the following sections that present additional problems for the threshold models, but the item and relational ROC results noted here have led most researchers to reject the threshold models as viable accounts of recognition memory.

## 2.23.4 Signal Detection Models

Signal detection theory (e.g., Tanner and Swets, 1954; Swets et al., 1961) is a statistical decision model that has been applied to studies of item recognition (e.g., Egan, 1958; Murdock, 1965; Parks, 1966; Banks, 1970) and source recognition (e.g., Marsh and Bower, 1993; Hoffman, 1997). In item recognition tasks, it is assumed that studied items have greater memory strength than nonstudied items, but there is variability in memory strength such that the old and new items form overlapping Gaussian (or normal) distributions as in **Figure 5**. The distance between the old and new distributions measured in z-scores is *d′*, which represents how much stronger the studied items are than the new items. Recognition decisions in standard old/new tests are made by setting a response criterion equal to some level of memory strength and responding ‘old’ only to items exceeding that criterion; in confidence-rating tests, decisions are made by placing n–1 criteria along the memory strength axis for an n-point confidence scale.

The core assumption that all pure signal detection models share is that the strength distributions of old and new items are normal (or Gaussian) in shape. The Gaussian shape of these distributions gives rise to curved ROCs that are perfectly linear when plotted in z-space, and thus the linearity of empirical zROCs can be used to test this assumption (see **Figure 5**). The reason Gaussian distributions produce curvilinear ROCs is because changes in response criteria result in disproportional changes in the hits and false alarms. When the response criterion starts off as strict (very far to the right), changes (moving to the left) will have large effects on the proportion of the old item distribution that will be recognized, but relatively modest effects on the proportion of the new item distribution that will be recognized. In contrast, as the response criterion

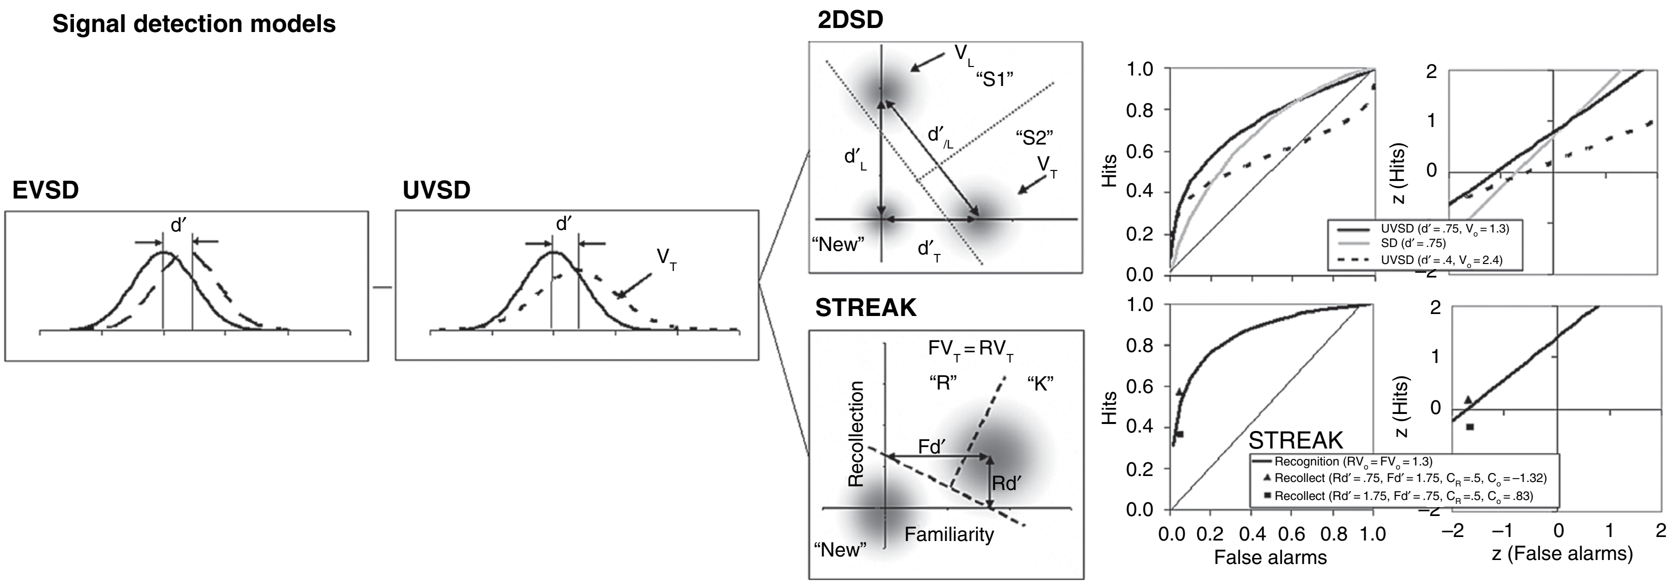

**Figure 5** Strength distributions and predicted ROCs and zROCs for the signal detection models, including the equal-variance signal detection (EVSD), unequal-variance signal detection (UVSD), two-dimensional signal detection (2DSD), and sum-difference theory of remembering and knowing (STREAK) models. Predicted ROCs on the left are plotted in probability space and the ROCs on the right are plotted in z-space. Adapted from Yonelinas AP and Parks CM (2007) Receiving operator characteristics (ROCs) in recognition memory: A review. *Psychol. Bull.* 133: 800–832, with permission.

becomes more and more lax, changes will have larger effects on the proportion of new items that are recognized and decreasing effects on the proportion of old items that are recognized. Thus, the slope of the ROCs starts off very steep, but then starts to decrease and eventually levels out as the false alarm rate increases, leading to a curvilinear ROC.

The primary theoretical difference between the signal detection models and the threshold models is that the signal detection models assume that memory can never truly fail. That is, signal detection models assume that there is a memory signal that always provides some useful information. Therefore, signal detection models eschew the idea that memory is probabilistic (i.e., it succeeds or fails) and instead treat memory as deterministic, meaning that there is a memory signal for every item encountered – or essentially, that memory is always successful, even if it does not always return a strength value that leads to an accurate response.

#### 2.23.4.1 Equal-Variance Signal Detection Model

The equal-variance signal detection (EVSD) model is the simplest signal detection model (see **Figure 5**), because it includes only one parameter – the accuracy measure $d'$, the difference in average strength of the new and old item distributions. The model assumes that the variance of the targets' strengths is equal to that of the lures. Because the old and new distributions are assumed to have the same shape, the model generates a symmetrical ROC that has a slope of 1.0 in z-space. Thus, assessing the slope of the zROC provides a direct test of the equal-variance assumption.

Although the core assumptions underlying the EVSD model are the Gaussian and equal-variance assumptions, a number of auxiliary assumptions have sometimes been adopted. For example, many theories have assumed that the memory signal reflects a continuous scalar index of memory strength or familiarity (e.g., global memory models such as TODAM (Murdock, 1993) and SAM (Gillund and Shiffrin, 1984)). Alternatively, the memory signal could also reflect how many different aspects or features of the test item are remembered, or it may reflect the products of two or more separate memory processes such as recollection and familiarity (e.g., Johnson et al., 1993; Wixted and Stretch, 2004; Wixted, 2007). Another assumption, which is often adopted in order to account for subjective reports of remembering and knowing (Tulving, 1985), is that remember responses simply reflect stronger or more confident memories than know responses (e.g., Donaldson, 1996; Hirshman and Master, 1997; Dunn, 2004). Thus, when RK scores are plotted in ROC space they should fall along the same symmetrical ROC that is expected in item recognition, with the remember point (i.e., the proportion of correct remember responses vs. the proportion of incorrect remember responses) falling to the left of the recognition point (i.e., remember plus know responses).

#### 2.23.4.2 Unequal-Variance Signal Detection Model

The unequal-variance signal detection model (UVSD) is probably the most common signal detection model of memory (see **Figure 5**), and it includes a distance measure between the means of the two distributions (similar to $d'$; see Wickens, 2002; Macmillan and Creelman, 2005, for details on accuracy measures for the unequal-variance model), as well as a second component: the variance of the old item distribution relative to the new item distribution ($V_T$). If the old item variance is greater than that of the new distribution, then the ROC will appear to be pushed up on the left side, as in **Figure 5**. If the old item variance is less than that of the new item distribution, the ROC will be pushed up on the right side (this is not illustrated, and it is rarely observed). Like the EVSD model, the UVSD model predicts curved ROCs that are linear when plotted in z-space. However, because the old item variance can vary, the model can produce asymmetrical ROCs (i.e., slopes in z-space greater or less than 1.0) – thus the variance parameter can also be thought of as a symmetry parameter, because it is the $V_T$ parameter that makes an ROC symmetrical or asymmetrical. The inclusion of separate parameters for sensitivity and symmetry also suggests that the two memory components might be experimentally dissociable. That is, there may be variables that influence $d'$ while leaving $V_T$ unaffected, whereas other variables might influence $V_T$ while leaving $d'$ unaffected. However, the UVSD model does not indicate which experimental variables might produce such dissociations.

One property of the UVSD model that is often overlooked (although see Green and Swets, 1966; Decarlo, 2002) is that, if the variance of the old item distribution is greater than that of the new item distribution, the model can predict a curved ROC that drops below the chance diagonal (see **Figure 5**).

This will happen when the old item variance becomes large, and some portion of the old distribution falls farther to the left than the new distribution. Psychologically, this means that the encoding phase must have decreased, rather than increased, the memory strength of some of the studied items.

The UVSD model does not specify why the old and new variances differ, or why the old item variance almost always exceeds the new item variance (see the section titled 'Evaluation' that follows), but one common assumption is that the old distribution is more variable because of encoding variability (e.g., Hilford et al., 2002; Wixted, 2007). That is, because encoding will likely increase the strength of some items more than others, the old item distribution will be more variable than the new item distribution. Such an account predicts that the ROCs should be asymmetrical such that the z-slopes are less than 1, rather than being equal to or greater than 1. Although the encoding variability explanation seems intuitively logical and, therefore, a potentially good account of increased old-item variability, it is not technically consistent with the UVSD model. The encoding variability hypothesis describes differences in how much items increase in memory strength as a result of study, but, quite logically, does not allow for decreases. Thus, encoding variability *per se* does not lead to the expectation that the ROC should drop below the chance diagonal, as will happen whenever the old item variance exceeds the new item variance (although this is most evident when the slope gets very low).

As with the EVSD model, one can potentially explain RK reports by assuming that remember responses simply reflect high-confidence recognition responses (e.g., Donaldson, 1996; Hirshman and Master, 1997; Wixted and Stretch, 2004). The UVSD model accordingly predicts that the RK data should fall on the same function that is observed in recognition ROC studies. In contrast to the EVSD model, however, the recognition ROC can be asymmetrical.

#### 2.23.4.3 Two-Dimensional Signal Detection Model

The two-dimensional signal detection model (2DSD) is an extension of the UVSD model that is aimed at explaining performance on source recognition tests (Hilford et al., 2002; Glanzer et al., 2004; for earlier development of multidimensional signal detection models see Tanner, 1956; Macmillan and Creeman, 1991; Ashby, 1992; Banks, 2000). In this model, there are two memory strength axes or dimensions (hence the name two-dimensional), one for each source. Therefore the distribution of strengths for items presented in Source A lies along the Source A dimension, and the strength distribution for items presented in Source B lies along the Source B dimension (see **Figure 5**). New items in the recognition test lie at the intersection of these two dimensions, and therefore there is a triangular relationship between the three distributions. The model assumes that studying items in one source will increase the items' strength along that source axis in the same way that study increases average strength in the EVSD and UVSD models (e.g., study of items in Source A will push the distribution up the Source A dimension). Note that the depiction of the model in **Figure 5** has transformed a model that exists in three dimensions (i.e., in the x, y, and z planes) into a two-dimensional illustration of the model viewed from the top. The 2DSD illustration **Figure 5** is similar to a topographical map because it is assumed that one is looking down at the model. There is an unseen axis (the y-axis) for the height of the distributions that would rise from the intersection of the two illustrated axes, and the circles actually represent three-dimensional Gaussian distributions (see Wickens, 2002; Macmillan and Creelman, 2005, for good introductions to multidimensional signal detection models). Although it is not illustrated, there is actually some overlap between the distributions lying along the two axes, as well as some overlap with the new item distribution.

The 2DSD model includes five free parameters – the strength and variance of each of the old item distributions relative to the new item distribution (with items from one source arbitrarily treated as targets and items from the other as the lures: target strength ($d'_T$), target variance ($V_T$), lure strength ($d'_L$), and lure variance ($V_L$)), as well as the distance between the two source distributions ($d'_{T/L}$). The target strength and lure strength refer to the distance between each source distribution and the new item distribution, thereby providing measures of item recognition for items from each source. The distance between the two source distributions is the measure of source recognition performance. Although the two source dimensions are presented as orthogonal in **Figure 5**, the angle is generally expected to be much less than 90° to account for the observation that people are more accurate in item than in source recognition (i.e., the distance between the two source distributions is typically shorter than between either of those distributions and the new item distribution). In general, there are not enough data points available in ROC studies to allow the degree of this angle to be estimated, but it could in principle be allowed to vary as a means of measuring the relationship between source and item performance; however, this would require a novel source memory paradigm (e.g., Banks, 2000).

The 2DSD model assumes that people make item recognition decisions by setting a criterion that runs between the new item distribution and both of the old distributions (the diagonal line that runs from the upper left to the lower right in the 2DSD illustration in **Figure 5**). Source recognition decisions are made by setting another criterion that runs perpendicular to the item criterion and runs between the two old source distributions (the diagonal running from the upper right to the lower left).

In addition to the core assumptions of the UVSD model, the 2DSD model makes two further assumptions, one of which is simply that there are two dimensions of strength, one for each source. In addition, the model assumes that item and source judgments are based on the same underlying strength distributions and therefore predicts that performance on these tasks should be directly related. That is, manipulations that increase source recognition will also necessarily increase item recognition. Note, however, that the model does not predict exactly how closely item and source recognition will be related – that relationship will depend on the angle between the two source dimensions and the types of source information that the subject brings to bear when making the item discrimination.

The 2DSD model makes the same ROC predictions as the UVSD model. That is, because the model is based on Gaussian strength distributions, it predicts that ROCs (both item and source) should be curved in probability-space and linear in z-space. Because the model includes free parameters for the variance of the old item distributions, it can produce item recognition z-ROCs with slopes less than 1, and it can produce dissociations between ROC accuracy and asymmetry.

#### 2.23.4.4 Sum-Difference Theory of Remembering and Knowing

The sum-difference theory of remembering and knowing (STREAK) is another two-dimensional extension of the UVSD model (see **Figure 5**; Rotello et al., 2004). The STREAK model was proposed to account for RK and item recognition ROC results. In a typical RK paradigm including remember, know, and new responses, an ROC can be constructed from two points: the remember hit and false alarm pair (which will be the lower left point on the ROC) and the remember + know hit and false alarm pair (also referred to as the ‘recognition’ point because it includes all recognized items). Adding in the ‘new’ responses would result in a point constrained to be (1,1). This is the same technique used to construct ROCs from confidence scales. The STREAK model assumes that one dimension of memory strength represents global familiarity and the other dimension represents the memory strength associated with recollection of specific details associated with an item. Every item, old or new, is assumed to have both recollection and familiarity strengths (indexed as R$d'$ and F$d'$, respectively), but the old items are expected to have higher strengths than the new items, on average. There are two distributions, corresponding to old and new items. New items lie at the intersection of the familiarity and recollection axes, and the old item distribution can occupy any space between the two axes (technically it can move beyond those axes as well, but that would indicate negative memory along one or both dimensions). Strength on each dimension is represented by the distance of the peak of the distribution from the axes. Thus, recollection strength is the distance of the peak of the distribution (the center of the circle in the STREAK illustration in **Figure 5**) from the recollection axis, and familiarity strength is the distance from the familiarity axis. The old item distribution is assumed to have greater variance than the new item distribution. In fact, in order for the model to be identifiable in standard RK experiments the new item variance is set at 80% of the old item variance (this approximates z-slopes of .80, the average slope found in item recognition). In confidence-based ROC studies, though, or studies in which both RK and confidence responses are collected, the old item variance is treated as a free parameter ($V_T$). Overall, then, the model has either two or three parameters, depending on whether $V_T$ is allowed to vary or not.

STREAK assumes that people make item recognition decisions by setting a response criterion between the new and old item distributions that runs parallel to the line that would intersect the R$d'$ and F$d'$ values on their respective axes (this criterion is shown actually intersecting those points in **Figure 5**). RK decisions are made by selecting a second response criterion, which runs perpendicular to the old/new criterion, that is used to determine if the item is more remembered or more familiar. Although not evident in the illustration of the model, the sum of the recollection and familiarity strength values dictates whether a person makes an old or new response (if recollection + familiarity > old/new criterion, 'old'), whereas the difference between the two strength values is used to make the RK response (if recollection − familiarity > RK criterion, 'remember'). Conceptually, STREAK treats standard item recognition in the same way as the UVSD model, but with 'memory strength' interpreted as the sum of recollection and familiarity strengths (see also Wixted, 2007, for a similar assumption in a UVSD model). In addition, the STREAK model assumes that recollection and familiarity lie along a single continuum and that people simply select a criterion between the two extremes in order to respond in RK experiments. This model differs markedly from the other signal detection models in that it explicitly assumes that two processes underlie recognition memory and produce the components that make up 'memory strength.'

Because the model is based on Gaussian strength distributions, it predicts curved item ROCs that are linear in z-space, like the UVSD model. If the $V_T$ parameter is fixed at .80 (the new-to-old item variance ratio), it predicts asymmetrical ROCs with z-slopes of .80. However, if $V_T$ is treated as a free parameter, then the item recognition process becomes identical to that of the UVSD model. The unique aspect of this model, however, is that because RK judgments are based on different decision rules than old/new judgments, the model can produce RK z-slopes that differ from the ROC z-slopes. That is, the model can produce a remember ROC point that can fall below, above, or along the regular item ROC, whereas the remember + know point has to fall exactly on the confidence ROC because it corresponds to all the items exceeding the old/new response criterion (see Figure 5). In this way, the RK-slope (i.e., the line joining the remember point to the recognition point to the right) can be greater, less than, or equal to that of the ROC slope.

### 2.23.4.5 Evaluation

The core assumption of all the signal detection models (i.e., the Gaussian assumption) is generally supported in tests of item recognition; that is, item ROCs have an inverted U shape in probability space and are approximately linear in z-space (e.g., Figures 3 and 4), a pattern that has been demonstrated repeatedly over the course of approximately 40 years. The EVSD model fails to account for the fact that z-slopes are less than 1 in item recognition, but all other signal detection models (which allow variance to differ between the targets and lures) account for this finding easily.

However, the results of relational recognition experiments present a challenge to all the signal detection models. ROCs in relational recognition tests can be either linear or curvilinear in probability space, but unlike item recognition, they are almost always U-shaped in z-space. For example, Figure 6 presents associative ROCs for word pairs along with item ROCs for single words (Experiment 3 from Yonelinas, 1997). The item ROC is significantly concave in probability space and does not differ significantly from linear in z-space. Conversely, the

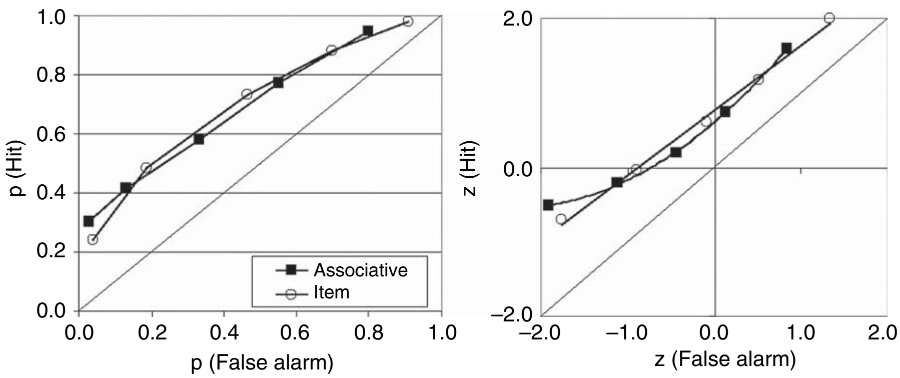

**Figure 6** Item and associative recognition ROCs. The item ROC is concave in probability space and linear in z-space, whereas, the associative ROC is linear in probability space and convex in z-space. From Experiment 3 in Yonelinas AP (1997) Recognition memory ROCs for item and associative information: The contribution of recollection and familiarity. *Mem. Cognit.* 25(6): 747–763.

associative ROC is linear in probability space and convex in z-space. Similar findings have been reported in other associative recognition studies (e.g., Yonelinas et al., 1999; Kelley and Wixted, 2001; Healy et al., 2005), in tests of source recognition (Yonelinas, 1999a; Slotnick et al., 2000; Hilford et al., 2002; Decarlo, 2003; Glanzer et al., 2004; Slotnick and Dodson, 2005), and in plurality reversed recognition tests (e.g., Rotello et al., 2000; Arndt and Reder, 2002). In fact, the regularity of the U-shaped zROCs across relational studies is quite striking. In 52 out of 59 conditions taken from 17 studies of relational recognition the quadratic coefficient was positive (Parks and Yonelinas, 2007). (The quadratic coefficient is the term of a polynomial regression equation that quantifies the degree of U-shaped curvature in a function. Positive quadratic coefficients indicate that the function is U-shaped, negative quadratic coefficients indicate that it has an inverted U shape, and 0 indicates that there is no U-shaped curvature.) Thus, the vast majority of the relational recognition studies have resulted in U-shaped zROCs. U-shaped zROCs directly contradict the Gaussian assumption of the signal detection models, and therefore indicate that they are unable to account for these data.

Although relational recognition presents a serious challenge to the signal detection models, the models are able to account for other types of recognition data, though of course some models perform better than others. The worst is the EVSD model, which can only account for inverted-U-shaped ROCs and fails to account for any other of the common findings in the recognition ROC literature. The other models, however, have had some success in accounting for some aspects of RK studies. The UVSD and 2DSD models can make the auxiliary assumption that RK responses are just confidence responses split into two categories, with 'remember' reflecting high and 'know' reflecting low confidence. Thus, the models predict that the remember and remember + know points should fall along the same ROC produced by confidence ratings. In fact, studies that have directly compared RK and confidence responses have shown that RK scores and confidence judgments typically fall along the same ROC. For example, **Figure 7** shows remember, and remember + know responses plotted along with confidence-based ROCs from the same subjects (the top function is from Experiment 1 of Wixted and Stretch (2004), and the bottom function is from Experiment 1 of Yonelinas et al. (1996)). As can be seen in **Figure 7**, the RK points fall along the same functions that fit the confidence

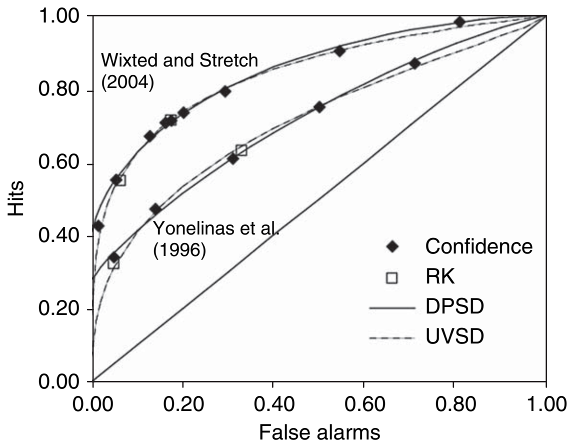

**Figure 7** Confidence ROCs and RK ROCs from Wixted JT and Stretch V (2004) In defense of the signal detection interpretation of remember/know judgments. *Psychon. Bull. Rev.* 11: 616–641 and from Yonelinas AP, Dobbins I, Szymanski MD, Dhaliwal HS, and King L (1996) Signal-detection, threshold, and dual-process models of recognition memory: ROCs and conscious recollection. *Conscious. Cogn.* 5: 418–441. The figure illustrates that when subjects make RK and confidence responses to each test item, the RK ROC points fall along the same function as the confidence ROC. The figure presents the fits of the DPSD and UVSD models and indicates that both models fit the empirical data quite well.

ROCs. Wixted and Stretch (2004) reexamined several previous studies that had collected RK and confidence judgments and found that the z-slopes from the two procedures were similar in 15 out of 16 different experiments from six different published studies. Malmberg and Xu (2006) also found that RK and confidence ROCs were indistinguishable. Overall, direct comparisons of RK and ROC results indicate that, in a vast majority of cases, sensitivity (z-intercept) and asymmetry (z-slope) are similar for recognition confidence and RK judgments and, thus, generally support the predictions of the UVSD and 2DSD models. The convergence of RK and confidence ROCs is also consistent with the STREAK model, but because it predicts that the remember point can have virtually any relationship to the confidence ROC, this convergence is not particularly useful for evaluating STREAK.

Although the UVSD, 2DSD, and STREAK models can account for the convergence of RK and recognition ROCs, all but the STREAK model are challenged by another common RK finding. Specifically, RK and confidence ratings produce very similar ROCs when they are directly compared within experiments, but in many other pure-RK experiments the z-slopes are much higher than would be expected from the item ROC literature. For example, Rotello et al. (2004) reviewed 373 published RK conditions and found that the average RK slope was close to 1.0, whereas item recognition slopes have an average around .80 (also see Dunn (2004) for a similar analysis), and in many cases the RK z-slopes were well above 1.0, something almost never seen in item recognition studies. Thus, the RK results are not always consistent with those from recognition ROC studies. Although the materials and test procedures may differ across the RK and ROC studies, thus complicating the comparison of the z-slopes, it is difficult to attribute the observed differences to this factor alone (see Wixted and Stretch, 2004).

To account for high RK z-slopes, Rotello et al. (2004) proposed the STREAK model, which can produce different slopes for confidence and RK studies, giving it an important advantage over the other signal detection models. However, a number of alternative measurement-artifact accounts have also been put forward to account for these results. For example, the RK z-slope would be artificially increased if subjects' criterion between remember and know responses varies over trials (Wixted and Stretch, 2004). Examining the z-slopes of the aggregate data (e.g., Rotello et al., 2004) rather than examining the subject-level z-slopes can also artificially increase the RK z-slope (Malmburg and Xu, 2006). Finally, Parks (2007) suggested that the remember responses might fall below the ROC if subjects adopt a strict definition of remembering such that only some aspects of the study event are treated as adequate to support a remember response. However, as of yet, none of these hypotheses have been extensively tested, and the reason for the high z-slopes remains somewhat of a mystery.

Other data that present some important challenges for the signal detection models are results from exclusion paradigms. In exclusion tests, subjects must reject or 'exclude' lures that are related in some way to the studied items or pairs. For example, on an associative test, subjects must reject rearranged pairs (e.g., 'magnet' – 'sheep,' after studying 'magnet' – 'phone' and 'corn' – 'sheep'); in conjunction tests they must reject compound words composed of previously studied words (e.g., 'blackbird,' after studying 'blackboard' and 'jailbird'); and in exclusion source tests, subjects must reject items from one source and accept only items from another source (e.g., accept only heard items as 'old' after studying both an auditory and a visual list). If unstudied items or pairs are included in the test list, then it is possible to plot the proportion of incorrectly accepted lures against the proportion of incorrectly accepted unstudied items or pairs, and this produces what we refer to as an 'exclusion ROC.' Like standard item ROCs, exclusion ROCs are curved downward, but they quickly approach the chance diagonal and in some cases pass below it. **Figure 8** presents representative exclusion ROCs from studies of source memory (Yonelinas, 1999a), word-pair recognition (Kelley and Wixted, 2001; Healy et al., 2005), and word-conjunction recognition (Lampinen et al., 2004). Each of the exclusion ROCs indicates that when subjects adopt a strict criterion they accept more lure items than new items (i.e., the ROC is above the chance diagonal), but as their criterion becomes more lax they are equally or more likely to accept a new item than a related lure item (i.e., the ROC approaches or goes below the chance diagonal). Curved, negative-going exclusion ROCs have been observed in several relational recognition experiments (Yonelinas, 1994; Kelley and Wixted, 2001; Lampinen et al., 2004; Healy et al., 2005), and the pattern appears fairly robust. Exclusion ROCs are linear in z-space, similar to item recognition, but their slopes range from .4 to .6 and, thus, appear to be considerably lower than those typically seen in item recognition tests.

The EVSD model cannot produce ROCs that cross the chance diagonal and, thus, fails once again, but the other signal detection models can account for the exclusion data. However, they do so by adopting rather questionable parameter values. For example, the UVSD model can often fit exclusion data well. However, in order to fit the conjunction data (Lampinen et al., 2004) in **Figure 8**, for example, the model parameters indicate that the study phase led to an average decrease in memory strength for the related lures ($d' = -1.20$), as well as a two- to threefold increase in the variance of the lures relative to the new items ($V_O = 2.71$). The fits of the UVSD model to the other exclusion ROCs are just as surprising. In the associative test (Kelley and Wixted, 2001), the model suggests that the study phase had virtually no effect on the average memory strength of the rearranged items (i.e., $d' = .096$), yet it almost doubled the variance of those items relative to the new pair distribution (i.e., $V_O = 1.83$), and a similar pattern was seen in the exclusion source test (i.e., $d' = 0.16$, $V_O = 1.95$; Yonelinas, 1994). These parameters indicate that the study phase increased the

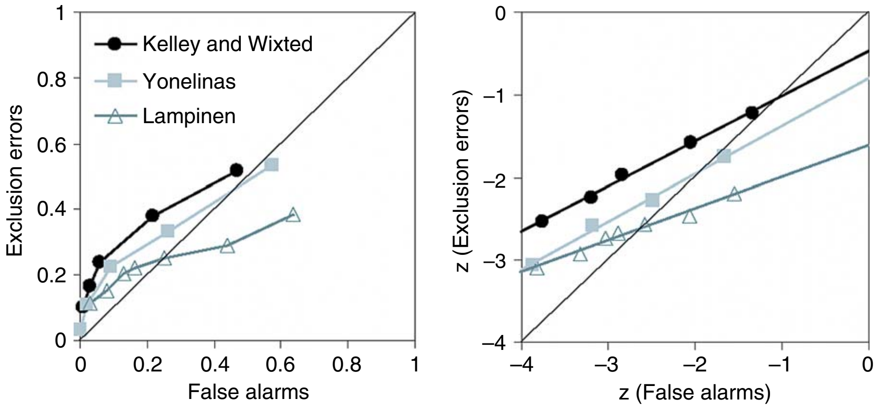

**Figure 8** Exclusion ROCs (left), which plot the probability of incorrectly accepting a related lure against the probability of accepting a new item, for (1) word-pair recognition (strong item condition from Experiment 1 in Kelley R and Wixted JT (2001) On the nature of associative information in recognition memory. *J. Exp. Psychol. Learn. Mem. Cogn.* 27: 701–722); (2) source recognition (short list condition from Experiment 1 in Yonelinas AP (1994) Receiver-operating characteristics in recognition memory: Evidence for a dual-process model. *J. Exp. Psychol. Learn. Mem. Cogn.* 20: 1341–1354); and (3) conjunction recognition (the multiple presentation condition from Experiment 2 in Lampinen JM, Odegard TN, and Neuschatz JS (2004) Robust recollection rejection in the memory conjunction paradigm. *J. Exp. Psychol. Learn. Mem. Cogn.* 30: 332–342). The exclusion ROCs are concave and negative-going in probability space. The right panel depicts the same data in z-space and shows that the zROCs are linear.

strength of about half of the exclusion items and decreased the strength of the other half, yet did not alter the Gaussian shape of the distributions. These paradoxical conclusions suggest that the model is simply not appropriate for exclusion ROCs.

## 2.23.5 Hybrid Models

Various models have been proposed that combine the assumptions of signal detection theory and threshold theory. These models assume that a signal detection process is supplemented by either a recollection process or a probabilistic attention process. Generally, these models differ from the previous models in that they assume that both types of processes (a threshold process and a signal-detection process) contribute to recognition memory. Therefore, the following models all assume that some component of recognition memory is deterministic and always successful in some sense (like the signal detection models), whereas another component is probabilistic and therefore subject to failure (like the threshold models).

### 2.23.5.1 Dual-Process Signal Detection Model

The dual-process signal detection model (DPSD) (e.g., Yonelinas, 1994, 2001) integrates signal detection theory and threshold theory within a dual-process framework of recognition memory (e.g., Atkinson and Juola, 1974, Mandler, 1980; Jacoby, 1991). The DPSD model was the first hybrid model in the recognition memory literature, and thus it has been applied to the widest range of recognition paradigms so far. The model assumes that recognition memory judgments are based on a recollection process whereby qualitative information about the study event is retrieved (e.g., where or when an item was studied), or if recollection fails, recognition is based on a familiarity assessment process like that underlying the equal-variance signal detection model (see **Figure 9**). Thus, recollection and familiarity are assumed to be qualitatively different processes that yield different types of mnemonic evidence. All items are assumed to evoke a familiarity signal, but only some items will be recollected. As such, recollection is indexed as the probability that subjects recollect some aspect of the study event ($R_T$), whereas familiarity is indexed as the increase in familiarity related to the study phase ($d'$). It is assumed that subjects can recollect different types or amounts of information about a study event, but that recollection will sometimes fail and no qualitative information will be retrieved. Because it is subject to failure, recollection is described as a threshold process. Note that recollection is assumed to have a distribution of strength, but the model does not specify what kind of distribution it

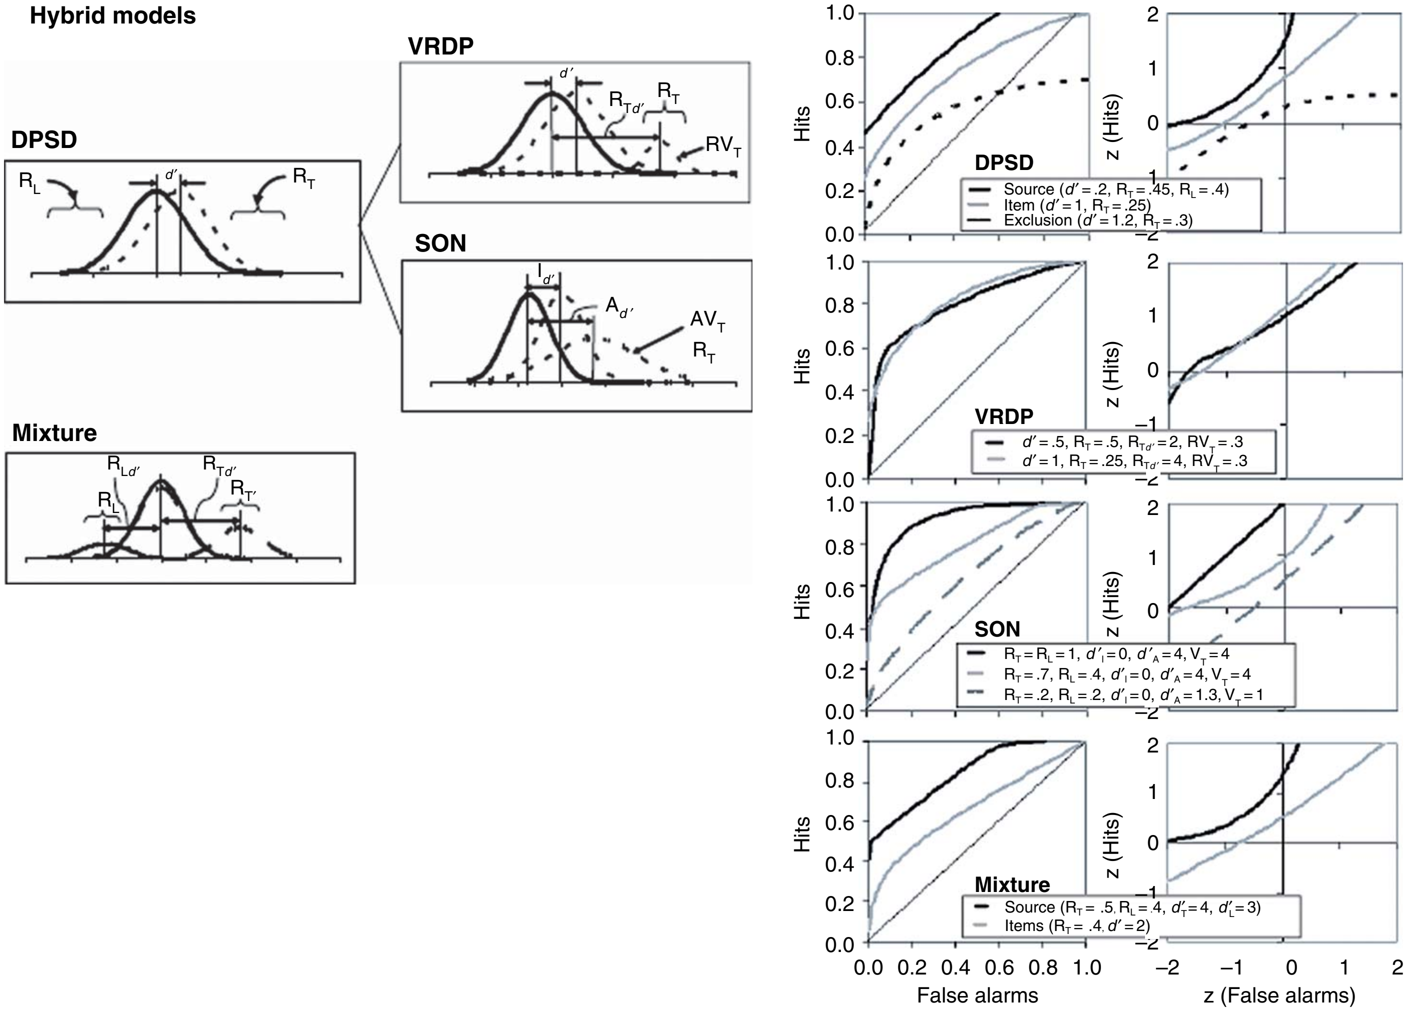

**Figure 9** Strength distributions and predicted ROCs and zROCs for the hybrid memory models, including the dual-process signal detection (DPSD), variable-recollection dual-process (VRDP), some-or-none (SON), and mixture models.

is and thus measures recollection in the probability of success (there is an arrow labeled $R_T$ pointing to an empty space in the depiction of DPSD in **Figure 9** because of this; i.e., the model doesn't specify what the recollection distribution looks like). Also, because recollection produces qualitative evidence of prior occurrence, it is assumed to lead to a relatively high-confidence recognition response. Familiarity-based responses are expected to be spread across the entire range of response confidence.

Unlike the signal detection models, which predict only curvilinear ROCs and linear zROCs, the DPSD model predicts different ROC/zROC shapes for different types of recognition depending on the relative contribution of recollection and familiarity. In tests of item recognition, the model predicts curved asymmetrical ROCs (see **Figure 9**). The familiarity component of the model leads to symmetrical curved ROCs like that of the signal detection model, but recollection increases the proportion of high-confidence recognition responses to old items and thus pushes the ROC up on the left side, making it asymmetrical. Although the predicted item ROCs are approximately linear in z-space, the threshold recollection process leads the zROCs to be slightly U shaped (Glanzer et al., 1999; Yonelinas, 1999b). However, the predicted curve for item recognition is typically so slight that it is not detectable (Yonelinas, 1999b). Overall, the two processes have different effects on ROC shape, which allows the model to predict experimental dissociations between sensitivity and symmetry. In general, both processes can increase overall performance, but recollection makes the ROC asymmetrical, whereas familiarity makes the ROC curved downward.

Because the shape of the ROC is determined by recollection and familiarity, and the functional nature of these processes has been reasonably well characterized (see Yonelinas, 2002), the DPSD model can be used to generate predictions about how different experimental variables will influence ROC shape. For example, because manipulations like deep versus shallow levels of processing and full versus divided attention increase recollection much more than familiarity, the model predicts that these manipulations should lead the z-slope of the ROCs to decrease as performance goes up. In contrast, manipulations that have comparable effects on both processes, such as study duration, should lead the z-slopes to be roughly constant as performance goes up. Additionally, because recollection is expected to be particularly disrupted in patient groups such as medial temporal lobe amnesics, the degree of asymmetry should differ for amnesics and controls, with much more symmetrical ROCs for amnesics than for controls. Further, if the hippocampus is critical for recollection, but not for familiarity (e.g., Eichenbaum et al., 1994; Aggleton and Brown, 1999; Yonelinas, 2002), an ROC analysis should indicate that individuals with selective hippocampal damage have a deficit in recollection, but not familiarity.

Because the model assumes that recollection and familiarity serve as two different bases for recognition responses, it allows recollection and familiarity to act in opposition to one another, as in exclusion tests (e.g., Jacoby, 1991), for which it predicts curved and negative-going ROCs (see **Figure 9**). For example, when subjects are instructed to accept items from one source as 'old' but to reject items from a different source as 'new,' familiarity for the to-be-excluded items will lead to a yes response and downward-curved ROCs. However, recollection, which is used to reject the excluded-source items, pushes the ROC downward. This happens because recollection decreases the number of exclusion errors (which are plotted on the y-axis instead of the hit rate in exclusion ROCs) by leading to many high-confidence rejections (i.e., many 'sure new' responses). Thus, while familiarity in the absence of recollection will result in a typical-looking ROC by leading to exclusion errors across the confidence range, recollection limits the number of errors that will be made, thereby forcing the right side of the ROC down. The resulting ROC is curved downward and crosses the negative diagonal as the familiarity response criterion is relaxed (Yonelinas, 1994; Yonelinas et al., 1995). In z-space the exclusion ROC is generally linear and will have a z-slope of less than 1.0, but with large recollection values the zROC starts to exhibit an inverted-U shape.

The DPSD model has also been applied to tests of relational recognition (see **Figure 9**; e.g., Yonelinas, 1997, 1999a). For relational recognition, an additional recollection parameter ($R_L$) is required to account for the probability of recollecting a lure item as a lure. For example, in source memory tests, the probability of recollecting items from the two different sources can be quite different; thus a separate recollection parameter is required for each source. One of the sources is arbitrarily referred to as the target source and the other as the lure source. Similarly, in associative memory tests subjects must discriminate between studied pairs (targets) and rearranged pairs (lures). Like the predicted item ROCs, familiarity leads the relational ROCs to be curved, and recollection tends to make them more linear. However, because familiarity is usually expected to play a lesser role in relational than in item recognition, and because recollection contributes to the recognition of lures as well as targets, the ROCs should be more noticeably linear, and the zROCs more U-shaped.

It is sometimes assumed that subjects are aware of recollection and familiarity, and that they can report on their occurrence (e.g., Yonelinas and Jacoby, 1995; Yonelinas et al., 1996). Remember responses are assumed to provide an indirect index of recollection and thus should be associated with high-confidence recognition responses, whereas know reports provide an index of familiarity in the absence of recollection, and thus can be associated with high and low levels of confidence. If this is the case, then the RK responses should fall along the same function as the confidence ROC. That is, the remember ROC point should fall to the left of the remember + know responses, and both points should fall along the confidence ROC. The remember point should be close to the highest confidence ROC point, but will be shifted slightly to the right if there are also high-confidence responses based on familiarity. Because the RK and ROC points should fall along the same function, the z-slope of the RK and ROC results should be comparable.

Finally, the DPSD model has also been applied to neural monitoring methods, such as ERP and fMRI methods, as well as studies of medial temporal lobe amnesics. At the most basic level, the model predicts that there should be two distinct neural signals associated with recognition performance, one related to measures of recollection and another related to measures of familiarity. In line with recent neuroanatomical models (e.g., Aggleton and Brown, 1999), the model also assumes that the hippocampus preferentially supports recollection, whereas the surrounding neocortex, such as the perirhinal cortex, supports familiarity-based recognition. Medial temporal lobe amnesics, who often have more damage to the hippocampus than to surrounding neocortex, are therefore expected to have greater recollection than familiarity deficits. The recollection deficits are expected to lead to more symmetrical ROCs than those typically seen for healthy control subjects. Finally, if the damage is restricted to the hippocampus, the model predicts that familiarity should be preserved and only recollection will be impaired.

### 2.23.5.2 Variable-Recollection Dual-Process Model

The variable-recollection dual-process model (VRDP) is a modification of the DPSD model in which recollection is assumed to be a thresholded signal detection process (see **Figure 9**; Sherman et al., 2003; for related modifications of the DPSD model also see Macho, 2004; Healy et al., 2005). As in the DPSD model, familiarity is treated as an equal-variance signal detection process ($d'$), and recollection is a threshold process in the sense that only some of the studied items will be recollected ($R_T$). The critical modification is the explicit modeling of recollective strength. Specifically, recollected items produce a Gaussian distribution with a mean level of strength ($Rd'$) and some variability around that mean ($RV_T$). Thus, items will be recognized if they are recollected and their recollection strength exceeds the response criterion, or if they are not recollected, but the familiarity strength exceeds the response criterion. Conceptually, the VRDP and the DPSD model are nearly identical. However, by allowing the variance of recollection to vary, the VRDP model allows for the possibility that recollection-based responses could receive lower confidence ratings than familiarity-based responses, contrary to the assumptions of the DPSD model. Psychologically, this would imply that recollection of contextual details sometimes produces less reliable evidence of prior occurrence than a feeling of familiarity. However, the VRDP model retains the assumption that recollection is the dominant process and, when successful, will dictate the final recognition response.

In general, the VRDP model makes the same predictions as the DPSD model. For example, the predicted item recognition ROCs are identical to the DPSD model, because if the recollection strength distribution falls above the high-confidence response criterion, then all the recollection responses lead to high-confidence responses, and the model collapses into the original DPSD model. However, if some portion of the recollection distribution falls below the high-confidence response criterion, then some of the recollected items can receive lower confidence responses. Thus, the model can produce ROCs that are slightly more curved than the DPSD model. In z-space, the ROCs are slightly U shaped across most of the range, but they can bend downward as the response criterion becomes strict (see **Figure 9**). The model is relatively new and has not been applied to many paradigms yet, and thus its predictions have not yet been specified. However, our own calculations suggest that the model is flexible enough to predict a wide array of ROC results. Nonetheless, it will clearly be important for more theoretical and empirical work to be done to further flesh out the model's predictions.

### 2.23.5.3 Some-or-None Model

The some-or-none model (SON) is another modification of the DPSD model proposed by Kelley and Wixted (2001) to account for associative recognition (see **Figure 9**). The model assumes that memory judgments are based on assessments of associative memory strength and item memory strength, both of which are signal detection processes. Kelley and Wixted use the terms item memory and associative memory, but to be consistent with the other models we use the terms familiarity and recollection, respectively. Although both familiarity and recollection are signal detection processes, the retrieval of associative information is also probabilistic, meaning that only some proportion of the pairs will be recollected, and thus recollection is also a threshold process. Because the model assumes that recollection can fail, but that it varies in strength when successful, recollection is referred to as some-or-none. The item and associative distributions each require a strength parameter ($d'_I$ and $d'_A$, for item and associative strength, respectively). The variance of the old item strength distribution is assumed to be 1.0 (equal to that of the new item distribution), whereas the variance of the old associative strength distribution is free to vary ($V_A$). The strength distributions for item and associative information are illustrated in **Figure 9**. The probability of retrieving associative information about a studied pair ($R_T$) is assumed to be greater than or equal to the probability of retrieving information about a rearranged pair ($R_L$).

Importantly, and in contrast to the other dual-process models, the SON model assumes that item and associative strength are combined and equally weighted when making associative recognition judgments. In fact, this is really the only difference between the SON and VRDP models. That is, although both models allow recollective strengths to fall below familiarity strengths, the VRDP model still assumes that recognition decisions are dominated by recollection such that successful recollection will dictate the final response. This is not the case for the SON model. In the SON model, an intact pair will be recognized if associative retrieval is successful ($R_T$) and the sum of the associative and individual item strengths exceeds the response criterion; or if associative retrieval fails but the item strength still exceeds the response criterion. In contrast, a rearranged pair will be correctly rejected if it is recollected as rearranged ($R_L$), and the item strength minus the associative strength is lower than the response criterion; or if recollection fails and the item strength is lower than the response criterion. Importantly, the resulting strength distributions for intact and rearranged pairs (which are not illustrated) form mixtures of two Gaussian distributions (item strength alone, and item plus or minus associative strength when recollection is successful); because the mixed distributions are usually not Gaussian, the model can produce nonlinear zROCs.

Kelley and Wixted (2001) argued that the variance of the associative distribution must be much greater than that of the item strength distribution in order to produce appropriate ROC results, but subsequent work with the model suggested that this was not a necessary assumption and indicated that the model could fit associative recognition without making this restrictive assumption (Macho, 2004; Healy et al., 2005). Our calculations support the latter claim.

In exploring the effects of the different parameter values on the predicted ROCs, we found that the model was capable of producing a wide variety of curved and linear ROCs at various different levels of performance (see **Figure 9**). Like threshold theory, the $R_T$ and $R_L$ parameters determine the apparent intercepts of the ROCs, and thus they control the degree of ROC asymmetry. That is, $R_T$ determines the left y-intercept, and $R_L$ determines the upper x-intercept. We refer to the intercepts as 'apparent' because the Gaussian distributions lead the ROCs to curve prior to actually intersecting the axes. In general, as associative strength increases, the predicted ROCs become more linear. This occurs because the farther apart the distributions are, the less Gaussian the mixed (item + associative) distributions will be. In contrast, as the variance of the associative strength decreases (i.e., approaches the variance of the item distribution), the ROCs become more curved. In z-space, the model predicts ROCs that have a slope less than 1.0 when $R_T$ / $R_L$. The zROCs are approximately linear but become nonlinear as associative strength increases, generally exhibiting a U shape, but bending slightly downward at extreme criterion values. Importantly, when $R_T$ and $R_L$ approach 1.0, the predicted ROC will become symmetrical, and as long as the associative strength is not too high, the zROC will be linear. That is, as recollection approaches 1.00, the mixed distribution upon which judgments are based becomes Gaussian.

### 2.23.5.4 Mixture Model

The mixture model is another extension of signal detection theory that has been proposed to account for item and source recognition (see **Figure 9**; DeCarlo, 2002, 2003; Hilford et al., 2002). In tests of item recognition, it is assumed that memory judgments are based on the assessment of item strength in a manner consistent with the signal detection model (e.g., it assumes equal-variance Gaussian memory strength distributions). However, an attentional process is also included such that only some proportion of the studied items will increase in memory strength (i.e., the attended items). Decarlo uses the term $\lambda$ (lambda) to designate the probability that a target item is attended, but to be consistent with the other models we use the term $R_T$. In this way, the new items form a normal strength distribution, but the old items form a mixture (which is not illustrated) of two equal-variance normal strength distributions (which are illustrated), one overlapping with the new item distribution and the other shifted to the right by some constant ($d'$). The one overlapping with the new items are those items that were part of the study phase but that were unattended; those that increase in strength are the items that were attended. Thus, the primary difference between this model and the previous hybrids is that it treats recognition as a simple evaluation of strength or familiarity (i.e., as a single process), and assumes that the threshold component (attention) is involved only during the study phase.

One motivating factor behind the development of this model was to avoid a perceived problem with the UVSD model, which is that the model predicts ROCs that cross the chance diagonal. As discussed earlier, the increased variance of old items relative to new items means that the study phase may have led some items to decrease, rather than increase, in memory strength. That is, it places no restriction on how the old items change in memory strength in order to achieve that greater variance. The mixture model avoids this problem by only allowing the memory strength to be increased or to remain unaffected by the study event.

The same model is used in tests of source memory except that memory strength is assumed to reflect how strongly each item matches one of two sources (**Figure 9**). That is, studying items in one source (i.e., the arbitrarily chosen 'target' source) increases source strength and shifts the items to the right ($R_T$), whereas studying items in the other source (i.e., the lure source) decreases source strength and shifts the items to the left ($R_L$). As in the item recognition model, only items that are attended at study will be associated with a change in memory strength; thus the source model requires two strength parameters and two attention parameters. Both the item and source models can be extended by adding additional parameters to allow for different levels of attention, but the effects of such modifications have not been explored.

In tests of item recognition, the model predicts asymmetrical curved ROCs that are approximately linear in z-space, with slopes less than 1.0 (see **Figure 9**). The equal-variance Gaussian distributions underlying the model lead it to generate curved symmetrical ROCs, but because only some of the old items increase in strength, this effectively increases the variance of the old item distribution relative to the new item distribution, leading the ROC to be asymmetrical and to have a z-slope of less than 1. Although the ROCs are approximately linear in z-space, the predicted zROCs can have a slight U shape and can even exhibit a subtle downward trend at the extreme criterion values. The nonlinearity arises because of the probabilistic attention process that effectively divides the old items into two distributions (i.e., the attended and unattended items). When attention is very low or high, the mixed distribution (i.e., the mixture of the attended and unattended items, which is not illustrated) is effectively normal, because nearly all items fail to increase in strength (low attention), or nearly all items do increase (high attention). At intermediate values of attention, though, the two portions of the mixture distribution will be more removed from one another, depending on the average strength of the attended items, thereby leading the overall old item (or mixed) distribution to be non-Gaussian.

In tests of source memory, the predicted ROCs are similar to those predicted in item recognition, but because there are two, rather than one, probabilistic attention parameters influencing performance, the ROCs tend to be flatter in probability space and more noticeably U shaped in z-space (see **Figure 9**).

To determine how the model's parameters influence the shape of the item ROC, we explored different parameter values and found that the degree of predicted nonlinearity in the zROC is not greatly affected by changes in attention when strength is held constant (and relatively low), except at the extremes. However, when attention is midrange, increases in strength result in more pronounced nonlinearity because the two portions of the mixture distribution move farther apart, making the resulting mixed distribution less normal in shape. In item recognition, increases in strength also produce more asymmetrical ROCs (i.e., the z-slope decreases). However, the attention parameter has a nonmonotonic relationship to z-slope. That is, intermediate levels of attention lead the old items to be distributed between the attended and unattended distributions, which increases old item variance and leads to z-slopes of less than 1.0. However, as attention either decreases toward 0 or increases toward 1.0, all the old items are forced into the lower portion (unattended) or the upper portion (attended) of the old item distribution, respectively, producing a symmetrical ROC (z-slope = 1.0).

Because the model assumes that one of the memory processes underlying the ROCs is an attentional encoding process, several general predictions can be made about the effects of different experimental manipulations on ROCs. For example, manipulations expected to influence attention at encoding (e.g., study duration, levels of processing, dividing attention, and word frequency – see Decarlo (2002, 2003) for a discussion of these variables) will not necessarily affect the degree of z-linearity, unless they result in large differences in attention and strength. However, increasing attention at study can lead to a decrease in slope (i.e., an increase of the variance of the old item distribution), then as attention increases further and goes toward 1.0 the pattern should reverse and could lead to an increase in slope (i.e., the variability of the mixed old item distribution decreases back toward that of the new item distribution). In contrast, experimental manipulations that do not affect attention during encoding (e.g., study-test delay or manipulations at the time of test) should only affect the ROCs by changing the strength parameter. Thus, these manipulations should lead the zROCs to become more nonlinear as strength increases (assuming a constant midrange attention parameter), and in the case of item recognition, the z-slope should decrease.

### 2.23.5.5 Evaluation

The hybrid models can account for item recognition as well as the relational recognition ROC data. The existing data do not clearly differentiate between the different hybrid models, although there is some suggestion that the models that incorporate recollection and familiarity process may fare best.

Because the hybrid models include a Gaussian signal detection process they can produce inverted U-shaped ROCs typically seen in item recognition and sometimes seen in relational recognition. And because they all incorporate a threshold process (recollection or attention), they can produce U-shaped zROCs found in relational recognition. Thus, the models are able to account for the shapes of the ROCs seen in both item and relational recognition studies, in both probability and z-space. Indeed, because the relative contributions of recollection and familiarity are expected to differ for the two types of tests, the hybrid models that incorporate those processes predict the different ROC shapes found in the two types of tests. The models also deal well with the variations in asymmetry found in item ROCs. For example, for the DPSD model, increases in recollection should be accompanied by increases in sensitivity and decreases in z-slope – a pattern found for manipulations such as levels of processing and divided attention (e.g., Yonelinas, 2001; Yonelinas et al., 1996). When both recollection and familiarity increase, overall sensitivity should increase too, but the degree of asymmetry should remain constant – a pattern seen with manipulations like repetition and study duration (see Glanzer et al., 1999, for a review). Because the SON and VRDP models are extensions of the DPSD model, it is likely that they too can account for these results. The mixture model can also account for these results, because it can accommodate changes in strength as well as changes in asymmetry.

The hybrid models also accurately predict the convergence found between RK and confidence ROCs when they are directly compared under the same conditions. For example, for the DPSD model, recollection is expected to lead to high-confidence responses, so the RK data should fall on the same function as the ROCs. A similar account can be provided by the VRDP model. Neither the SON nor the mixture model has been directly applied to RK results yet, but they might account for this convergence by assuming that remember responses simply reflect the strongest items.

The DPSD, VRDP, and SON models can all account for the curved and negative-going exclusion ROCs, as described earlier. Because each of these models includes separate recollection and familiarity processes that can work in opposition to each other, the familiarity component of the model produces the curvilinear shape of the ROC, and the recollection component pushes the ROC toward the chance line as the criterion becomes more lax. The mixture model has not yet been applied to exclusion data, but our simulations suggest that it is not able to account for the exclusion ROCs in its current form. That is, the model predicts that the probability of accepting a new item should always be greater than the probability of accepting a lure item in an exclusion test, and therefore the entire exclusion ROC falls below the chance line, contradicting observed data.

However, none of these hybrid models can easily account for the high RK z-slopes that are sometimes reported (e.g., Rotello et al., 2004). The DPSD model predicts that the remember point should fall on the confidence ROC function, although it may be possible that the model could account for these high slopes by incorporating a false recollection parameter (Rotello et al., 2004). If successful, then a similar modification might allow the other models to account for these data as well, but this possibility remains to be explored. If the measurement artifact accounts of this finding can be ruled out then, these results will pose a serious problem for these models, and would suggest an approach like that underlying the STREAK model might be useful.

The DPSD and VRDP models both predict that distinct neural correlates of recollection and familiarity should be found and, therefore, match the neural findings from ERP and fMRI methods to date (Eichenbaum et al., 2007). That is, ERP studies have identified two dissociable correlates of accurate recognition decisions (see **Figure 10** for an example; for reviews see Friedman and Johnson, 2000; Mecklinger, 2000; Rugg and Yonelinas, 2003; Curran et al., 2006). The first is a frontocentral negativity that onsets about 400 ms after stimulus onset, and the second is a late positive component largest over the left parietal region that arises approximately 500 ms after stimulus onset. The slower component has been linked to recollection in the sense that it is associated with (1) remember compared to know responses, (2) accurate compared to inaccurate source recognition responses, (3) accurate compared to inaccurate judgments in plurality-reversed recognition, and (4) high-confidence old responses in item recognition. In contrast, the earlier effect has been linked with familiarity in the sense that it is associated with accurate recognition, but does not distinguish between (1) remembering and knowing, (2) accurate compared to inaccurate source

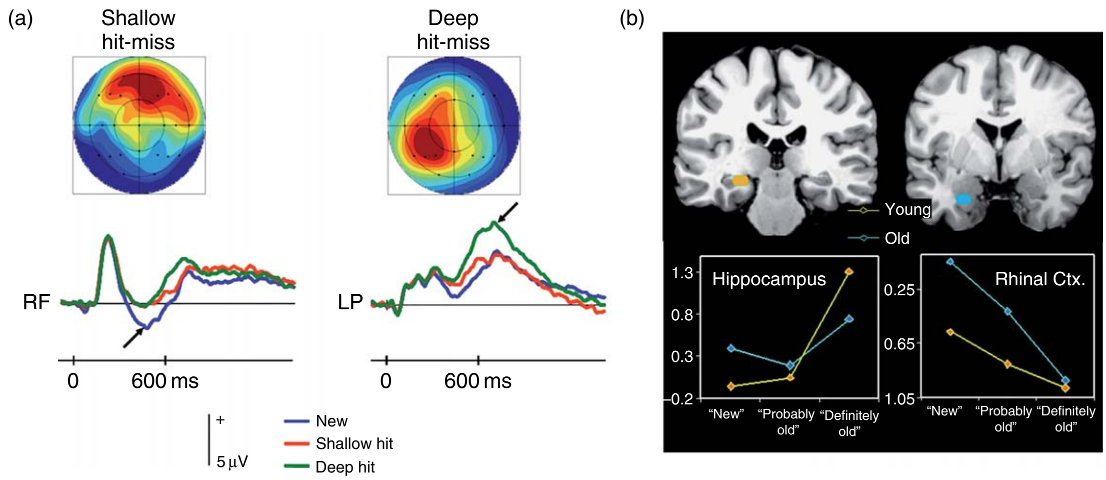

**Figure 10** (a) ERPs illustrating an early N400 negativity (left panel) associated with familiarity and a late positive component (right panel) related to recollection. From Rugg MD, Allan K, and Birch CS (2000). Electrophysiological evidence for the modulation of retrieval orientation by depth of study processing. *J. Cogn. Neurosci.* 12(4): 664–678. In this study, the familiarity effect was evident for deeply and shallowly encoded items, whereas the recollection effect was most pronounced for the deeply encoded items. (b) Neural activity related to recognition confidence. From Daselaar SM, Fleck MS, Dobbins IG, Madden DJ, and Cabeza R (2006) Effects of healthy aging on hippocampal and rhinal memory functions: An event-related fMRI study. *Cereb. Cortex* 16(12):1771–1782. Hippocampal activity was associated with high-confidence old responses, but did not change across lower levels of confidence. In contrast, rhinal activity decreased monotonically as recognition confidence increased.

recognition, (3) accurate compared to inaccurate plurality recognition judgments, or (4) high versus low recognition confidence.

fMRI studies have revealed similar dissociations (for a review see Eichenbaum et al., 2007). For example, studies using RK, relational recognition, and ROC confidence methods have indicated that recollection is consistently associated with hippocampal activation and only rarely with perirhinal activation. In contrast, familiarity is consistently associated with perirhinal activation and only rarely related to changes in hippocampal activation (see **Figure 10** for an example).

The ERP and fMRI results present challenges to the mixture and SON models. First, the mixture model assumes that recognition decisions are based solely on an assessment of familiarity strength and therefore does not deal well with the finding of dissociations between neural signals during test. Because the SON model includes two components, it can deal with these dissociations, but it assumes that recognition responses are based on the summed and equally weighted familiarity and recollection information, such that items high in memory strength may reflect any combination of familiarity and recollective strengths. Thus, the relationship seen between measures of recollection, distinct neural signals, and high-confidence recognition responses is not readily explained by the model. Specifically, because the information from the two processes is combined to make a decision, it is not clear why the neural correlates of these processes would have such specific relationships to recognition confidence.

Results from studies of medial temporal lobe amnesia also seem to be in accord with the predictions of the DPSD and VRDP models. First, studies using RK, ROC, and confidence methods of measuring recollection and familiarity have shown that patients with damage to the hippocampus and surrounding cortex have deficits in recollection and a smaller, but consistent, deficit in familiarity (e.g., Cipolotti et al., 2006; Yonelinas et al., 1998, 2002). Second, patients with damage that is restricted to the hippocampus have relatively selective recollection deficits (Aggleton et al., 2005; Yonelinas et al., 2002; but see Manns et al., 2003; Yonelinas et al., 2004, for discussion). These differences have been demonstrated experimentally in rats – damage restricted to the hippocampus produced a selective recollection deficit (Fortin et al., 2004). And in accord with the DPSD model's third prediction, amnesics' ROCs are typically more symmetrical than those of controls (e.g., Yonelinas et al., 1998, 2002; Aggleton et al., 2005; Cipolotti et al., 2006; Wais et al., 2006), and this is true even when performance is equated between the groups (e.g., Yonelinas et al., 1998). The SON model may also be able to account for these data because it includes both recollection and familiarity, but it is less clear how the mixture model would deal with these findings, because it assumes that recognition is based on a single strength-assessment process.

Overall, the DPSD, VRDP, and SON models deal with the neural findings the most easily. The DPSD has been most extensively applied to these data and specifically predicts the dissociations of neural signals, the relationship between hippocampal activity and recollection measures, as well as the differences in ROC asymmetry found in amnesics and controls. The VRDP model, as an extension of the DPSD model, can also account for these data. The SON model has not been applied to neural data, but given its similarity to the DPSD model, should be capable of handling these patterns, though whether the parameters will provide psychologically reasonable accounts is still unknown. The mixture model is the only one to face immediate challenges by the neural data. Specifically, because it assumes a single process underlying recognition performance at test, it cannot easily account for the dissociations found in the ERP and fMRI literature or for the patterns of differential deficits in amnesia.

## 2.23.6 Alternative Theoretical Frameworks

The models just evaluated represent a broad range of different theoretical approaches to recognition, but the list is hardly exhaustive. The current analysis, however, is relevant to many more current models, because many of the predictions reviewed here parallel those of models that we did evaluate. In this section we discuss the implications of the current findings to a number of these alternatives.

A number of models have adopted the assumption underlying threshold theory, such as multinomial models (for a review see Batchelder and Riefer, 1990) that are often applied to source memory tests (e.g., Bayen and Murnane, 1996; Bayen et al., 1996; Belleza, 2003). Given the poor performance of the threshold models in item recognition, it follows that the multinomial models also fail to provide an acceptable account of item recognition. The story in source recognition is a little more complicated, where it appears as though the threshold notion does work reasonably well for some source memory studies, in the sense that the ROCs can be close to linear. However, even if restricted solely to source decisions, multinomial models still seem inadequate because of the finding that source ROCs can often be curved. This indicates that the threshold notion is not entirely correct for relational recognition either. Although there may be ways of modifying the multinomial models to bring them more in line with the curved ROCs (e.g., adding more thresholds or considering different response strategies, Malmberg, 2002), it is clear that without modification those models do not provide a very good account of item or relational recognition performance.

The problems that arise for signal detection theory also have far-reaching implications, because so many current theoretical accounts of recognition memory have been built upon this framework. For example, the $d'$ statistic used to measure memory sensitivity depends critically on the validity of the Gaussian and equal-variance assumptions. Although the Gaussian assumption appears to be approximately right in tests of item recognition, it is certainly not appropriate in relational recognition tests, and the equal-variance assumption is violated in nearly every item recognition experiment (i.e., ROC slopes are less than 1.0). However, even if one opts to use $d'$ despite these problems, it is not a sufficient measure by itself – a measure of the second memory component (i.e., the variance ratio, recollection, or attention) is necessary to accurately describe performance as well. The observed ROCs are also problematic for various other models that are based on signal detection theory. For example, global memory models such as TODAM and SAM generally base recognition judgments on an assessment of a Gaussian memory strength signal, and as such they are not consistent with the U-shaped zROCs observed in relational recognition tasks. Moreover, the dissociation of sensitivity and asymmetry observed in item and relational recognition studies also presents problems for these models (for earlier discussions see Ratcliff et al., 1992; Clark and Gronlund, 1996). For example, models like SAM and Minerva 2 (Hintzman, 1984) predict that the ROCs should become more asymmetrical as performance increases, which is not consistent with what is seen with manipulations like study duration, which increase performance but not the slope. In contrast, TODAM predicts that the slope should remain relatively constant, which is not consistent with what is observed with manipulations like levels of processing, which affect both performance levels and slope. Note, however, that some of these models include recall mechanisms that might be used to supplement standard recognition in such a way as to produce non-Gaussian memory strength distributions, though it is not yet known whether such modifications would produce the observed pattern of ROC results. The SAC model of Reder et al. (2000) is another computational model (it starts at the level of representations), but one that incorporates familiarity and recollection processes. The model assumes that familiarity reflects the assessment of the activation of word nodes, whereas recollection reflects the assessment of activation of nodes that represent specific events. Both processes rely on assessments of activation in a manner consistent with signal-detection theory, so the model does not provide an account for the U-shaped zROCs, but whether it can be modified to do so is not yet clear (for discussion see Diana et al., 2006).

One computational model that appears to be consistent with the dual-process models considered is the complementary learning systems model (e.g., McClelland et al., 1995; O'Reilly and Rudy, 2001; Norman and O'Reilly, 2003). The model is based on the assumption that the hippocampus supports recollection by developing minimum overlapping representations of prior episodes, whereas the surrounding cortex gradually tunes populations of cortical units to respond strongly to different stimuli in such a way that it can discriminate between familiar and new items. A review of the model goes beyond the scope of the current paper (for a detailed discussion see Norman and O'Reilly, 2003), but the results from preliminary simulations are promising, because they indicate that the model can account for the differential importance of hippocampal versus the surrounding neocortex in recollection and familiarity and successfully predicts behavioral properties of recollection that other computational models have not (Elfman et al., unpublished data). For example, the hippocampus produces a threshold output such that it can produce linear ROCs, whereas the cortex produces curvilinear ROCs. It is not yet clear whether the model is able to account for the full body of results that have been discussed; however, models such as this one are particularly promising, because they aim to incorporate the behavioral and neuroanatomical knowledge about recollection and familiarity within the same theoretical framework.

## 2.23.7 Conclusions

In this chapter, we have examined several quantitative models of recognition memory, highlighting their assumptions and predictions, and finally focusing on how well those predictions have been supported by the data. The evidence strongly disconfirms the pure threshold and signal detection models. Pure threshold models fail outright in nearly every recognition domain. Although there are some sets of relational recognition data that threshold theories can adequately describe, they still fail to explain the wider range of findings of both linear and curvilinear ROCs. Pure signal detection models fare better than the pure threshold models, but they too face a fairly overwhelming challenge. They are unable to deal with curvilinear zROCs and therefore cannot account for the relational recognition results, including source, associative, and plurality-reversed recognition. However, they may still be relevant in particular tasks – for instance the UVSD model accounts for item recognition very well, and STREAK can account for nearly any RK pattern found. In our view, though, a model aimed at describing recognition performance should be aimed at more than a single task, especially given that there are several models which do so already.

The examination of ROC data from a wide range of recognition memory paradigms also indicates that single-component models of recognition memory are inadequate, and that there are at least two functionally and anatomically distinct component/processes involved in recognition. To account for ROC results, current models have incorporated several different theoretical divisions such as the distinctions between recollection/familiarity, item/associative information, attention/familiarity, and strength/variance. Although there is support for all of these distinctions, in general, only the hybrid models assuming the contribution of signal detection and threshold processes were successful at accounting for the existing literature (e.g., recollection/familiarity; attention/familiarity).

Although the existing results argue strongly against pure threshold and pure signal detection models and strongly in favor of the hybrid models, the current review does not provide definitive evidence for the superiority of one hybrid model over the others. And importantly, models that produce non-Gaussian distributions by means other than including both signal detection and threshold processes have yet to be seriously explored. Our hope, however, is that in examining the theoretical background and core assumptions of the existing models we have come to more clearly see which classes offer the most promise in explaining the data, as well as the important empirical and theoretical questions that need to be answered. In so doing, we hope that the next phase of ROC research will focus on testing competing predictions of these various hybrid models and lead to a deeper understanding of recognition memory.

# 2.24 Memory Search: A Matter of Time

**W. E. Hockley**, Wilfrid Laurier University, Waterloo, Ontario, Canada

## 2.24.1 Introduction

> In short, we make search in our memory for a forgotten idea, just as we rummage our house for a lost object. In both cases we visit what seems to us the probable neighborhood of that which we miss. We turn over the things under which, or within which, or alongside of which, it may possibly be; and if it lies near them, it soon comes to view. (William James, 1890: 290)

In most instances, memory retrieval occurs in a seemingly automatic and effortless fashion, as when we recognize an acquaintance or type in a password. These successful, and underappreciated, acts of retrieval suggest memory is a direct, immediate, content-addressable type of filing system. That is, we do not appear to engage in a search of memory in the literal sense of the term. There are occasions, though, when the desired information does not come easily to mind, and we then must engage in a more conscious and effortful interrogation of memory, as in William James' example above. Everyone has, from time to time, tried to remember where they parked their car in a busy lot, or what that funny joke was they heard last week. A salient feature of these types of retrieval attempts is that they seem to involve a search of memory that takes some appreciable amount of time.

Many researchers have measured response time (or reaction time or response latency; hereafter termed RT) in different memory tasks as a means to try to identify the nature of the underlying retrieval processes.

The measurement and interpretation of response time have a long history. For example, Donders (1868/1969) proposed a method to measure the time it takes to complete a particular set of mental processes, and Jastrow (1890) argued that, by working backward from response time, one might be able to infer the particular processing structures that were used to perform the task. Luce (1986) and Welford (1980) discussed the broader use of response time to study cognitive processes and the detailed methods used in the analyses of response times.

In this chapter we review the analyses of RT for different tests of explicit memory as a way to examine and compare different characteristics of intentional memory search and retrieval processes. Measures of RT and response accuracy are sometimes viewed as complementary because they often show the same effects, suggesting that they are reflections of the same underlying processes. These measures, however, are not equivalent because some variables can have large effects on accuracy but have little or no effect on response latency (e.g., Rohrer and Wixted, 1994), and RT can be highly informative when accuracy is perfect (e.g., Mewhort and Johns, 2000). The problem of speed–accuracy tradeoffs can also lead to incorrect interpretations of RT if error rates across conditions are not considered (e.g., Pachella, 1974; Wickelgren, 1977). Thus, one should be cautious in considering only one of these two measures of performance. See Kahana and Loftus (1999) for a review and comparison of accuracy and RT in the study of memory. The measurement and analysis of RT include mean RT, the analysis of RT distributions, and speed–accuracy tradeoff functions. These measures will be considered in turn for the principal tasks that have been used to study different features of human memory – item recognition, associative recognition, cued recall, and free and serial recall.

## 2.24.2 Item Recognition

### 2.24.2.1 Item Recognition for Subspan Lists

The beauty of Helen of Troy is said to have launched a thousand ships. It might also be the case that Sternberg's (1966) classic study of memory search in short-term memory launched a thousand experiments. In Sternberg's procedure, participants view short lists of items (usually one to six) presented one at a time. Each list is followed by either an old or new test probe. Participants are instructed to respond whether or not the probe is a member of the preceding study set as quickly as possible while minimizing errors. In the varied-set version of this procedure there is one test following each list, and list length varies over trials. In the fixed-set variant, a given list is prememorized and followed by a series of test probes, and this process is repeated for lists of different lengths. Because the lists are less than the span of immediate memory, accuracy is very high, and RT is the primary dependent measure.

Sternberg found the same pattern of results in both the varied- and fixed-set versions of this task: RT increased in a linear fashion with the number of items in the memory set for both correct old and new decisions. This pattern of results has been replicated many times by many different researchers. An example of the linear RT set size function for the varied-set version of the Sternberg task is shown in the left panel of **Figure 1**. The linearity of the memory set function is not affected by considerable practice at the task (Kristofferson, 1972) and is found for a wide range of stimulus materials – letters, digits, faces, geometric shapes, colors, and words (cf. Sternberg, 1975), suggesting that this result reflects a basic property of the short-term memory search process.

Sternberg (1966, 1969) proposed that these results reflect a high-speed serial search process. That is, the probe item is compared to each item in the memory set one at a time. The time for each individual comparison is given by the slope of the function relating RT to set size, which is typically in the range of 35 to 40 ms per item. Such a search rate is indeed extremely fast – in the order of 25 items per second. The comparison process was also assumed to be exhaustive such that the probe is compared with every item in the memory set before a single yes or no match decision is made. This assumption is based on the finding that the slopes of the correct 'yes' and 'no' memory set functions are parallel. An exhaustive search process would seem inefficient compared to a self-terminating search process that would end when a positive match is found. Sternberg argued, though, that an exhaustive search is more efficient because it requires only one match decision following the entire comparison process as opposed to a decision after each individual comparison that would be required for a self-terminating serial search process.

The plausibility of Sternberg's exhaustive serial search process was later called into question, not on logical grounds but on empirical grounds. One problem concerned the characteristics of the underlying RT distributions. Schneider and Shiffrin (1977) noted that the variance increased more for positive than for negative responses at larger set sizes. An exhaustive search process predicts that, like mean RT, the

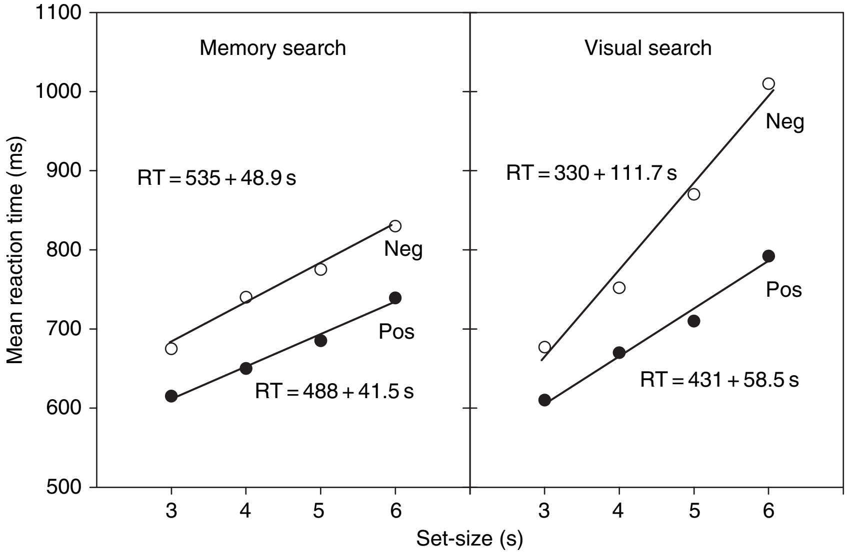

**Figure 1** This figure shows mean response time (RT) for correct positive (solid circles) and correct negative (open circles) responses as a function of set size for Sternberg's (1966) short-term search task (left panel) and Neisser's (1963) visual search task (right panel). The data are from Hockley WE (1984) Analysis of response time distributions in the study of cognitive processes. *J. Exp. Psychol. Learn. Mem. Cogn.* 10: 598–615; used with permission.

variance of the RTs should be similar for old and new responses.

Hockley (1984; see also Hockley and Corballis, 1982) analyzed RT distributions in the Sternberg paradigm using the ex-Gaussian distribution to describe the shape and the changes of the RT distributions with memory set size. Ratcliff and Murdock (1976) showed that the ex-Gaussian distribution provides a very good description of observed RT distributions for a number of recognition memory phenomena. It has subsequently been used by investigators to characterize RT distributions in a variety of cognitive tasks (e.g., the Stroop effect; Heathcote et al., 1991).

The ex-Gaussian distribution is the convolution of normal and exponential distributions and is described by the following equation:

$$f(t) = \frac{\mathrm{e}^{-(\mathrm{t}-\mu)/\tau+\sigma^2/2\tau^2}}{\tau\sqrt{2\pi}} \int_{-\infty}^{(\mathrm{t}-\mu)/\sigma-\sigma/\tau} \mathrm{e}^{-\frac{y^2}{\mathrm{d}y}}$$

where $\mu$ (mu) and $\sigma$ (sigma) represent the mean and standard deviation, respectively, of the normal distribution component, and $\tau$ (tau) represents the parameter and mean of the exponential distribution component. Although the equation appears quite daunting, this distribution is much simpler conceptually. Imagine a normal distribution, and then extend or stretch out the right tail of this distribution (examples are shown in **Figure 2** and in **Figures 8 and 12** later in the chapter). In general terms, mu reflects the left or leading edge of the RT distribution, while tau reflects the elongated right tail, or the positive skew, of the distribution. Thus, mu and tau quantify two important properties of RT distributions, namely, the minimum or fastest RTs and the spread of the distribution determined by the slowest responses.

Hockley (1984) contrasted the nature of the RT distributions in the Sternberg memory search task with a visual search task. The visual search task was based on the search experiments reported by Neisser (1963) in which participants are first presented with a target letter followed by a vertically presented set of three to six letters. Participants determined whether or not the target item was contained in the search set. The RT set size functions for positive and negative responses are shown in the right panel of **Figure 1**. The results of the visual search task were consistent with a self-terminating serial search process where the visual search proceeds from the top to the bottom of the column of letters. Correct mean RT was a linear function of the size of the search set, the slope of the function for negatives was almost twice as steep as that for positives, and the serial position functions showed a recency gradient.

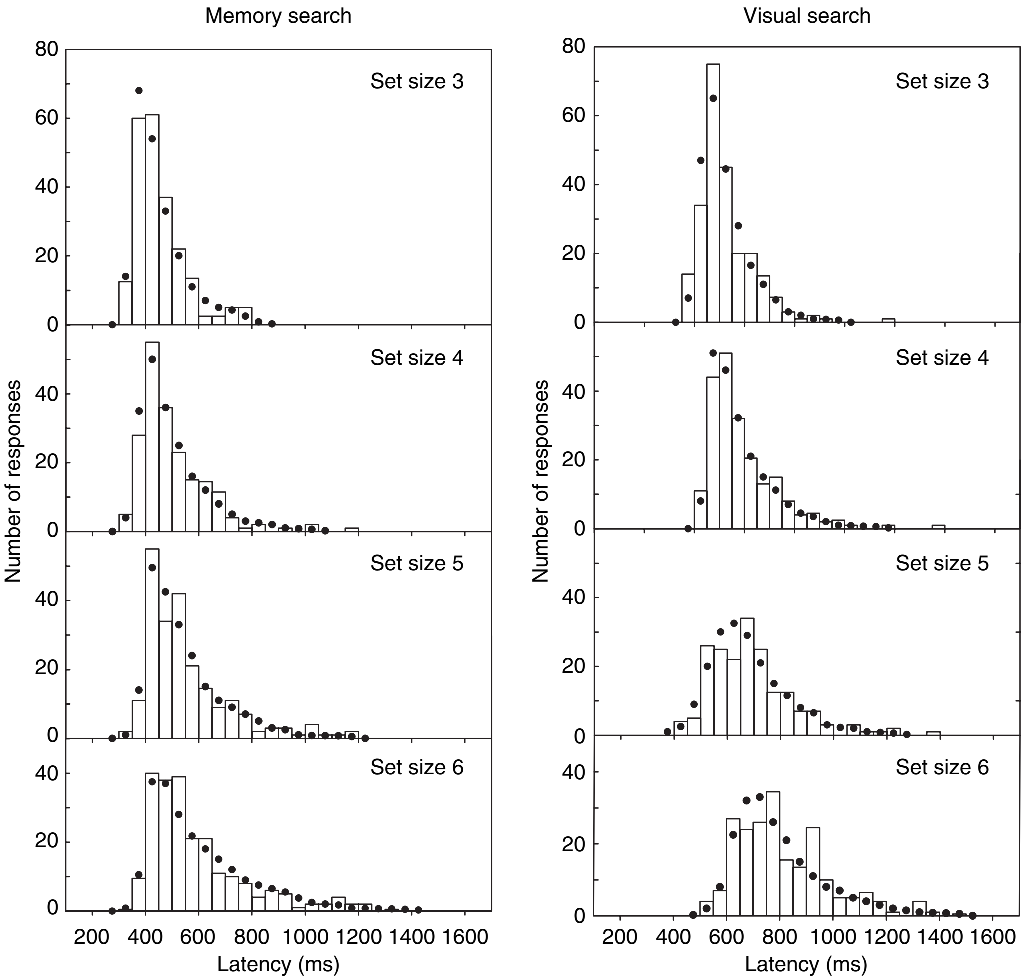

**Figure 2** The bar graphs show the observed RT distributions for correct negative responses for one participant for the memory search task and the visual search task. The fits of the ex-Gaussian distribution are shown by the dots. Data are from Hockley WE (1984) Analysis of response time distributions in the study of cognitive processes. *J. Exp. Psychol. Learn. Mem. Cogn.* 10: 598–615; used with permission.

The analysis of the RT distributions for the visual search task were also consistent with a self-terminating serial search process, as the increase in mean RT was largely captured by increases in the parameter mu, which reflects changes in the leading edge of the latency distribution, or the fastest responses. In contrast, while the pattern of mean RTs in the memory search task replicated Sternberg's findings as shown in **Figure 1**, the increase in mean RT was largely seen in the tau parameter, which reflects the increasing skew of the RT distribution, or an increase in the slower responses.

The differences in the changes of the underlying distributions in the visual and memory tasks are illustrated in **Figure 2**. This figure shows the observed RT distributions and the fits of the convolution model for correct negative responses in each task for one of the six participants in the experiment. In the visual search task the entire distribution shifts to the right as set size increases. Thus the minimum as well as the maximum RTs increase with the number of items in the search set. In contrast, the minimum or fastest RTs change very little in the memory search task, a result that is inconsistent with a serial search process. These results for the Sternberg task have been replicated more recently by Ashby et al. (1993).

A second empirical problem for Sternberg's serial search hypothesis concerned the findings of serial position effects (e.g., Corballis, 1967; Burrows and Okada, 1971; Corballis et al., 1972; Ratcliff, 1978; Aube and Murdock, 1974; Monsell, 1978; Murdock and Franklin, 1984; McElree and Dosher, 1989).

Contrary to predictions of exhaustive scanning, mean RT for yes decisions was influenced by the position of the target item in the memory set. Generally, except for a small primacy effect, these studies showed that mean RT increased with decreasing recency of the positive test probe. Monsell (1978) demonstrated that when serial position is defined in terms of recency, or the number of items intervening between study and test (test lag), the serial position functions for memory set sizes of one to five were the same for all positions except the primacy item. The coexistence of both serial-position and set-size effects led to the suggestion that set-size effects arise due to the effects of serial position (Murdock, 1971, 1985; Monsell, 1978).

McElree and Dosher (1989) replicated Monsell's (1978) recency results using the response signal version of the speed–accuracy trade-off (SAT) procedure. This procedure provides a way to examine the time course of retrieval (Wickelgren and Corbett, 1977; Corbett and Wickelgren, 1978; Wickelgren et al., 1980; Dosher, 1981). In this paradigm retrieval is interrupted at different temporal intervals (typically between 0.1 and 3 s) after the probe is presented by having participants make a recognition decision as soon as the cue to respond is given. By examining performance over the different intervals one can assess the increase in accuracy as retrieval time increases until accuracy reaches an asymptote. SAT functions are characterized by three parameters: an intercept or starting point of the function, the rate of rise from chance accuracy to asymptotic or final level of accuracy, and the asymptotic level of accuracy. The intercept provides a measure of when information first becomes available, the rise parameter indexes the rate of accrual of information over time, and the asymptote reflects the maximum level of accuracy. **Figure 3** shows McElree and Dosher's SAT functions for different serial positions for memory set sizes of 3 and 5. These functions show that serial position primarily affects the asymptotic accuracy of recognition performance. The differences in the retrieval dynamics of the functions (the intercept and rate parameters) were restricted to differences between probes from the most recent serial position (the last study item before the test probe) and all other probes. Thus, with the exception of the last item, serial position influenced accuracy but not the speed of retrieval.

One criticism of the response signal procedure is that it cannot distinguish between variable all-or-none processing and continuous accumulation of information. That is, if all of the retrieved information

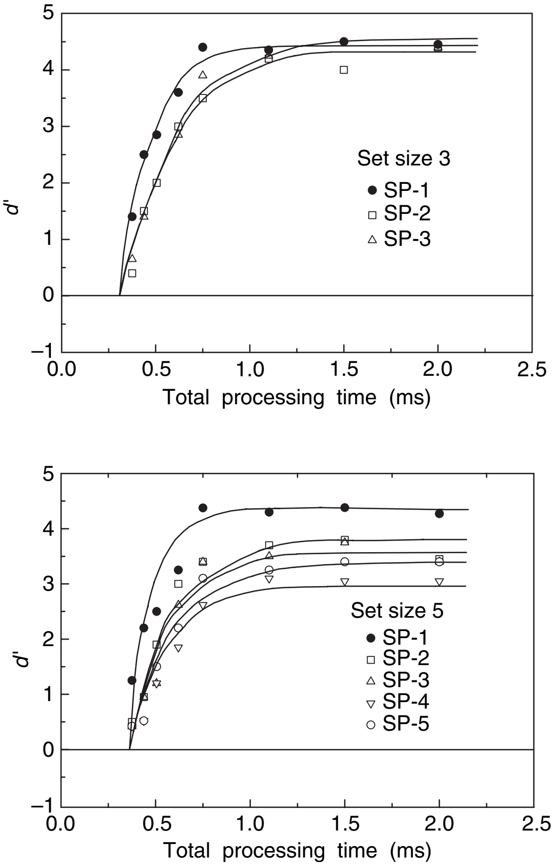

**Figure 3** This figure shows mean d' values (a measure of discrimination or sensitivity from signal detection theory; cf. Macmillan and Creelman, 2005) as a function of total processing time for each serial position for set size 3 (top panel) and set size 5 (bottom panel). The solid lines represent the best-fitting exponential SAT functions. The results are from McElree B and Dosher BA (1989) Serial position and set size in short-term memory: The time course of recognition. *J. Exp. Psychol. Gen.* 118: 346–373; used with permission.

becomes available at one time and this time is variable, the SAT curves from the response signal procedure would still increase in a gradual fashion. Meyer et al. (1988) introduced a variant of the response signal procedure – speed–accuracy decomposition (SAD) – as a way to address this problem. In the SAD procedure regular (no signal) trials are randomly interspersed with signal trials, and the RT distributions are compared (see Ratcliff (1988) and Kahana and Loftus (1999) for a discussion of these SAT procedures). These results provide support for the view that information accumulates continuously.

A third problem for Sternberg's model was the finding of repetition effects (Burrows and Okada, 1971; Baddeley and Ecob, 1973). Responses to items that were repeated in the memory set (e.g., 9 1 9 3) are faster than responses to nonrepeated items. Most damaging, perhaps, for Sternberg's serial search account were the findings of recency effects for negative probes. Both RT and accuracy suffer the more recently a negative probe on a current trial had been presented as a memory set item on a previous trial (e.g., Atkinson et al., 1974; Monsell, 1978; Hockley and Corballis, 1982; McElree and Dosher, 1989). This finding demonstrates that recognition decisions are influenced by the longer-term presentation history of the items outside the current short-term memory set, a finding that is not easily reconcilable with serial search models of immediate memory (Monsell, 1978; Ratcliff, 1978).

Van Zandt and Townsend (1993) evaluated the different classes of exhaustive and self-terminating search models in light of the results observed in the Sternberg paradigm and found that exhaustive processing models were not tenable. They concluded that self-terminating models provide the best description of rapid visual and memory search processes. A number of researchers have proposed versions of strength-based models as alternatives to Sternberg's original model (e.g., Wickelgren and Norman, 1966; Baddeley and Ecob, 1973; Murdock, 1985; McElree and Dosher, 1989). Ratcliff's (1978) diffusion model is one of the most developed and influential models illustrating this approach.

In Ratcliff's (1978) theory of memory retrieval the recognition test probe is compared to all of the items in the search set in parallel. Evidence is accumulated for each comparison based on the degree of relatedness between the probe and the memory item. This process is modeled by a continuous random walk process; positive evidence causes the random walk to approach an upper match boundary, while negative evidence drives the process downward toward a nonmatch boundary. A positive recognition decision is made when one of the comparison processes reaches the match boundary. If all the comparison processes terminate at the nonmatch boundary a negative decision is made. Ratcliff showed that this model can produce all of the findings observed in the Sternberg paradigm: linear and parallel RT set size functions, serial position effects, and the appropriate characteristics of the RT distributions and the SAT functions.

### 2.24.2.2 The Extralist Feature Effect

In Ratcliff's (1978) retrieval model, the latency of correct negative decisions depends on the slowest mismatch between the test probe and the items in memory that enter into the comparison process. Thus, negative decisions are treated as a default option that is reached when there is insufficient evidence (or strength or familiarity) to support a positive decision. Mewhort and Johns (2000; Johns and Mewhort, 2002, 2003) have recently challenged this notion. They proposed instead that correct rejections are based on information in the probe that contradicts the information represented in the study set.

Mewhort and Johns (2000) used stimuli that comprised a small number of features with finite values (e.g., a red star, a yellow triangle, etc.). Like Sternberg (1969), Mewhort and Johns used subspan study lists, and they also conditionalized the data on sure (or high confident) recognition responses to ensure that they were examining retrieval based on accurate encoding of the study items. The use of two-dimensional stimuli allowed the researchers to vary the similarity between the probe and the studied or target items. In the example given by Mewhort and Johns, a participant studies the following set of items: a blue cross, a red triangle, and a green circle. A yellow diamond would be a negative probe that does not share any features with the studied items (condition 0:0), a yellow cross or a red diamond would be a negative probe that shares one of its two features with the study set (condition 1:0), and a blue triangle or a green cross would be a negative probe that shares both of its features with the study set (condition 1:1). The similarity of the negative probe could also be varied in terms of the number of study items that share the same feature. For example, if two of the study items had the feature red, then a red star lure would share a repeated feature of the study set (condition 2:0).

Mewhort and Johns (2000; Johns and Mewhort, 2002, 2003) found that participants were fastest to correctly reject negative probes when they did not share a feature with the study set (the extralist feature effect) and became progressively slower as the number of shared features increased. That is, condition 0:0 was faster than condition 1:0, which in turn was faster than condition 1:1. In addition, the number of times a probe feature was studied did not affect RT when an extralist feature was present. That is, mean RT in condition 2:0 was similar to that of condition 1:0. This finding poses problems for familiarity-based accounts of recognition. Mewhort and Johns also showed that the extralist feature effect could be found using words as stimuli where the manipulated features were the letters within the words, and also for prememorized lists that exceeded memory span.

As Mewhort and Johns argued, these results do not support the view that correct rejections are a default decision that occurs when insufficient evidence accrues to support a positive response. Rather, the extralist feature effect shows a clear role of contradiction in recognition decisions, at least when the information supporting contradiction is available, and also perhaps when the memory set is very well-defined.

### 2.24.2.3 Item Recognition for Supraspan Lists

Burrows and Okada (1975) measured RT for memorized lists of items that varied from 2 to 20 in length. RT was an increasing function of list length. Their results were best fit by bilinear functions with the break point occurring between lists of six and eight items, the traditional measure of memory span, and they argued that these results support the view that memory search processes are different above and below short-term memory span. Burrows and Okada noted, though, that a single continuous logarithmic function also provided a good description of the relationship between RT and list length. Similar results were found by Banks and Fariello (1974), who tested memory for lists of pictures of common scenes that varied from 2 to 24.

Hockley and Corballis (1982) replicated and extended Burrows and Okada's results. They also compared conditions in which negative probes were and were not repeated across lists in a session. Their results are presented in **Figure 4**. Again, mean RT increased as a function of memory set size, and a bilinear function with the break point at memory span provided a better fit than a single logarithmic function. When negatives were repeated, the slopes of each limb of the bilinear function and the rate constant of the logarithmic function were almost doubled. The fact that this manipulation had a similar effect on both subspan and supraspan list lengths suggests that these results reflect the operation of one retrieval process rather than retrieval from different memory systems.

Similar results have also been observed in the continuous recognition paradigm. In this procedure items are repeated in a long list of items, and participants make a recognition decision for each list presentation. Thus, an item is 'new' on its first appearance in the list and 'old' on its second presentation. Accuracy decreases and response latency increases as a function of the number of items, or test lag, between the first and second presentations of an item. Hockley (1984) found that a logarithmic function provided a good description of the increase in RT with test lag that varied from 1 to 24 intervening items. Moreover, he also found that both between-list and within-list stimulus manipulations (nouns versus nonnouns) influenced the slope of the logarithmic function with no appreciable effect on the intercept, whereas item repetition decreased the intercept with little effect on the slope.

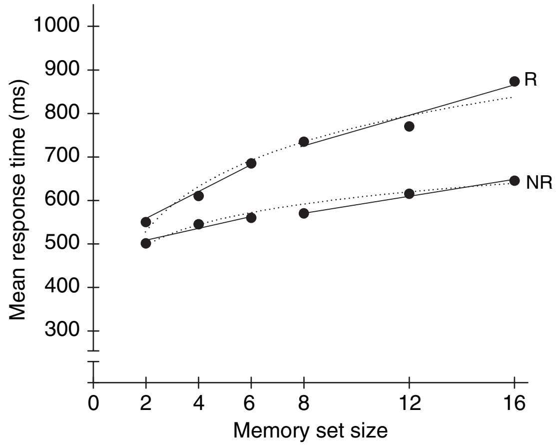

**Figure 4** This figure shows mean response time (RT) as a function of memory set size (M) for lists with repeated negatives (R) and lists with nonrepeated negatives (NR). The dashed lines represent the best fitting logarithmic functions ($RT(R) = 415 + 159 \log_e M$; $RT(NR) = 445 + 81 \log_e M$), and the solid lines show each limb of the best-fitting bilinear functions with the breakpoint at the estimate of short-term memory span ($RT(R) = 468 + 38M$, and $RT(NR) = 471 + 20M$ for set sizes 2, 4, and 6; $RT(R) = 605 + 17M$, and $RT(NR) = 522 + 10M$ for set sizes 8, 12, and 16).

Findings from the response deadline SAT procedure further support a recency or strength-based view of recognition memory over both the subspan and supraspan range. Wickelgren et al. (1980) used a single-item probe recognition task to examine the temporal dynamics of retrieval for different serial positions of 16-item lists. They fit SAT retrieval functions for three subspan serial positions (16, 15, and 14, or the last three items of the list), and three supraspan sets of items (serial positions 13–11, 10–6, and 5–3). Asymptotic accuracy decreased monotonically with the decreasing recency of the test probe's serial position, indicating that memory strength declines systematically over this range. Retrieval speed (as estimated by the intercept and rate parameters of the SAT functions), however, was constant across all serial positions exception for the last (most recent) item, which was processed 50% faster than the items from all of the other serial positions. Wickelgren et al. concluded that retrieval speed is constant except for the last item, which is in a privileged state of active awareness. (See McElree, 2001, for further evidence that the capacity of focal attention is limited to a very small number of representations, perhaps just one.)

### 2.24.2.4 Short-Term versus Long-Term Memory

Sternberg (1966) developed his subspan item recognition paradigm in order to study memory search processes in short-term or immediate memory. But is the distinction between short-term and long-term memory relevant to item recognition perfomance? When list length has been varied above and below memory span, both bilinear functions with the breakpoint at or near memory span, and continuous functions provide a good description of the increase in RT with list length or the lag between study and test (e.g., Banks and Fariello, 1974; Burrows and Okada, 1975; Hockley, 1984). Which function provides the more appropriate description of changes in RT with list length?

Three findings indicate that the continuous function provides the more meaningful description of recognition performance. First, the effects of repeating items from previous trials (e.g., Monsell, 1978; McElree and Dosher, 1989) show that recognition is not solely based on the current contents of short-term memory. Second, manipulations have similar effects on subspan and supraspan list lengths and have been shown to differentially affect the intercept and slope parameters of the continouous span functions (e.g., Hockley and Corballis, 1982; Hockley, 1984). Finally, results from the response-signal SAT procedure show that retrieval speed is constant below and above span except for the most recent item which appears to be in a privileged state of awareness (Wickelgren et al., 1980; McElree and Dosher, 1989; McElree, 2001). All of these results indicate that, with the possible exception of the most recent item, recognition proceeds in the same fashion above and below memory span.

### 2.24.2.5 Regularities of Item Recognition

Ratcliff and Murdock (1976) summarized a number of functional relationships between accuracy and response latency obtained in the study-test recognition paradigm. These relationships are shown in **Figure 5**. They provide a set of benchmarks that any model of recognition performance must be able to accommodate. In general, changes in mean RT mirror changes in accuracy. Accuracy increases while mean RT decreases with the confidence of the recognition decision. Accuracy and RT for high-confidence responses change in a complementary fashion as a function of output (test) and input (study) position and the number of study presentations of the items. Correct 'new' decisions (correct rejections) are almost as fast as correct 'old' decisions (hits). In addition, the changes in mean RT are seen to a greater extent in the tau parameter (the measure of skewness or variance) than in the mu parameter (minimum latencies) of the ex-Gaussian analysis of the RT distributions. As discussed previously, similar effects of recency, repetition, and list length effects, and changes in RT distributions and SAT functions have been observed in item recognition for subspan lists, indicating that these effects are basic characteristics of recognition memory.

Ratcliff (1978) showed that his diffusion model could not only fit the pattern of results found in the Sternberg paradigm, but also provide an impressive account of the accuracy and latency results obtained in the study-test paradigm and illustrated in **Figure 5**, as well as results from the prememorized list and continuous recognition procedures. Ratcliff's diffusion model is a formal theory of the retrieval and decision process, but it does not provide an account of how items are represented in memory or how they are compared. Nevertheless, the diffusion model can be incorporated into models that do make explicit assumptions concerning how items are represented and compared, such as Gillund and Shiffrin's (1984) search of associative memory (SAM) model and Hintzman's (1988) MINERVA 2 model.

A more recent regularity of recognition memory is the mirror effect (Glanzer and Adams, 1985, 1990). This effect refers to the finding that, when two classes of stimuli, A and B, are compared and class A is more accurately recognized than class B, the difference in accuracy is seen both in terms of a higher hit rate for class A old items and a lower false alarm rate for class A new items. If one thinks in terms of the underlying distributions representing the strength of the old and

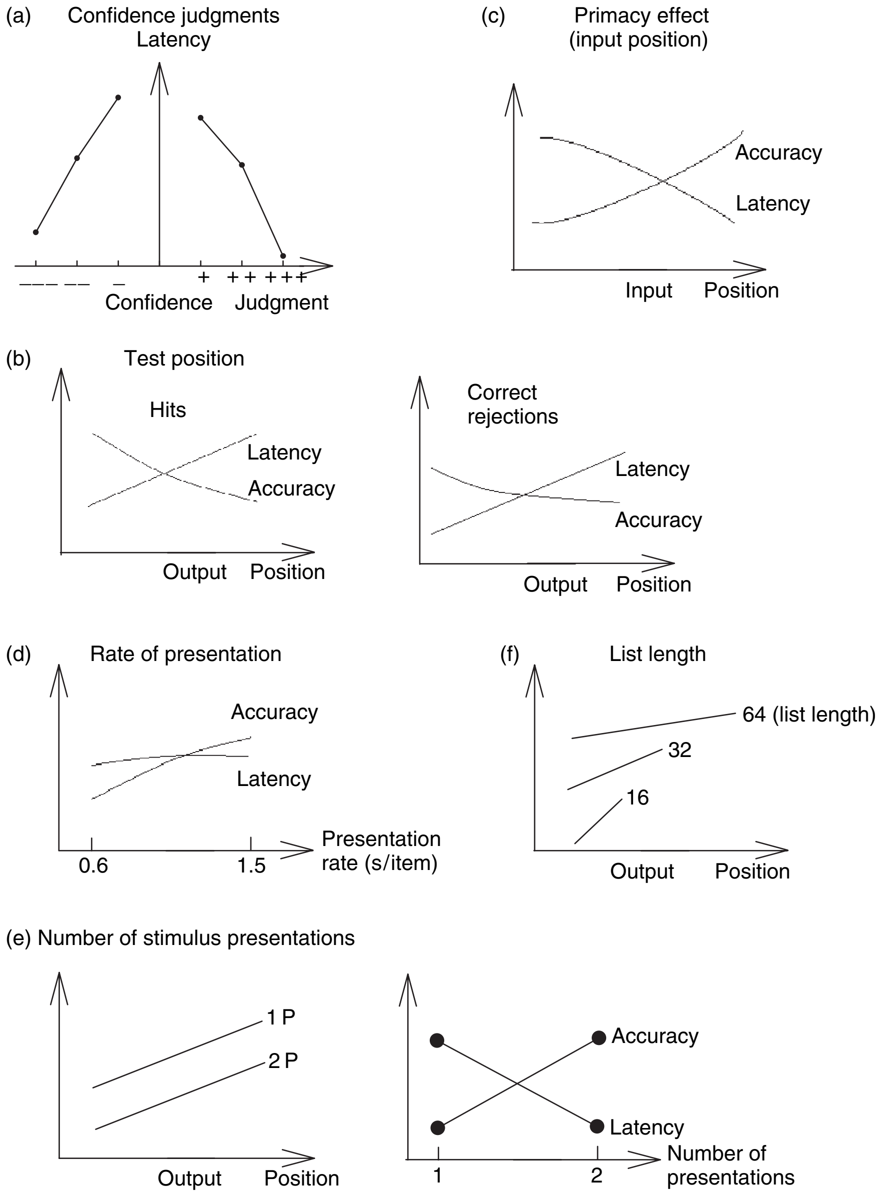

**Figure 5** This figure summarizes the functional relationships of recognition decisions described by Ratcliff R and Murdock BB Jr. (1976) Retrieval processes in recognition memory. *Psychol. Rev.* 83: 190–214; used with permission. These relationships show that: (a) mean RT decreases as confidence increases; (b) accuracy and latency vary inversely with test (output) position, (c) study (input) position, (d) presentation rate at study, and (e) number of presentations at study; and (f) the increase in response latency as a function of output position decreases as list length increases. (Note that relationships (b) through (f) are for high-confidence responses only.)

new items of each class (as assumed in signal detection theory), then the order of the class A and B new item distributions mirror the order of the class A and B old item distributions. The mirror effect is also reflected in the pattern of mean RTs for the correct 'old' (hits) and 'new' (correct rejections) responses of each stimulus class (Hockley, 1994). The comparison of low- and high-frequency words, where low-frequency words are more accurately recognized than high-frequency words, is a prototypical example of the mirror effect in item recognition.

The mirror effect posed a challenge for simple strength-based models of recognition memory, because these models cannot easily account for why, for example, low-frequency items have a lower average strength than high-frequency items when they are new, but have a higher average strength than high-frequency items after one study presentation. The mirror effect provided the impetus for a new generation of single-process models of recognition memory that could accommodate the mirror effect (e.g., Anderson and Milson, 1989; Shiffrin and Steyvers, 1997; McClelland and Chappell, 1998; Dennis and Humphreys, 2001; Murdock, 2003). The word-frequency mirror effect has also been taken as evidence in support of dual-process models of item recognition (Joordens and Hockley, 2000; Reder et al., 2000).

### 2.24.2.6 Dual-Process Views of Recognition

A debate that has received considerable attention has been waged between single-process theories of recognition decisions on the one hand (e.g., the global matching models of Murdock (1982), Gillund and Shiffrin (1984), and Hintzman (1988) and the more recent models of Shiffrin and Steyvers (1997), McClelland and Chappell (1998), and Dunn (2004)) and dual-process views on the other (e.g., Atkinson and Juola, 1973, 1974; Mandler, 1980; Jacoby, 1991; Yonelinas, 1994; Joordens and Hockley, 2000; Reder et al., 2000). Although single-process models differ in many interesting ways, they share a common assumption that recognition decisions are based on a single evidence dimension that has been variously characterized as memory or matching strength or familiarity. In contrast, the unifying assumption of dual-process theories is that recognition involves both familiarity and the recollection or retrieval of specific details of a prior experience (for recent reviews see Yonelinas, 2002; Diana et al., 2006).

No one questions that recollection can play a role in memorial decisions; indeed, a number of paradigms have been developed to examine the retrieval of specific details of the occurrence of past instances such as plurality discrimination (where participants must discriminate between old words such as *frog* and highly related distractors such as *frogs,* e.g., Hintzman and Curran, 1994; Rotello and Heit, 1999). Malmberg et al. (2004), for example, have proposed a version of Shiffrin and Steyvers' (1997) retrieving effectively from memory (REM) model that incorporates a recollection component for such cases. The controversial question is not about recollection *per se*, but rather whether recollection routinely plays an important role in the normal course of item recognition.

In the dual-process framework, it is generally assumed that familiarity-based processes occur in a rapid and automatic fashion. In contrast, recollection is a slower and more intentional retrieval process. Studies of the temporal dynamics of recognition decisions have provided evidence in support of this view. As discussed earlier, in the response-signal SAT procedure, participants must respond at different temporal deadlines during retrieval, allowing one to plot the growth of the accuracy of recognition decisions with increasing retrieval time. Studies using this procedure have shown that decisions that can be informed by familiarity alone, such as item recognition, can be made more accurately earlier than decisions that require retrieval of specific details such as source judgments (e.g., Hintzman and Caulton, 1997; Hintzman et al., 1998; McElree et al., 1999). These results are consistent with the view that familiarity is available very early after the presentation of the test probe, whereas recollection is a slower retrieval process. Another finding that indicates the early availability of familiarity is seen in false alarms to lures that are similar to studied items. These incorrect responses show an initial early increase and then a decrease with response lag (e.g., Dosher, 1984; Dosher and Rosedale, 1991; Hintzman and Curran, 1994), suggesting that the early responses are based only on familiarity. Somewhat later, item-specific information is retrieved that provides a basis for correctly rejecting similar lures.

Boldini et al. (2004) found a dissociation using the response-signal SAT procedure that they interpreted as further support for the dual-process view of recognition. Under incidental learning conditions, these investigators varied the level of processing of the items at study (pleasantness ratings that would promote deep processing versus maintenance rehearsal that supports only shallow encoding; cf. Craik and Lockhart, 1972) and whether or not the perceptual characteristics (modality) of the stimuli matched between study and test (auditory-visual vs. visual-visual presentations). Modality or perceptual match influenced recognition performance at the short response-signal delays (<300 ms), while level of processing affected accuracy at longer delays (>300 ms). Boldini et al. concluded that both a fast familiarity-based process and a slower recollection-based process contribute to recognition memory decisions.

A number of researchers have adopted Tulving's (1985) remember-know response procedure to distinguish between familiarity- and recollection-based recognition decisions. In this procedure, participants are instructed to classify their old decisions as either 'remember' if they recall any specific detail or details of the prior episode, or 'know' if the test item felt familiar but no specific details of the previous experience were recollected. Researchers have demonstrated that a number of variables differentially affect these two types of responses (see Gardiner and Richardson-Klavehn, 2000, for a comprehensive review). For example, elaborative rehearsal (deep processing) affects remember but not know responses, whereas maintenance rehearsal (shallow processing) affects know responses without influencing responses classified as remember (Gardiner et al., 1994). Such dissociations have been taken as evidence for the separate contributions of familiarity and recollection to recognition decisions.

This subjective response procedure, however, is not without its critics. Donaldson (1996) and Hirshman and Master (1997) have argued that remember and know responses reflect differences in confidence (or strength of evidence) rather than distinguishing between decisions that are based on two different types of memorial information. Extending this view, Dunn (2004) developed a signal-detection type model in which remember and know responses are derived from two different decision criteria that bisect a single dimension of familiarity. In this model a new decision would be made if the familiarity associated with the test probe was below the lower of the two decision criteria, and an old 'know' response would be made if the familiarity value exceeded the lower criterion. If the familiarity value exceeded the higher of the two criteria, the old decision would then be classified as 'remember.' Dunn showed that such a model can, with appropriate placement of the two decision criteria, account for all of the dissociations between remember and know responses that are taken as support for the dual-process view. In reply, dual-process theorists have questioned whether participants are capable of adjusting their decision criteria in each experimental condition in the manner that Dunn assumed in his model (Diana et al., 2006).

The interpretation of the latency of remember and know responses is also controversial. Remember responses have typically been found to be faster than know responses (Dewhurst and Conway, 1994; Dewhurst et al., 1998, 2006; Henson et al., 1999; Hockley et al., 1999). Wixted and Stretch (2004) have shown that a single-dimension signal-detection model of remember/know responses predicts just this result. In contrast, this finding would appear to be in conflict with the results obtained with the response-signal SAT procedure that shows that familiarity processes are faster than recollection, and with the predictions of dual-process theory. Yonelinas (2002), however, suggests that the slower latency of know responses is an artifact of the remember/know instructions. These instructions specify that a know response should be made when there is no contextual information available to support a remember response. As a consequence, participants must assess recollection before making a know response. Remember responses, in contrast, can be made as soon as any contextual details are retrieved.

A different dual-process interpretation of the latency of remember and know responses has been offered by Henson et al. (1999) and Dewhurst et al. (2006; see also Gardiner et al., 1999; Konstantinou and Gardiner, 2005). Henson et al. suggested that know decisions take longer because it is more difficult to make recognition decisions in the absence of the recollection of contextual details. Dewhurst et al. showed that slower know responses are found both when participants make a single timed remember/know/new decision (one-step procedure) and when the untimed remember-know decision follows a timed old/new response (two-step procedure). Perhaps more interestingly, know responses were also slower when the remember-know decisions were made retrospectively. In this experiment, test items were presented once, and participants made old/new decisions. The test items were then presented a second time, and the participants were asked to indicate whether their previous old/new decisions had been based on familiarity or recollection. The mean RT of the old decisions that were subsequently identified as based on recollection (796 ms) was faster than the old decisions later classified as know (930 ms) or guess responses (1059 ms). Dewhurst et al. reasoned that these RTs reflect genuine differences in the speed of the recognition decision that is not influenced by the requirement to make a remember-know distinction. They concluded that the faster RTs for remember responses reflect the greater ease in making recognition decisions that are supported by the recollection of contextual information. Thus, in their view, recollection need not be a slow and effortful process but "can occur rapidly and automatically" (Dewhurst et al., 2006: 158).

### 2.24.2.7 Judgments of Event Frequency

It has been previously noted that different tasks, such as source or plurality judgments, have been used to examine memory for specific details of the prior presentation of events. Another illuminating task concerns memory for frequency, or the number of separate occurrences of an event. Memory for frequency has been studied, in part, to try to determine how multiple occurrences of the event are encoded and represented in memory (for reviews see Howell, 1973; Hintzman, 1976, 1988). Our ability to remember the frequency of events is surprisingly accurate, even in the absence of any intention to do so, and it has been suggested that the encoding of frequency information represents an automatic process (Hasher and Zacks, 1979, 1984).

Logically, estimates of the frequency of prior events could be made in several different ways. Participants might, when asked, try to recollect and count each individual occurrence of an event. Or, participants could estimate the number of occurrences based on the cumulative strength or familiarity that is associated with the event. In either case, participants could also adjust or extrapolate their counts or derived estimates to compensate for failures of encoding or retrieval. These different possibilities form part of the multiple-strategy perspective of frequency estimation developed by Brown (1995, 1997, 2002). This framework provides an excellent example of the flexible manner in which we can interrogate and use our memory. Brown's basic distinction between enumeration-based and nonenumeration-based strategies of frequency estimation also provides a compelling example of a dual-process type of account of memory decisions.

Brown (1995) examined frequency judgments for words presented in either a variable or a consistent context. In each condition participants studied a list of pairs, each consisting of a category label and an exemplar. Different category labels were presented different numbers of times in the list, varying from 0 to 16. In the variable-context condition a different exemplar was presented with each category label (e.g., MAMMAL – dog, MAMMAL – tiger, MAMMAL – horse), whereas in the consistent-context condition the exemplar was always the same (e.g., CITY – London, CITY – London, CITY – London). At test, participants estimated the frequency of the different categories.

A major finding that indicated that subjects used an enumeration or counting strategy in the variable-context condition and a nonnumeration strategy in the consistent-context condition was the changes in the mean RTs of the frequency judgments. The mean frequency estimates and the mean RTs as a function of presentation frequency are shown in **Figure 6**. Mean RT increased sharply as a function of presentation frequency in the variable condition, consistent

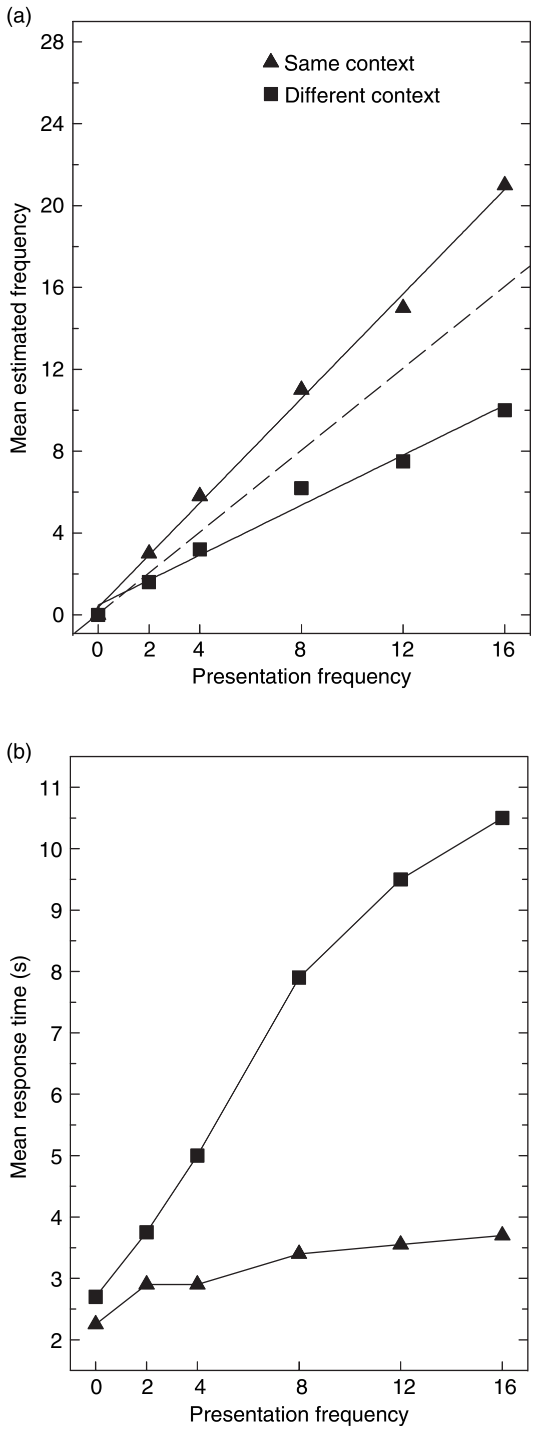

**Figure 6** The figure shows the mean frequency estimates (a) and the mean response times (b) for the different-context and same-context conditions from Brown NR (1995) Estimation strategies and the judgment of event frequency. *J. Exp. Psychol. Learn. Mem. Cogn.* 21: 1539–1553; used with permission. In (a), the solid lines represent the best linear fit to the means, and the dashed line represents the actual presentation frequency.

with participants' retrieving and counting the different presentations of the target categories. The different contexts in this condition would support the search and retrieval of the individual occurrences of the categories. In contrast, the increase in mean RT with presentation frequency was far more modest in the same-condition context, indicative of participants' using a more global or inferential estimation strategy that did not involve searching and retrieving memories of the individual presentations.
