Three additional findings supported the use of different estimation strategies in the same- and different-context conditions. Participants in the variable-context condition tended to underestimate actual frequency (consistent with failing to retrieve all instances of each event), while participants in the same-context condition tended to overestimate frequency (consistent with a strength-based estimation strategy). Moreover, information about the frequency range influenced the magnitude of participants' estimates in the same- but not in the variable-context condition. Finally, the participants' own verbal protocols indicated their use of the two different strategies.

The evidence indicates that there are two different bases for item recognition decisions and judgments of event frequency – a form of general or global familiarity and recall or recollection. In the next section we consider two tasks that involve memory for associations, or information that represents the relations between items. Each task is believed to involve a recall process, and each task is supported by retrieval cues presented at the time of test.

## 2.24.3 Associative Recognition and Cued Recall

### 2.24.3.1 Associative Recognition

In the standard associative recognition paradigm, participants study random pairs of items and then, at test, try to discriminate between intact or studied pairs and new pairings of rearranged study items. This procedure provides a relatively pure test of memory for the associations between unrelated items formed at study, because both intact and rearranged pairs consist of two old items that individually would be similar in their degree of familiarity. Since this task requires memory for specific associations formed at study, it is usually assumed that recall or recollection plays a dominant role in associative recognition decisions (e.g., Yonelinas, 1997; Hockley and Consoli, 1999; Cameron and Hockley, 2000; Rotello and Heit, 2000; Verde and Rotello, 2004).

Gronlund and Ratcliff (1989) compared the time course of the availability of item and associative information using the response-signal SAT procedure following the study of random word pairs. The response signal functions they obtained in their second experiment are shown in **Figure 7**.

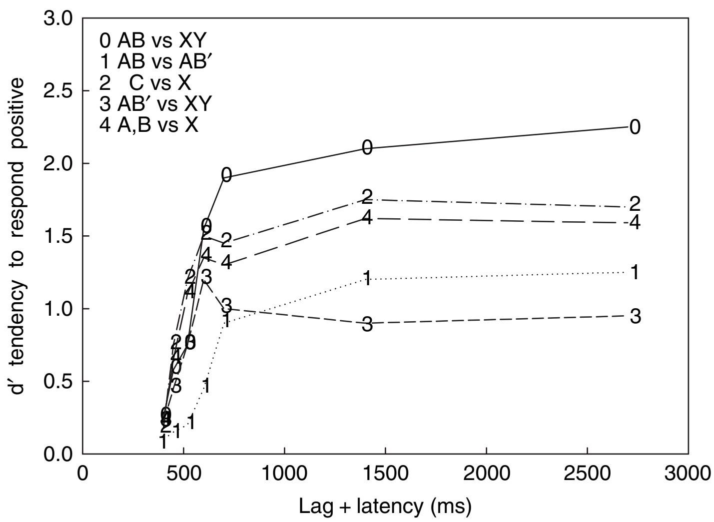

**Figure 7** This figure shows averaged response signal functions from Gronlund SD and Ratcliff R (1989) Time course of item and associative information: Implications for global memory models. *J. Exp. Psychol. Learn. Mem. Cogn.* 15: 846–858; used with permission. (The d' tendency to respond positively is given as a function of the total processing time [lag + latency]. Function 0 is AB vs. XY; Function 1 is AB vs. AB′; Function 2 is C vs. X; Function 3 is AB′ vs. XY; and Function 4 is A,B vs. X.)

These functions represent the different types of discriminations that the participants were asked to make. Discriminating between two studied old words versus two new words is shown by Function 0, between intact studied pairs versus rearranged pairs by Function 1, between studied old single words versus new words by Function 2, between rearranged pairs versus pairs of new words by Function 3, and between old words studied in pairs versus new words by Function 4. Functions 0, 2, 3, and 4 represent discriminations that can all be based on item information, or memory for the individual words from the study list. These functions all show similar initial increases in accuracy with response time.

In contrast, the discrimination of intact versus rearranged pairs represented by Function 1 requires memory for the associations made at study. The familiarity of the individual items cannot aid in this discrimination. This function remains at chance at the earliest test lags, and discrimination is delayed relative to the other functions. Gronlund and Ratcliff (1989) also showed that these results are not due to the requirement that participants must read both words of the test pair to discriminate intact from rearranged pairs. Similar results were obtained when the first word of each test pair was presented 200 ms before the second word, and the response signal was measured from the onset of the second word.

Gronlund and Ratcliff (1989) considered two possibilities to explain why the availability of associative information is delayed relative to the availability of item information. One was that for associative recognition a compound cue must first be created. This cue would provide the means to derive a joint match of the two words to memory. Such a matching operation would provide a familiarity value in the same manner as is generally assumed for item recognition. The second possibility was that, whereas item recognition is based on familiarity, associative recognition is based on a slower recall process. In the second view, associative recognition would be similar in nature to cued recall.

### 2.24.3.2 Cued Recall

In the typical episodic memory cued-recall task, participants study random pairs of items, and at test, one item of each pair is presented as a cue to recall the associated member of the pair. We can also consider questions that require participants to retrieve a specific label, name, or fact in a cued-recall test of semantic memory.

In self-paced recall tasks the typical finding is that average error latency is longer than the latency of correct responses, and these two variables are interpreted differently. Correct latency is taken to be a measure of the amount of information about the item that is available in memory. Error latency, on the other hand, is interpreted as an index of the rememberer's willingness to continue searching memory for the item (e.g., Millward, 1964; MacLeod and Nelson, 1984).

In the cued-recall experiments carried out by MacLeod and Nelson (1984), participants studied number-noun pairs (e.g., 48-dollar) or noun-noun pairs (e.g, forest-elbow) and at test tried to recall the second item given the first item of the pair as a retrieval cue. Participants responded aloud, and a voice key was used to measure response time. The instructions emphasized accuracy with no mention that response time was being measured. Participants could take as much time as they needed, but they had to make a response on every trial even if it was a guess. Across their experiments MacLeod and Nelson manipulated retention interval (1, 3, or 5 weeks), levels of processing at study (classifying the nouns in terms of physical size or number of syllables), and study versus test trial repetitions. All of these manipulations had large and reliable effects on accuracy. For example, in Experiment 1 the mean probability of an error increased with retention interval: 0.54 (1 week), 0.75 (3 weeks), and 0.79 (5 weeks). The corresponding mean latencies (in seconds) for correct responses were 3.78, 6.90, and 7.11, and for incorrect responses were 18.12, 17.91, and 14.97. The results suggest a positive correlation between accuracy and correct RT, but the increase in mean RT was not statistically reliable (similar patterns and statistical outcomes were observed in all of the experiments). The results are, though, very clear in showing that mean RTs for incorrect responses do not vary with the manipulations that affected accuracy and are very much slower than correct responses, consistent with the view that correct and incorrect RTs are measuring different processes.

There is considerable evidence to support the conclusion that the latencies of errors are a measure of the rememberer's willingness to continue searching memory in the belief that the additional effort might prove successful. Thompson (1977, as described by MacLeod and Nelson, 1984) measured response times to respond to general-information questions. Then she asked her participants to make feeling-of-knowing judgments in terms of the likelihood of recognizing the correct answer for the questions that they could not recall. Finally, she gave participants a forced-choice recognition test for the nonrecalled answers. The initial error latencies were reliably correlated with the feeling-of-knowing judgments, but not with the final recognition performance. Error latency thus appears to reflect what the rememberer believes to be in memory whether or not the belief is true.

Costerman et al. (1992) and Nelson et al. (1984) have also shown that retrieval latencies are longer for nonrecalled targets that are given higher feeling-of-knowing ratings. Participants will also spend more time attempting to retrieve the correct answer when they are in a ‘tip-of-the-tongue’ state (when they have a strong feeling that a particular answer is in memory and can be retrieved) compared to retrieval failures not accompanied by such a feeling (Schwartz, 2001). Finally, people will also spend longer searching memory and make more correct responses when the rewards for correct responses are high and the penalties for slowness are low, and will spend less time at retrieving with a resultant lower success rate when the penalties for slowness are high and the rewards for correct responses are lower (Barnes et al., 1999).

We have separately considered associative recognition and cued recall. Nobel and Shiffrin (2001) compared the retrieval dynamics of these two tasks with item recognition in order to determine the similarities and differences in the retrieval processes that are involved in each task.

### 2.24.3.3 A Comparison of Item versus Associative Recognition and Cued Recall

Nobel and Shiffrin (2001) used a voice key to measure RT for item recognition and cued recall following study lists of random word pairs. They found that both correct responses (hits vs. correct recalls) and incorrect responses (false alarms vs. intrusions) were much slower for cued recall compared to item recognition. These differences are clearly captured in the plots of the RT distributions fitted by the ex-Gaussian distribution and shown in **Figure 8**. The RT distributions for cued recall and item recognition are markedly different; the cued-recall distributions are shifted to the right, with a greater positive skewness and higher variance.

Nobel and Shiffrin also compared the retrieval dynamics of discrimination for item recognition (old vs. new single items), associative recognition (intact vs. rearranged study pairs), and paired recognition (intact pairs vs. pairs of new words) with cued recall using the response-signal SAT procedure. Their SAT functions for the three recognition tasks

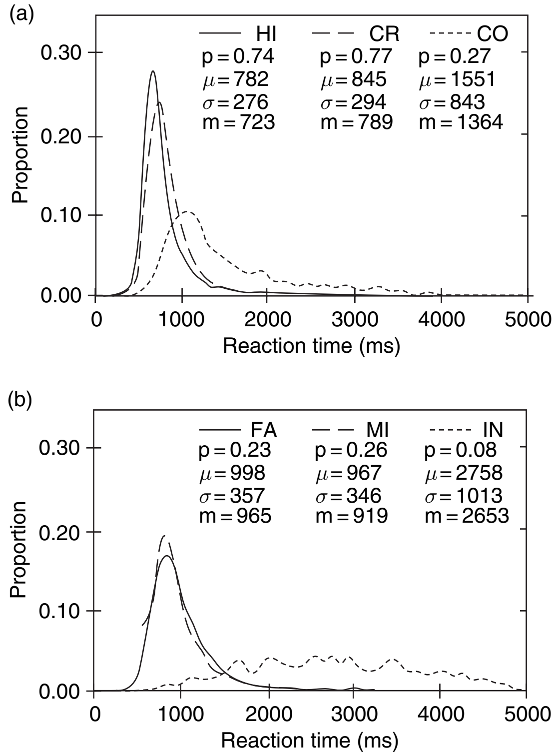

**Figure 8** This figure shows the response time distributions for correct responses: (a) item recognition hits (HI) and correct rejections (CR), and correct cued recalls (CO), and for incorrect responses: (b) item recognition false alarms (FA) and misses (MI), and recall intrusions (IN). Observed by Nobel PA and Shiffrin RM (2001) Retrieval Processes in recognition and cued recall. *J. Exp. Psychol. Learn. Mem. Cogn.* 27: 384–413; used with permission. The proportion of each type of response (p), mean RT ($\mu$), standard deviation ($\sigma$), and median RT (m) are shown in each panel.

are shown in the top portion of **Figure 9**, and the function for cued recall is shown in the bottom portion. These results show that, compared with item and paired recognition, the retrieval dynamics of associative recognition and cued recall are much slower. Moreover, the retrieval dynamics of associative recognition were statistically consistent with those of cued recall.

Based on their different temporal properties, Nobel and Shiffrin proposed that different retrieval processes give rise to associative and cued-recall performance on the one hand, and single-item and paired recognition on the other. In their view, item and paired recognition are based on a familiarity process that involves parallel access to recent episodic representations and leads to relatively fast ‘old’ or ‘new’ responses. In contrast, they argued that cued recall and associative recognition are carried out

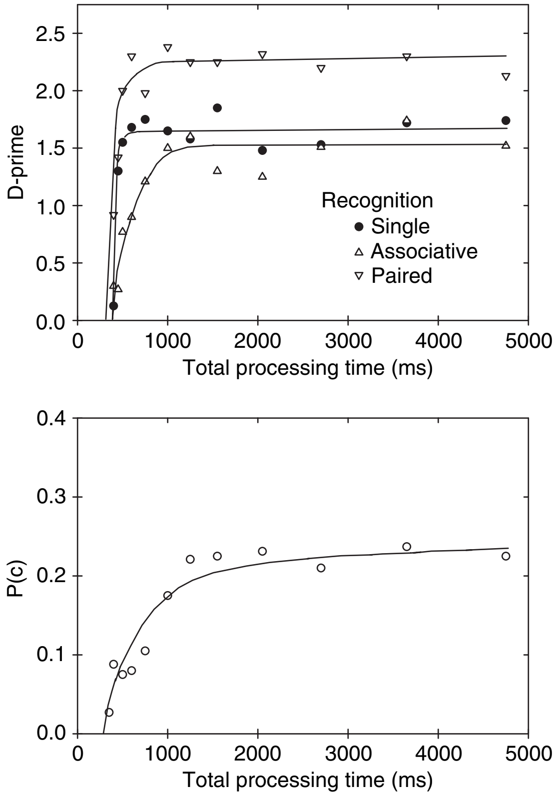

**Figure 9** These functions show signal-to-response accuracy as a function of total processing time for single item, associative, and paired item recognition (top panel), and correct cued recall (bottom panel). The data are from Nobel PA and Shiffrin RM (2001) Retrieval processes in recognition and cued recall. *J. Exp. Psychol. Learn. Mem. Cogn.* 27: 384–413; used with permission.

through a memory search process that involves successive sampling and recovery until the relevant representation of the target is found, or the search is abandoned. Diller et al. (2001) provide a formal description of these processes and fits of this model to their results. The general search process that Nobel and Shiffrin suggested underlies cued recall and associative recognition has also been proposed to account for free recall performance.

## 2.24.4 Recall

### 2.24.4.1 Analyses of Interresponse Times in Free Recall

Free recall requires participants to output as many items from the study list as possible in any order. Thus, it is a sequential task that is spread out over time. While response times in recognition and cued-recall tasks are relatively fast and typically in the order of a few seconds, free recall occurs over many minutes and is characterized by much longer pauses between responses. For this reason an extended sequential search process is assumed in most models of free recall (e.g., Atkinson and Shiffrin, 1968; Shiffrin, 1970; Raaijmakers and Shiffrin, 1980; Metcalfe and Murdock, 1981; Rohrer and Wixted, 1994; Howard and Kahana, 1999).

Although the analysis of the temporal dynamics of free recall has a long history dating back to the seminal work of Bousfield and Sedgewick (1944), measures of response latency in studies of free recall have not been as common as in studies of recognition memory. Indeed, much of the research on free recall has used probability of recall as the dependent measure. This can be problematic, or even misleading, as Roediger and colleagues (e.g; Roediger and Thorpe, 1978; Roediger et al., 1982; see also Wixted and Rohrer, 1994) have pointed out. For example, in a typical free-recall experiment, performance is evaluated after a fixed retrieval period usually lasting only a few minutes. Few studies have examined recall over extended retrieval periods, yet recall can continue to increase even after 20 minutes (e.g., Roediger and Thorpe, 1978).

In the study of free recall, most of the analysis and modeling of response time has been based on interresponse times (IRTs), the time between consecutive retrievals (e.g., Bousfield et al., 1954; Murdock and Okada, 1970; Roediger et al., 1977; Roediger and Thorpe, 1978; Roediger and Tulving, 1979; Raaijmakers and Shiffrin, 1980; Gronlund and Shiffrin, 1986). The basic finding is that IRTs increase in a positively accelerated fashion with output position.

Bousfield and Sedgewick (1944) asked their participants to recall as many different items as possible from specific categories (e.g., quadruped mammals, U.S. cities) for a period of 18 min. Every 2 min the participants were also asked to draw a line under the last recalled item. Bousfield and Sedgewick then plotted the cumulative number of items recalled as a function of time. This analysis revealed that recall slowed continuously; the greatest number of recalled items occurred in the first interval, and fewer numbers of items were recalled in each successive interval. These latency distributions are well described by the cumulative exponential:

$$R(t) = N(1 - e^{-t/\tau})$$

where $R(t)$ equals the total number of items recalled by time $t$, $N$ represents asymptotic recall (r recall after infinite time), and $\tau$ represents the mean latency of the recalled items (Bousfield and Sedgwick, 1944; Indow and Togano, 1970; Roediger et al., 1977). An example of a cumulative recall latency distribution and its best-fitting cumulative exponential distribution is shown in **Figure 10**.

IRTs have also been shown to increase in a positively accelerated fashion with output position, and at any given output position, IRT is a good predictor of the number of items yet to be recalled (Raaijmakers and Shiffrin, 1980). Representative data from Murdock and Okada (1970) are illustrated in **Figure 11**. In this experiment, participants studied lists of 20 common words. Vocal responses were tape-recorded, and IRTs were measured as a function of output position. Each of the different curves in **Figure 11** represents a different total of words recalled that varied from four to nine. Rohrer and Wixted (1994) have shown that the increase in IRTs with output position is found for different list lengths and presentation rates of the study list and is thus a general feature of free recall.

Rohrer and Wixted (1994; see also Wixted and Rohrer, 1994) analyzed the characteristics of IRT distributions by fitting the observed latency distributions with the ex-Gaussian distribution that has been used to describe response time distributions for recognition decisions. **Figure 12** shows the recall latency distributions with the best-fitting ex-Gaussian distributions for different list lengths that varied from three to nine words. Longer study lists resulted in a decrease in the probability of recall and an increase in the latency of recall. The estimates of mu, representing the minimum response times, averaged about 1 s and did not vary significantly with list length. In contrast, the estimates of tau, reflecting the skewness of the distributions, increased reliably from approximately 3 to 7 s across list length. Thus, all of the increase in response time with list length was seen in the exponential component of the ex-Gaussian distribution. Rohrer and Wixted proposed that free recall is based on a relatively brief, normally distributed initiation stage (represented by mu) followed by an exponentially distributed search stage (represented by tau).

Bousfield and Sedgewick (1944) and McGill (1963) noted that the exponential increase of the cumulative latency distributions is consistent with a random search model of memory. In this model, individual items are randomly sampled from a search set, evaluated, and replaced. Thus, early in the process almost every sample from the search set will yield a new item to report. As the random search process continues, however, the probability of retrieving a previously sampled item increases until almost every iteration produces an already sampled item. Retrieval of each new item, therefore, becomes progressively slower. Rohrer and Wixted (1994; Wixted and Rohrer, 1994) also supported this basic account of free recall and considered both serial and

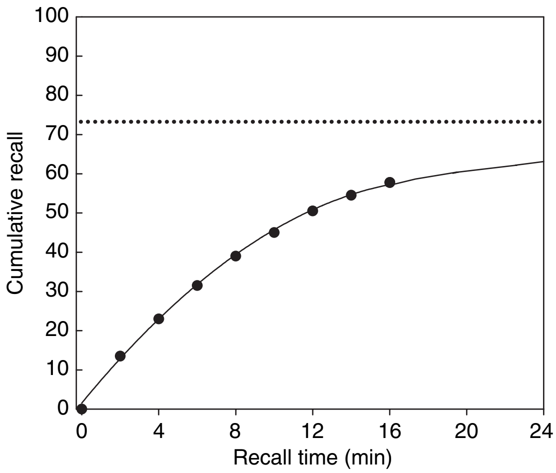

**Figure 10** This figure shows a cumulative free recall latency distribution based on Wixted and Rohrer's (1994) plot of Bousfield and Sedgewick's (1944) results for the cumulative recall of pleasant activities over time. The solid curve represents the best-fitting exponential function and the dotted line indicates the asymptotic level of recall.

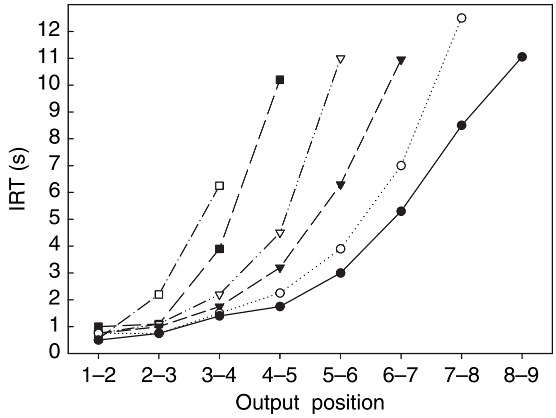

**Figure 11** The increase in interresponse time (IRT) with output position. The six curves represent different total numbers of words recalled varying from four to nine. Data from Murdock BB Jr. and Okada R (1970) Interresponse times in single-trial free recall. *J. Exp. Psychol.* 86: 263–267; used with permission.

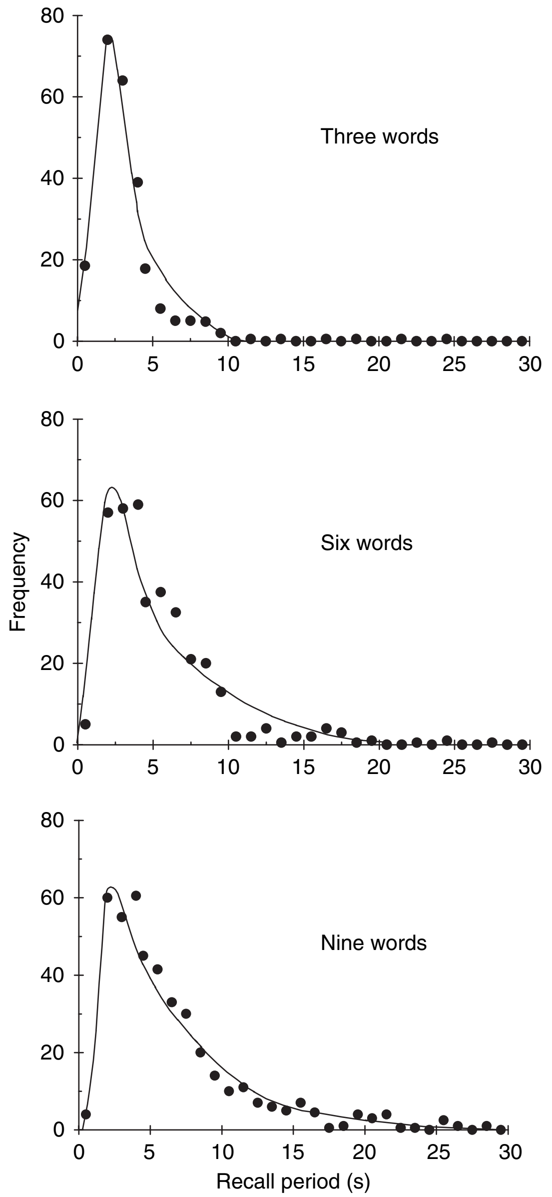

**Figure 12** This figure shows recall latency distributions, grouped into 1-s bins, for three different study list lengths reported by Rohrer D and Wixted JT (1994) An analysis of latency and interresponse time in free recall. *Mem. Cogn.* 22: 511–524; used with permission. The fit of the ex-Gaussian distribution is also shown for each observed distribution.

parallel forms of the search process. They also noted that Raaijmakers and Shiffrin's (1980) search of associative memory model, which was developed as an extension of Shiffrin's (1970) random search model, shares many aspects in common with the random search account.

### 2.24.4.2 The Search of Associative Memory Model

The SAM model (Raaijmakers and Shiffrin, 1980, 1981; Shiffrin and Raaijmakers, 1992) is a sophisticated model of recall that has been successfully applied to a number of different phenomena. Although SAM has given way to the REM model (Shiffrin and Steyvers, 1997), the extension of REM to free recall is borrowed from SAM (Shiffrin, 2003). Very briefly, it is assumed in SAM that memories are represented as 'images' that vary in terms of their associative strengths to each other and the retrieval cue. The retrieval cue serves to activate the search set. In free recall the retrieval cue is the context of the study list. Retrieval consists of repeated sampling of the search set, and the retrieval probability of each item is a function of its associative strength. When an item is retrieved and output, it serves as the retrieval cue for the next sampling. This process continues until a stop rule is invoked based on the elapsed time without a successful retrieval. As Wixted and Rohrer (1994) note, if all images in the search set were activated to the same degree by the retrieval cue, and this remained the case during the entire recall period, then the search process would be equivalent to the random-search-with-replacement model.

A central notion in SAM is that items are associated to varying degrees. Kahana (1996) provided evidence for such associations between items presented sequentially in tests of free recall. Kahana reanalyzed data from a number of free recall studies in terms of the probability of recalling a given item as a function of its distance in the study list from the last item recalled (the conditional response probability). An example of such a function is shown in the left panel of **Figure 13**. Two aspects of these results are notable and are consistent across studies. Kahana termed these aspects of the results contiguity and asymmetry. Contiguity refers to the fact that items tend to be recalled after items that were studied in adjacent list positions. That is, item 8 is more likely to be recalled after item 7 is recalled than after item 5. Asymmetry refers to the finding that for items that were adjacent to each other in the study list and that were recalled after each other, forward transitions (recall item 7 then recall item 8) are about twice as likely as backward transitions (recall item 8 then item 7).

Kahana also examined conditional response latency functions, where IRTs between successively recalled items are plotted as a function of their

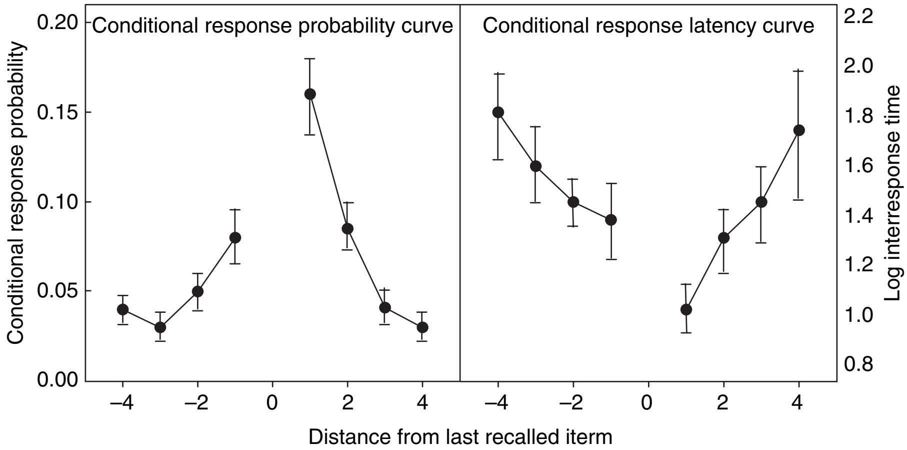

**Figure 13** The conditional response probability (left panel) and conditional response latency (right panel) curves reported by Kahana MJ (1996) Associative retrieval processes in free recall. *Mem. Cogn.* 24: 103–109, based on Murdock and Okada's (1970) free recall results; used with permission. (The error bars reflect 95% confidence intervals for each mean.)

proximity in the study list. These IRTs are shown in the right panel of **Figure 13**, and it is clear that the IRT functions mimic the conditional response probability functions – mean IRT increases as the distance between the items' positions in the study list increases. These results indicate that participants studying random lists of words tend to associate the list items in a pair-wise fashion, and the conditional response probability and conditional response latency functions reflect the strength of these associations, as SAM would predict.

### 2.24.4.3 The Search Set

A critical aspect of any version of the random search-with-replacement model is defining the search set. In the SAM model it is assumed that the retrieval cue serves to activate the search set. Research has shown that certain types of retrieval cues are able to delineate or reduce the search set, whereas others do not.

In categorized free-recall tasks, participants study random lists of words drawn from different semantic categories such as precious stones and occupations and, at test, recall the semantically related items together (i.e., semantic clustering; Bousfield, 1953). Within-category IRTs increase with output position, and IRTs are longer when recall changes from one category to another (Pollio, 1964; Patterson et al., 1971; Graesser and Mandler, 1978; Wingfield et al., 1998). The pattern of IRTs is consistent with a random search and replacement model that operates at the level of the individual categories and with the SAM model given the assumption that the association between items is greater for within-category than between-category items.

Wixted and Rohrer (1994) discuss two studies of semantic memory that illustrate how some retrieval cues can serve to narrow the search set, while other types of cues cannot. Herrmann and Murray (1979) asked participants to recall items from large categories such as bodies of water, and smaller, nested categories such as lakes. Metlay et al. (1971) asked participants to recall items from different categories (e.g., names of U.S. presidents) that could be further subdivided (e.g., presidents' names that contain the letter *y*, n = 5, or the letter *s*, n = 11). Analyses of the cumulative latency functions indicated that participants could search lakes separately from the larger category of bodies of water, but could not restrict their search for presidents based on letters in their names. Presumably, lakes are stored as a separate category in semantic memory, and people can use this information to reduce the search set. Presidents' names, however, are not stored by their component letters, and the participants thus had to generate the entire set of 32 names and only report those names that conformed to the letter cue.

Roediger and Tulving (1979) provide two episodic memory examples of the failure of retrieval cues to restrict the search set. They presented participants with lists of 64 words in which there were eight words from eight different common semantic categories (e.g., vegetables). In addition, the words in each category began with the same set of eight letters. Participants were informed about the categorical nature of the lists, and the list was presented blocked by category, with the category name presented before the category exemplars. The participants were not informed of the initial letters of the words in each category. There were three groups of subjects. A control group was instructed to recall all items from all categories. A second group was given four letters on their recall sheets and instructed to recall only the words that did not begin with those letters. The third group was given four category names and were told not to recall items from these categories, but only recall items from the other four categories which were not named. As one would expect based on the results of Metlay et al. (1971), participants could not restrict their search based on letter cues. Surprisingly, and in contrast to the results of Herrmann and Murray's (1979) nested category-cued experiment, participants could also not restrict their search based on the category cues. The mean cumulative recall functions for the critical words were the same in all three groups of Roediger and Tulving's experiment. It is not at all clear why participants would apparently 'waste time' in retrieving an excluded category or continue to search a category after retrieving and rejecting one exemplar from an excluded category.

### 2.24.4.4 Serial Recall

Serial recall requires participants to report list items in the order of their presentation. The emphasis on order information in this task has led to a focus on transposition errors that occur when an item is recalled in an incorrect list position. Transposition errors are categorized as anticipation errors when an item is recalled in an earlier serial position, and postponement errors when an item is recalled in a later list position.

Transposition errors can be measured in terms of the numeric difference between an item's study position and recalled position. Thus, an item recalled in its correct position would have a transposition value of zero. Anticipation errors have a negative transposition value, and postponement errors have a positive value. Transposition gradients can be measured by plotting the proportion of recalled items as a function of the transposition value. As summarized by Farrell and Lewandowsky (2004), these gradients reveal three regularities of serial recall. First, the gradients peak at a value of zero because most items are recalled in their correct position. Second, the probability of errors declines as the absolute transposition value increases; most errors occur near their correct position. Finally, the transposition gradients tend to be symmetrical. That is, the anticipation and postponement error gradients mirror each other.

In contrast to the long history of measuring response time in free recall, latency has only recently been used as a dependent measure of serial recall performance. Investigators have examined total output times (Dosher and Ma, 1998; Hulme et al., 1999) and correct IRTs for each serial position (e.g., Anderson and Matessa, 1997; Anderson et al., 1998; Cowan et al., 1998; Kahana and Jacobs, 2000; Mayberry et al., 2002; Oberauer, 2003; Farrell and Lewandowsky, 2004). In forward serial recall for subspan list lengths, mean IRTs typically show longer output times for recall of the first item and a relatively flat latency serial position curve for recall of the subsequent items. The delay in recalling the first item may reflect an initial preparatory stage (Farrell and Lewandowsky, 2004). Thus, when cumulative latency is plotted as a function of serial position, the increase in time is approximately linear (e.g., Dosher, 1999). Representative error transposition gradients and serial position curves for accuracy, latency, and cumulative latency reported by Farrell and Lewandowsky (2004) are shown in **Figure 14**.

IRT serial position functions for list lengths that exceed memory span also show the longer output time for the first item, but the remainder of the curve appears to show a more inverted-U shape with faster IRTs at the beginning and end of the list. **Figure 15** shows such functions obtained by Kahana and Jacobs (2000). In this experiment, participants learned lists of 11, 12, and 13 items over 12 experimental sessions. The latency serial position functions are similar for each list length and degree of learning (the first two sessions vs. the last six sessions of the experiment). For middle serial positions, IRTs vary in a nonmonotonic fashion, indicating consistencies in the participants' temporal groupings of the items. The averaged IRT functions, however, obscure individual variability of the groupings. Kahana and Jacobs examined these functions for each participant and reported that the individual IRT functions show that some participants grouped the lists in a consistent manner with longer IRTs for every second, third, or fourth item in the list. The IRT functions for other participants did not show such pronounced patterns, but still showed strong tendencies for longer IRTs in the middle and shorter IRTs at the beginning and end of the lists. Kahana and Jacobs suggested that these patterns reflect the participants' grouping of items into different-sized

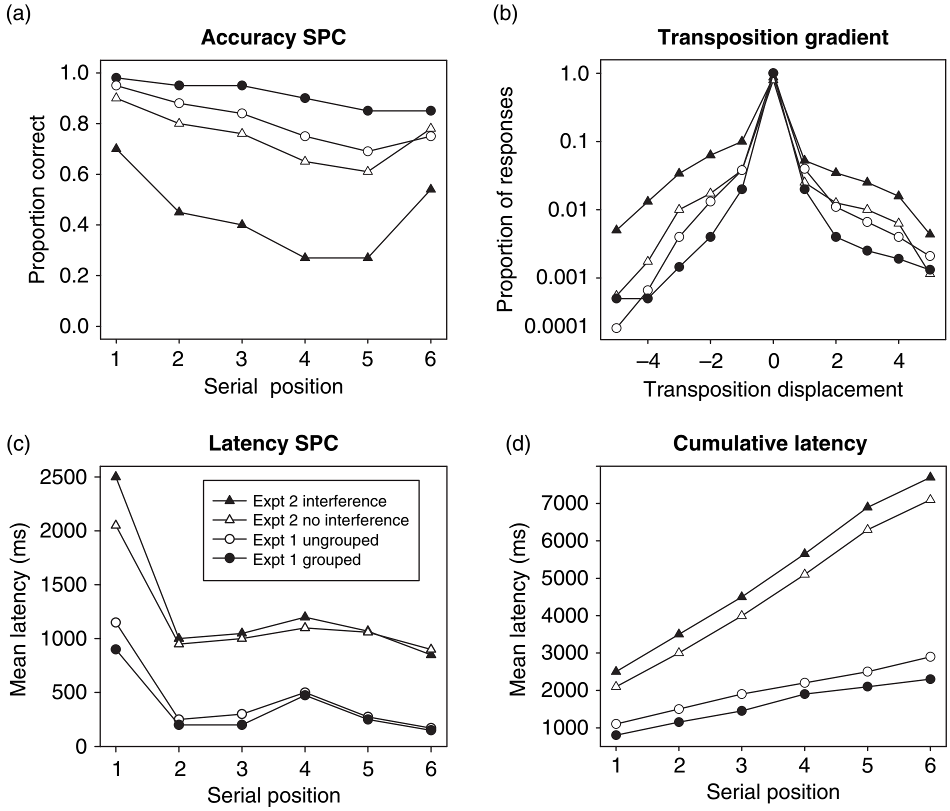

**Figure 14** This figure shows the serial position curves (SPC) for (a) accuracy, (b) transposition error gradients, (c) latency serial position curves, and (d) cumulative latency serial position curves for Experiments 1 and 2 of the study of serial order recall from Farrell S and Lewandowsky S (2004) Modelling transposition latencies: Constraints for theories of serial order memory. *J. Mem. Lang.* 51: 115–135; used with permission.

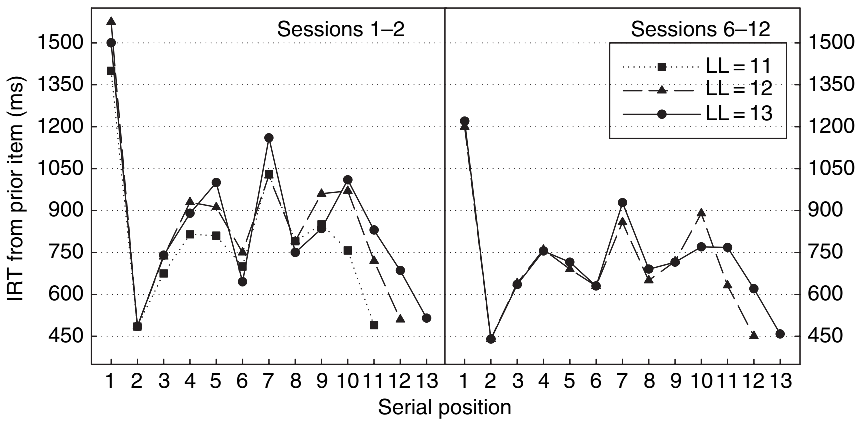

**Figure 15** Average interresponse times (IRT) as a function of serial position for all perfect trials for each list length. From Kahana MJ and Jacobs J (2000) Interrersponse times in serial recall: Effects of intraserial repetition. *J. Exp. Psychol. Learn. Mem. Cogn.* 26: 1188–1197; used with permission. The left panel shows data from the lists from sessions 1–2, and the right panel shows the results for sessions 6–12.

chunks such that IRTs are longer for the first item of a group than the items within a group.

## 2.24.5 Conclusions and Controversies

### 2.24.5.1 Matching versus Searching

It is quite clear that there are both qualitative and quantitative differences between the temporal dynamics of item recognition on the one hand, and associative recognition, cued recall, free recall, and serial recall on the other. Item recognition responses are generally quite fast for both correct old and new decisions. In contrast, RT is much slower in associative recognition and recall-based tasks, and the latencies of correct and incorrect recall responses are measures of different processes.

It seems reasonable to conclude, therefore, as did Nobel and Shiffrin (2001), that item recognition is generally based on a strength-of-evidence variable, or familiarity, that is derived from a relatively fast matching process that is carried out in parallel, whereas associate recognition and recall are based on slower, sequential, search-based processes. Such a conclusion must be correct in the broader sense. Familiarity alone would usually provide a sufficient basis for item recognition decisions, but would not suffice for associative recognition or recall where more specific information must be retrieved. Such a sweeping conclusion, however, glosses over a number of important questions and details that remain to be resolved. This chapter concludes with brief considerations of some of these controversies.

### 2.24.5.2 Familiarity versus Recollection in Item Recognition

Most, if not all, researchers agree that recollection can play a role in recognition decisions, and most global matching models of recognition memory allow for decisions to be based on either matching strength or on recollection of details (see Hintzman and Curran, 1994, for a discussion of this point). The controversial question is whether recognition is largely based on familiarity, as single-process theorists advocate, or routinely involves recollection, as dual-process theorists have argued.

An argument in favor of the single-process view is that recognition decisions are typically much faster than decisions involving recall. If recollection involves a slower search process, it cannot be a general feature of recognition decisions. Nobel and Shiffrin (2001), however, point out that response latency would not be sufficient to distinguish between single-process and dual-process views of recognition if it were assumed that recollection involves a fast, truncated search process. An example of such a truncated search process would be stopping after the retrieval of the first sample in a successive sampling and recovery search process. Nobel and Shiffrin also noted that it might be almost impossible to distinguish between single- and dual-process views of recognition if there is a strong correlation between familiarity and the probability of retrieval success of such a truncated search process.

The notion of a truncated search process underlying recollection also provides an answer to the question of whether recollection-based recognition decisions are slow relative to familiarity-based decisions (e.g., Yonelinas, 2002) or the reverse (e.g., Dewhurst, et al., 2006). Recognition decisions that are based on any retrieved detail of the prior experience, and that participants characterize as a ‘remember’ rather than a ‘know’ old response, could be associated with very fast RTs, as Dewhurst et al. (2006) have proposed, when retrieval is based on a truncated search process. In contrast, recognition decisions that must be based on the retrieval of a specific detail or details of the prior episode, such as source discriminations or discriminations between targets and highly similar lures (e.g., ‘frog’ vs. ‘frogs’; Hintzman and Curran, 1994), would be much slower decisions, because the search process could not be truncated or abbreviated. Thus, recollection might be fast or slow, depending on the task requirements.

### 2.24.5.3 Defining the Search Set

In models of recognition memory the search set is often defined in functional terms. For example, Ratcliff (1978) used a resonance metaphor to describe the memory set. In this metaphor, the test probe and item representations in memory are seen as tuning forks. The tuning fork representing the probe rings and evokes sympathetic vibrations from all items in memory that have tuning forks with similar frequencies. Thus the search set is defined by the degree to which items in memory are similar to the test probe. Search sets are also defined by degree of activation or match in several global matching models such as MINERVA 2 (Hintzman, 1988), SAM (Gillund and Shiffrin, 1984), and REM (Shiffrin and Steyvers, 1997). In distributed global matching models such as TODAM (theory of distributed associative memory; Murdock, 1982) and CHARM (composite holographic associative recall model; Metcalfe, 1982), the functional memory set is the entire memory representational system. In all of these models the size of the search set is not a critical issue, because the potentially large number of items in the search set that are not highly activated, or are very dissimilar to the probe, do not greatly influence the decision system and thus do not affect performance.

The size of the functional search set may also not be a problem for dual-process models of recognition that assume that recollection is based on a truncated search process, and for models of associative recognition and cued recall. In these cases, the search process may be very focused because of the retrieval cues that are present at test.

The size of the search set is, though, a critical aspect of any version of the random search-with-replacement model of recall. In the SAM model it is assumed that retrieval cues serve to activate the relevant search set. These retrieval cues are the context and successively retrieved items, and they will activate images in memory that are associated with them. Thus, the functional search set comprises the memory images that have an association with a given set of cues. SAM has been successively applied to a broad range of recall phenomena, but its applications have largely been restricted to recall of a given list based on the associations formed between the list items. Thus the functional search set for most of the simulations of SAM has been restricted to the study list.

Sirotin et al. (2005) present an extension of the SAM model (eSAM) that adds a semantic memory store, a contextual drift mechanism, and a memory search mechanism that uses both episodic and semantic associations. These researchers show that eSAM is capable of simulating the effects of both preexperimental semantic knowledge and prior episodic information in an episodic free-recall task. These additions mean that the functional search set in eSAM is thus potentially very large. This model has not been extended to fitting IRTs, and the temporal characteristics of many of the effects that the model has been applied to have not been evaluated. Thus, the implications of the assumptions of this extended search model for the temporal dynamics of free recall are not known.

As previously discussed, research has shown that certain types of retrieval cues are able to delineate or reduce the search set, whereas others do not. For example, cues defining a semantic category are effective cues in recall from semantic memory (e.g., Hermann and Murray, 1979) and give rise to semantic clustering in recall of categorized lists (e.g., Graesser and Mandler, 1978). While participants can use such relevant cues to guide search and retrieval, it is not clear why the participants in Roediger and Tulving's (1979) episodic memory study could not use similar types of cues to omit categories and exemplars from the search process.

### 2.24.5.4 Contradiction and Knowing Not

A problem conceptually related to the issue of defining the relevant search set is the question of how we know what we do not know, or what Kolers and Palef (1976) termed 'knowing not.' Most models of recognition memory, such as Sternberg's serial search model of short-term memory, Ratcliff's diffusion model, and the family of global matching models, treat a negative response as a default decision that is reached when there is insufficient evidence to support a positive decision. In this view, the latency of correct rejections cannot take less time than the slowest positive responses. This has been shown to be generally the case in standard recognition studies involving lists of unrelated words.

Mewhort and Johns (2000; Johns and Mewhort, 2002, 2003) have challenged this view with their demonstration that participants were fastest to correctly reject negative probes when they did not share a feature with the study set (the extralist feature effect). Mewhort and Johns argued that negative decisions are not a default decision, but rather, are based on an assessment of contradictory evidence. Kolers and Palef (1976) also challenged the default interpretation of negative responses based on their demonstration that participants can make faster negative than positive responses when deciding whether or not they had visited different cities. Shanon (1974, as cited in Kolers and Palef, 1976) found that the latency of negative responses was faster when the participant also had not visited the country in which the city is located. That is, participants were faster to say that they had never visited Paris if they had also never been to France. Kolers and Palef took this as evidence that participants might have used a hierarchical search strategy. With such a strategy one might be able to quickly respond that they have not been to Paris if they have not been to Europe or have not been to France, but their response time would become progressively slower the more specific or fine grained the search set must become. To borrow Mewhort and Johns' concept of contradiction, participants are faster to reject an item when the features of the probe (have you been to Toronto) contradict a large search set (North America) than progressively smaller search sets (Canada and Ontario). Thus, knowing not may involve the use of contradiction or be another manifestation of the extralist feature effect. Both effects may require that the appropriate search set be distinct or well defined, and that the relevant feature dimension or dimensions be highly salient.

### 2.24.5.5 Temporal Dynamics and Models of Memory

The analysis of RT provided the initial basis for search models of free recall and has provided a means to test and compare models of recognition and cued recall and, more recently, serial recall. Nevertheless, models of memory have not, for the most part, been directly concerned with accounting for RT. Gronlund and Ractliff (1989) pointed out that a general problem of the first generation of global matching models of item recognition was that they were essentially static and thus did not have mechanisms that are able to naturally predict the temporal dynamics of the search, retrieval, and decision processes. Diller et al. (2001) essentially echoed this comment when they noted that

> . . . although the use of single-step retrieval for recognition and sequential search for cued recall has rather obvious implications for RT predictions, the SAM and REM models have been restricted for the most part to accuracy predictions. (Diller et al., 2001: 414).

In a similar vein, Farrell and Lewandowsky (2004) commented that models of serial recall have neglected recall times because they have historically been concerned with measures of accuracy.

Gronlund and Ratcliff went further to suggest that temporal retrieval dynamics "provide a set of phenomena with which the next generation of theories must deal" (Gronlund and Ractliff, 1989: 857). This prediction has not been fulfilled because, I believe, we still do not fully understand the relationship between accuracy and RT. As we have seen, it is typically the case that accuracy and latency covary. That is, a number of variables such as confidence, list length, presentation rate, number of presentations, test, and study position influence accuracy and RT in complementary ways. It is therefore tempting to conclude that these two dependent variables are "two sides of the same coin" (to coin the phrase used by Kahana and Loftus, 1999). But there are also examples in which accuracy and RT are not highly correlated and therefore provide different measures of performance (e.g., MacLeod and Nelson, 1984; Rohrer and Wixted, 1994; Nobel and Shiffrin, 2001). As Kahana and Loftus (1999) argued, accuracy and RT can only be two sides of the same coin when the cognitive process of interest is a single operation that acts on a single type of information. Clearly, the processes underlying memory search and retrieval are much more complex, and thus accuracy and RT, although often highly correlated, cannot be simply two sides of the same coin.

Because it is not obvious how to marry the processes that produce changes in accuracy with those that give rise to the observed changes in RT, different approaches have been taken to model accuracy and RT. To use models of item recognition as an example, in Ratcliff's (1978) diffusion model the temporal dynamics are a property of the comparison process. In contrast, Hockley and Murdock (1987) proposed a dynamic model of the decision system which evaluates the outcome of the matching process over time to provide a means for Murdock's (1982) distributed associative model of memory, TODAM, to account for RT. Diller et al. (2001) adopted yet another approach in their assessment of retrieval completion (ARC-REM) model that they developed to enable REM to account for RT in recognition and recall. In this model it is assumed that the features of the probe are activated and become part of the comparison process gradually over time. The rememberer, given time, will wait until a sufficiently high proportion of probe features have become active and then interrupt the retrieval process to read out the current odds value and respond accordingly. This model has the ability to dissociate accuracy from RT.

Just as there are different ways to represent information in memory and different ways to search and retrieve this information, there are different ways to represent the temporal dynamics of the search, retrieval, and decision processes. I do not believe we will be able to solve one answer at a time. Rather, we must continue to explore different ways to represent the interplay between the encoding, representation, and retrieval of information on the one hand, and their associated temporal dynamics on the other, in order to eventually understand how they are related to one another.

# 2.25 Mathematical Models of Human Memory

**J. G. W. Raaijmakers**, Universiteit van Amsterdam, Amsterdam, The Netherlands

## 2.25.1 Introduction

In this chapter, I will provide a brief introduction to formal models of memory. Although such approaches have become quite successful, it would be an overstatement to say that they enjoy a great popularity among mainstream experimental researchers interested in human memory processes. There are probably several reasons for this skepticism, but an important one seems to be that it is not always easy to see what a model adds compared to a verbal theory or explanation. In this chapter, I will discuss a number of the most important theoretical approaches, paying special attention to the issue of what these models can do that could not be done using only verbal theorizing.

Formal or mathematical models of memory can be broadly classified in terms of their scope and generality. At the simplest end, we have descriptive models that try to characterize lawful empirical regularities. Memory researchers, for example, have tried to characterize the form of the forgetting function, the function that relates memory performance (percent recalled or some other measure) to the retention interval, the time since the item was studied. Although several promising candidate functions have been proposed (most notably power and logarithmic functions; see Wixted and Ebbesen, 1991), the issue of which function best describes the forgetting curve has not been resolved. One reason is that many candidate functions capture the basic aspects of the forgetting curve, i.e., a curve that is characterized by a decreasing rate of decline (the older the trace, the less likely it is that it will be forgotten in the next unit of time). Another reason is that the comparison between different functions is complicated by the fact that some models are more versatile than others (can handle more different shapes, can mimic data generated by other models), which means that it is easier for such a model to fit any given set of data, although at the expense of its generalizability to new data (for a discussion of these issues, see Lee (2004) and Myung and Pitt (2002)). Hence, although such descriptive models may be useful for predictive purposes, a shortcoming of these models is that they are limited in scope, predicting only one type of relation. What is lacking in such models is an account of what causes the forgetting, making it difficult to devise experimental tests that would pit one model against the other. Similar issues arise in attempts to model the learning curve, the function that describes the increase in performance as a function of the number of learning or training trials.

At the next level, we have models that try to account for the basic learning and forgetting data in terms of what happens to individual memory traces. One issue that the descriptive models usually do not discuss is whether the proposed forgetting (or learning) function describes each and every memory trace or just the average of a large number of separate curves. This question was the main focus of a large number of studies conducted in the 1950s and 1960s. In a series of studies using the so-called RTT paradigm, in which one study or reinforcement trial (R) was followed by two test trials (T) without any additional study in between, it was shown that the probability of a correct response (success) on the second test trial given no success at the first test trial was nearly zero and much lower than the average probability of a success. This seemed to be indicative of one-trial or all-or-none learning: The item was either completely learned on the study trial or not at all. This contradicted the standard assumption that learning was gradual. Such gradual learning functions were predicted by so-called linear operator models that assumed that the probability of a success on a given trial $n$ was a simple linear function of the probability of success on the previous trial. Thus,

$$p_{n+1} = Q(p_n) = \alpha p_n + \beta \qquad [1]$$

where $\alpha$ and $\beta$ are parameters that depend on the nature of the reinforcement given on trial $n$. The crucial assumption here was that this function described the behavior of each and every item independent of whether the response to that item had been correct on trial $n$.

To account for the results of the RTT paradigm, an alternative model was proposed in which the learning of an item was all-or-none: The item was either learned, always leading to a correct response, or not learned, in which case the probability of a success was at chance level. This model still predicts a gradual learning curve because such a curve represents the average of a number of items and subjects, each with a different moment at which learning takes place. The learning process in the all-or-none model may be represented by a simple Markov chain with two states, the conditioned or learned state ($L$) in which the probability correct is equal to 1, and the unconditioned state ($U$) in which the probability correct is at chance level (denoted by $g$). The following matrix gives the transition probabilities, the probabilities of going from state $X$ ($L$ or $U$) on trial $n$ to state $Y$ on trial $n+1$.

state on trial $n+1$ P(Correct)

$$\begin{array}{c} \\ L \\ U \end{array}\begin{array}{c} \begin{array}{cc} L & U \end{array} \\ \begin{bmatrix} 1 & 0 \\ c & 1-c \end{bmatrix} \end{array} \begin{array}{c} \\ \begin{bmatrix} 1 \\ g \end{bmatrix} \end{array} \qquad [2]$$

state on trial $n$

Strong support for the all-or-none model was obtained in an experiment by Bower (1961) in which subjects were presented lists of ten paired associate items consisting of a consonant pair and either the digit 1 or 2. This experiment was a breakthrough in the mathematical modeling of learning and memory because it did not just fit the learning curve but also a large number of other statistics (such as the distribution of the number of errors and of the trial of last error). The model fitted Bower's data remarkably well and this set a new standard for mathematical modelers.

One of the key predictions of the model was what became known as presolution stationarity: If the all-or-none assumption holds, the probability of responding correctly prior to learning (or prior to the last error) had to be constant:

$$P(e_{n+1}|e_n) = \text{constant for all } n \qquad [3]$$

Figure 1 shows the data from Bower's (1961) experiment and the predictions from the all-or-none and linear models. The data are in almost perfect agreement with the predictions of the all-or-none model and clearly inconsistent with those of the linear model. It may be shown that this presolution stationarity property is crucial for the all-or-none model in that the combination of this property together with the distribution of the trial of last error is a sufficient condition for the all-or-none model. That is, if both of these properties hold, the all-or-none model has to be the correct model. Since this property is strong evidence for the all-or-none model, it is understandable that proponents of gradual learning models tried to reconcile the finding with a model in which learning was more gradual. The argument that was used was based on the idea that the result might be explained if individual differences in the speed of learning were assumed. If items and/or subjects differ in their learning rate, errors on later trials might be

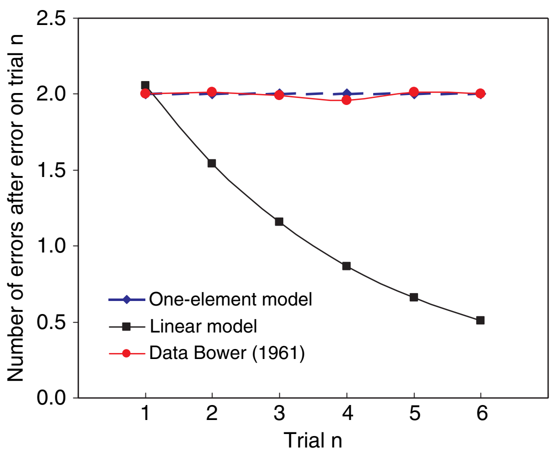

**Figure 1** Number of errors following an error on trial *n* as a function of *n*. Data from Bower GH (1961) Application of a model to paired-associate learning. *Psychometrika* 26: 255–280; predictions for the all-or-none model and the linear model.

coming mainly from the more difficult items and from subjects with slower learning rates. However, in an ingenious analysis, Batchelder (1975) showed that this could not work. Batchelder analyzed the predictions of the linear operator model (eqn [1]) using a completely arbitrary distribution for the learning rate parameter and proved that it was impossible for the linear operator model to fit these results.

The success of the all-or-none model soon led to a series of related models that were based on the notion of discrete changes in the state of studied items. One issue that was investigated was whether this notion could account for transfer effects based on underlying conceptual categories. For example, suppose that several lists of paired associates are learned in succession where the stimulus items that belong to a particular conceptual category all have the same response. If learning is all-or-none, we might assume that a particular item will be learned in an all-or-none fashion as long as the conceptual relation is not yet discovered, but that once the relation has been discovered (which itself involves an all-or-none process) any new item belonging to the same category will start in the learned state rather than the unlearned state (i.e., no errors will be made on this item). Greeno and Scandura (1966), Batchelder (1970), and Polson (1972) showed that a relatively simple generalization of the all-or-none model gave a good account for the results of such experiments.

Although the all-or-none model was quite successful, the experiments that it was applied to were extremely simplified (simple stimuli, coupled with one of two possible responses). From the outset it was clear that the model would not hold for more complex experiments. However, perhaps the basic idea of the all-or-none model could be generalized in such a way that more complex learning tasks might be described as involving a series of stages, each stage being completed in an all-or-none manner. The most successful attempt at this type of generalization of the all-or-none model can be seen in the work of Greeno and associates (Greeno, 1968, 1974; James and Greeno, 1970; Humphreys and Greeno, 1970). Greeno did an extensive theoretical and empirical analysis of a two-stage learning model. As there are now two learning rate parameters, one for each stage, it becomes possible to look at the factors that affect each of these parameters and hence provide an interpretation for what the separate stages stand for. Contrary to the traditional two-stage theory of paired-associate learning (Underwood and Schulz, 1960), which maintained that the first stage involved a process of response learning and the second stage stimulus–response association, the results from the two-stage model proposed by Greeno were largely consistent with the idea that the first stage involved storage of the pair and the second stage learning to retrieve the pair.

Perhaps the most significant extension of the all-or-none model was proposed by Atkinson and Crothers (1964), who included the notion of a short-term memory state. The assumption here was that an item could move to a short-term state when it was studied but that it could move back to the unlearned state on subsequent trials when other items were being studied. Thus, such an item would show short-term forgetting: When tested immediately after having been studied, the response would be correct; however, when retested after several intervening trials, the probability of a correct response would be back at the baseline level (unless the item had moved to the learned state). The learning process in such models can be described using two transition matrices, one that applies when the target item is presented ($\mathbf{T_1}$) and one that applies when another item is presented ($\mathbf{T_2}$):

$$\mathbf{T}_1 = \begin{array}{c} \\ L \\ S \\ U \end{array} \begin{array}{c} \begin{array}{ccc} L & S & U \end{array} \\ \begin{bmatrix} 1 & 0 & 0 \\ d & 1-d & 0 \\ wc & w(1-c) & (1-w) \end{bmatrix} \end{array} \qquad [4a]$$

$$\mathbf{T}_2 = \begin{array}{c} \\ L \\ S \\ U \end{array} \begin{array}{c} \begin{array}{ccc} L & S & U \end{array} \\ \begin{bmatrix} 1 & 0 & 0 \\ (1-f)r & (1-f)(1-r) & f \\ 0 & 0 & 1 \end{bmatrix} \end{array} \qquad [4b]$$

where $L$ is the state in which the item has been learned, $S$ is the short-term memory state, and $U$ is the state in which the item is not learned.

Several variants of such LS-models (Long-Short) were introduced, including ones that assumed that there could be additional storage (as well as forgetting) on intervening trials (note the parameter $r$ in $\mathbf{T_2}$). This notion is of course related to the more general concepts of rehearsal and consolidation. The idea of storage on trials intervening between presentations might provide an explanation for the spacing effect, the finding that (in general) spaced study presentations are more beneficial for later recall than massed presentations. Bjork (1966), Rumelhart (1967), and Young (1971) developed (increasingly complex) models to account for such spacing effects in paired-associate recall, leading to a model that became known as the General Forgetting Theory. However, these models never gained much popularity, perhaps because they were introduced at a time when the emphasis in the formal modeling of memory processes shifted to the next level following the 1968 publication of the Atkinson-Shiffrin model.

The theoretical framework that was proposed by Atkinson and Shiffrin (1968) made a distinction between structural properties of the memory system that were fixed and permanent, and control processes that operated on those structures. Control processes included such processes as rehearsal, coding, and retrieval strategies. The Atkinson-Shiffrin model assumed that information first enters a Short-Term Store (STS) and that the processing within STS determines storage in a permanent memory system, Long-Term Store (LTS). Information that is still present in STS at the time of testing will be readily available, but information that is no longer in STS will have to be retrieved from LTS. The probability of successful retrieval from LTS was a function of the strength of the LTS trace, which was itself determined by the nature of the processing in STS.

An important advancement of the Atkinson-Shiffrin theory was the model that was proposed for rehearsal processes in STS. It was assumed that at any time only a few items could be simultaneously in STS and that once STS was filled, any new item would have to replace one of the other items in STS. This idea led to the introduction of the concept of a rehearsal buffer as a simple model for rehearsal in STS, or rather a family of models since various alternatives were considered that differed in whether older items were more or less likely to be replaced by a new item. In these models, it was assumed that storage in LTS is directly related to the length of time that a particular item stays in the buffer. This storage assumption has often been misinterpreted as implying that the Atkinson-Shiffrin theory would assume that only time in STS determines how much information gets stored in LTS. However, Atkinson and Shiffrin proposed that rehearsal in STS is a control process and that the nature of the processing in STS will vary depending on the requirements of the task. In some tasks, the emphasis will be on simply maintaining the information in STS, but in other tasks the emphasis is on coding the information in LTS. This distinction between coding and rehearsal (or elaborative and maintenance rehearsal as it was later called) made it possible to accommodate levels-of-processing effects, i.e., the notion that the nature of the processing in STS determines the probability of later recall. Thus the standard textbook story that supposes that there is a fundamental difference between the Two-Store model and the levels-of-processing framework proposed by Craik and Lockhart (1972) is incorrect (see also Raaijmakers, 1993).

The major significance of the Atkinson-Shiffrin model was that it was not simply a model for one specific experimental task but a general framework within which models could be formulated for specific tasks. Thus, in addition to the short-term memory tasks investigated in the 1968 paper, the same general framework was applied to search and retrieval processes in long-term memory (see Shiffrin, 1968; Shiffrin and Atkinson, 1969), free recall (Shiffrin, 1970), and recognition memory (Atkinson and Juola, 1974). This was a major step forward compared to, for example, the General Forgetting Theory that did not allow a simple generalization to free recall or recognition paradigms. This type of approach in which a general framework is presented within which specific models are developed for specific tasks is a common characteristic of most current models of memory. In the next sections, I will discuss a number of such approaches with special attention given to the question how these models are able to provide novel explanations for experimental findings.

## 2.25.2 The ACT Model

The first model that we will discuss in more detail is the ACT theory developed by John Anderson. The ACT theory (Adaptive Control of Thought) has its roots in early theories of spreading activation (Collins and Loftus, 1975) and the work of Newell and Simon on cognitive architectures. ACT is not just a model for memory processes but aims to provide a general framework or architecture for all cognitive tasks (sometimes termed a Unified Theory for Cognition). Although ACT has undergone many changes since it was first presented in 1976, there are a number of aspects of the theory that have remained more or less the same over the years. First, ACT does not make a fundamental distinction between semantic and episodic memory. All knowledge facts and all experiences are stored in a single declarative memory system. Second, ACT makes a distinction between a working memory system, a declarative memory system, and a procedural memory system. Declarative memory is modeled as a large set of interconnected nodes or chunks, while the procedural system has the form of a large set of production rules (rules of the form IF conditions A, B, and C are satisfied, THEN action Y is performed) that fire whenever their conditions are satisfied. Although one sometimes gets the impression that ACT is more a programming language in which various cognitive tasks may be modeled, the ACT framework has been used to develop detailed quantitative models for various memory tasks that do make specific and testable predictions.

In the original ACT model (Anderson, 1976), retrieval of a target item B from a cue item A was based on a notion of spreading activation in which a particular node was either active or inactive. The spreading of activation was controlled by the relative strength of the links from the cue to the nodes that were connected to the cue node. Once a node was activated, it would in turn start to activate other nodes associated with it (a threshold was assumed to prevent activation of all nodes). Since activation is all-or-none, response latency was determined by the time it took for activation to spread to the target node. However, using a primed lexical decision task, Ratcliff and McKoon (1981) showed that the semantic distance between the prime and the target does not affect the time at which the facilitation due to priming begins to have its effect, although it does affect the magnitude of the facilitation. Anderson (1983a,b) proposed a revised version of ACT, named ACT*, in which nodes were no longer activated in an all-or-none fashion. In ACT*, each node had a continuously varying activation value. The larger the activation value, the faster and the more likely it was that the trace would be retrieved.

Anderson (1981, 1983b) showed how this model could be used to explain a number of memory phenomena. In ACT*, performance is determined by the strength of the target trace relative to that of other traces associated with the retrieval cues used. On each presentation of an item, there is a probability that a trace will be formed and once formed, further presentations provide additional strength to the trace. The strength added to a trace was assumed to decay according to a power law. More specifically, the trace strength ($S$) for a trace that has been strengthened $n$ times is equal to:

$$S = \sum_{i=1}^{n} t_i^{-b} \quad [5]$$

where $t_i$ is the time since the $i$-th strengthening and $b$ is a decay parameter (between 0 and 1).

Anderson (1981, 1983b) showed that the ACT* model predicts a large number of standard findings from the memory literature. One intriguing result that came out of this analysis was that performance in recall tasks is a function of both the absolute and the relative strength of the target trace. In ACT*, the probability of recall is a function of both relative and absolute strength, but the latency is a function of the relative strength only. Anderson (1981) demonstrated that this implies that in a standard interference task there will be an interference effect on latency, even when the conditions are equated on percent correct. This result implies that it will not be possible to completely equate interference and control conditions at the end of second-list learning, as was implicitly assumed in many experiments on interference and forgetting (e.g., when both conditions learn to the same criterion). Basically, this prediction is due to the fact that if probability of recall is a function of both relative and absolute strength, it must be the case that in the condition in which it takes longer to reach a particular recall criterion, the absolute strength will be larger at the point where the criterion is reached. Hence, to get equal percent recall, this must be compensated for by a lower relative strength, hence a longer latency.

In a similar way, it can be shown that if the second list is again learned to a fixed criterion, performance on the second list may show proactive facilitation instead of interference, when it is tested after a delay in such a way that differences in relative strength are less important and performance is mostly determined by the absolute strength of the target trace. The latter may be experimentally accomplished by giving an unpaced test in which subjects are given ample time to produce the response. In such a test, differences in relative strength become less important since eventually the trace will be retrieved, although it may take a long time. Anderson (1983b) reports results that confirm this counterintuitive prediction. Mensink and Raaijmakers (1988) showed that these predictions hold not only for the ACT* model, but for all models in which performance is a function of both relative and absolute strength.

The latest version of ACT, called ACT-R (ACT-Rational), is based on a number of assumptions that are quite different from ACT*, yet the model shares enough features with the older models to justify using the same acronym. There are two important differences with ACT*. First, ACT-R no longer assumes a spreading activation conception of memory retrieval. Rather, it is assumed that activation of a memory trace or chunk is a direct function of the association between the source elements (the retrieval cues) to that chunk and there is no spread of activation to other chunks from a chunk that is not itself a source of activation. Second, ACT-R is based on the assumption that the cognitive system is a rational system, i.e., the rules that govern the activation of information from memory are such that they optimize the fit to the environmental demands. This rational approach to cognition has been very influential (see also more recent models such as the REM model (Shiffrin and Steyvers, 1997) that will be discussed later in this chapter).

To appreciate this rational approach, it is helpful to consider some of the results discussed by Anderson and Schooler (1991). Anderson and Schooler showed that many of the functional relationships that we know from standard memory experiments (e.g., the typical learning and forgetting functions) can also be seen in the environment with material that has little to do with memory *per se*. For example, the probability that a particular word will appear in the headline of *The New York Times* or the probability that one will get an e-mail from a specific person obey the same functional relations as we know from memory research. If a particular word has appeared in the headline the probability that it will appear again after X days follows the same power law that we are familiar with when looking at standard retention functions. Thus, the basic idea of ACT-R is that the cognitive system has developed in such a way as to provide an optimal or rational response to the information demands of the environment: The probability that a particular item will be remembered at a particular time reflects the probability that it will be needed at that time.

This rational approach is reflected in the equations that ACT-R uses to describe the activation of a particular trace given that specific cues are present. In the ACT-R approach to memory (see Anderson et al., 1998) it is assumed that the activation of a chunk $i$ depends both on its base-level activation ($B_i$, a function of its previous use) and on the activation that it receives from the elements currently in the focus of attention:

$$A_i = B_i + \sum_j W_j S_{ji} \qquad [6]$$

where $S_{ji}$ is the strength of the association from element $j$ to chunk $i$ and $W_j$ is the source activation (salience) of element $j$. If we interpret the base-level activation as similar to the prior odds of the chunk being needed and the second term as similar to the (log) likelihood of the trace given the available evidence (the cues), then the similarity of eqn [6] to Bayes' rule becomes evident. (According to this rule, the logarithm of the posterior odds is equal to the log prior odds plus the log likelihood ratio.) According to ACT-R,

$$S_{ji} = S + \ln(P(i|j)) \qquad [7]$$

where $P(i, j)$ is the probability that chunk $i$ will be needed when element $j$ is present or active. Note that since $P(i, j) \leq 1$ the logarithm of $P(i, j)$ will be $\leq 0$ and hence $S$ represents the maximum value that $S_{ji}$ can obtain. For all practical purposes, these $S_{ji}$ may be viewed as reflecting the associations between the cues $j$ and the target trace. In ACT-R (see Anderson et al., 1998: 344), it is typically assumed that if there are $m$ elements associated to the cue $j$, each will have a probability of $1/m$, hence:

$$S_{ji} = S + \ln(1/m) = S - \ln(m) \qquad [8]$$

Note that this equation assumes that for the associative activation $S_{ji}$ it does not matter that a particular association may have become stronger in the course of the experiment: all that matters is the number of associative links from the cue to other elements or its fan. This seems a rather strong assumption, yet it does play an important role in ACT-R's handling of data from recognition experiments.

The first part of eqn [6], the base-level activation, reflects the activation that remains from previous presentations of the target trace or chunk. The activation of a chunk is subject to decay so that the longer ago the chunk was strengthened, the less the contribution of that activation to the current base-level activation. The equation for the base-level activation is thus given by:

$$B_i = \ln\left(\sum_{j=1}^{n} t_j^{-d}\right) + B \qquad [9]$$

In this equation, $n$ is the number of times the chunk has been retrieved from memory, $t_j$ indicates the length of time since the $j$-th presentation or rehearsal, and $d$ and $B$ are constants. It is evident that eqn [9] is closely related to eqn [5] that describes the activation in ACT*.

Finally, as in ACT*, it is assumed that the latency of a response is an exponentially decreasing function of the activation level of the corresponding chunk. However, unlike ACT*, ACT-R does not simply look at the activation of the target trace but takes into account other traces or chunks that might be activated. It is assumed that the system will always retrieve the chunk with the highest activation (provided it is above the threshold). Due to the presence of noise in the system, the activation values will not have a fixed value but rather a probability distribution (a logistic distribution is assumed). The probability that a chunk with a mean activation value of $A_i$ (and variance $\sigma^2$) is above a threshold $\tau$ is then equal to:

$$\Pr(i) = \frac{1}{1 + \exp[(A_i - \tau)/s]} \quad \text{where } s = (\sigma\sqrt{3})/\pi \qquad [10]$$

If there are more chunks above threshold, the system will choose the one with the largest activation. The probability that the target chunk has the largest activation is given by an equation similar to the Luce choice rule:

$$P(choose\ i) = \frac{\exp(A_i/t)}{\sum_j \exp(A_j/t)} \quad \text{where } t = (\sigma\sqrt{6})/\pi \qquad [11]$$

Although ACT-R is much more than a model for memory, it does explain quite a number of findings from the memory literature. We will briefly discuss two such applications, the analysis of recognition memory proposed by Anderson et al. (1998) and the model for spacing effects developed by Pavlik and Anderson (2005).

Any ACT-R model begins with the specification of a number of production rules. In the recognition model, the basic production rules are the rules for Yes and No responses, which simply state that if a trace is found that corresponds to seeing the item in the list context, a Yes response will be made and another rule that applies when the first one fails and that generates a No response. Hence, contrary to most other current models for recognition, ACT-R is not based on a signal-detection-like approach but rather on the retrieval of a trace representing the item in the list context. Note that in such a model negative responses (No responses) are not based on a low familiarity value but on the fact that the rule for generating a positive response passes a waiting time threshold. Although such an approach may work well for explaining data observed on positive responses, there are some problems when negative responses are to be explained. First, this type of model has no simple solution to generate fast negative responses. Second, the model predicts that negative responses are not affected by various experimental factors (e.g., list length) unless one assumes that the waiting time threshold itself is a function of those factors (a solution that is hard to defend).

According to ACT-R, performance in a standard recognition task is determined by the activation of the chunk representing the tested item. According to eqn [6], this is a function of the base-level activation and the associative activation that it receives from the cues (the presented word and the list context). Hence,

$$A = \ln\left(\sum_{j=1}^{n} t_j^{-d}\right) + B + W_W S_W + W_L S_L \qquad [12]$$

where $W_W$ is the weighting given to the word, $S_W$ is the strength of the association from the word to the trace, $W_L$ is the weight of the list context, and $S_L$ is the strength of the context association. According to Anderson et al. (1998: 348), the first term may be approximated by:

$$\ln\left(\sum_{j=1}^{n} t_j^{-d}\right) = \ln\left(\frac{anT^{-d}}{1-d}\right) = C + \ln(n) - d\ln(T) \qquad [13]$$

where C captures the constant terms. Since $W_W S_W$ is also a constant and $S_L$ is equal to $S - ln(L)$ according to eqn [8], the activation of eqn [12] may be written as:

$$A = B' + \ln(n) - d\ln(T) - W_L \ln(L) \qquad [14]$$

where $B'$ combines all the constant effects, $n$ equals the number of presentations/rehearsals, $T$ is the time since presentation, $L$ is the list length, $d$ is the decay rate, and $W_L$ is the attentional weighting of the list context. In their analyses, Anderson et al. (1998) set $d$ and $W_L$ equal to 0.5.

One interesting finding that this model predicts (and that would have been difficult to foresee without actually running the simulations) is the differential effect of list length and list strength in recognition. The list length effect refers to the effect of the number of other items on the list, while the list-strength effect refers to the effect of the strength of those other items (where strength might be manipulated by such factors as presentation time or additional presentations). In recall paradigms, both of these effects are present but in recognition tasks there is no effect of list strength (or a slightly reversed effect), although there is a list-length effect. Shiffrin et al. (1990) showed that it is very difficult for many models to predict both the presence of an effect of the number of other items, yet no effect of the strength of those other items. ACT-R's recognition model, however, does explain this intricate pattern of results. The basic reason is that in ACT-R, strength manipulations affect the base-level activations whereas the length of the list mainly affects the associative activation (i.e., the fan effect; see eqn [13]). There are a few other factors that play a role (such as small differences in retention interval when presentation time or the length of the list is varied) but the main effects are due to these two factors. Hence, increases in strength affect the base-level activation for the tested item but do not affect the interfering effect of the other items on the list. Of course, one might question the assumption that strength manipulations do not affect the associative activation (as was the case in ACT*), but even so, the ACT-R analysis points to a possible solution to the puzzle of length and strength effects, a pattern of results that has proved difficult to accommodate in other models for recognition.

Pavlik and Anderson (2005) presented an application of ACT-R to account for spacing effects in paired associate recall tasks. They showed that their model could account for all of the standard findings in the spacing literature including a new experiment that they performed in which spacing was varied over much longer intervals than is normally the case in these experiments. In their experiment, there were two sessions separated by 1 or 7 days. During the first session, the subjects learned the English translations for a number of Japanese words. The pairs were presented four or eight times during the first session with interpresentation spacings of two, 14, or 98 trials. During the second session, they were given a number of test trials on the pairs learned during the first session. The data showed a crossover interaction such that the shorter spacings led to better performance at the end of the first session but worse performance at the start of the second session (see **Figure 2**).

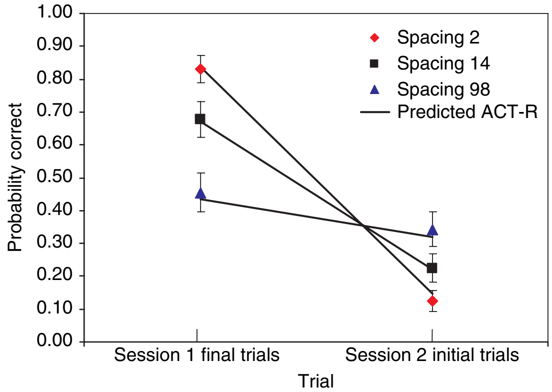

**Figure 2** Probability of a correct response before and after the retention interval as a function of the spacing between the presentations during session 1. Observed data from Pavlik PI and Anderson JR (2005) Practice and forgetting effects on vocabulary memory: An activation-based model of the spacing effect. *Cogn. Sci.* 29: 559–586; predictions from the ACT-R model. Error bars correspond to two standard errors.

In the application of ACT-R to this experiment, the associative activation will be constant and hence the analysis focuses on the base-level activation. Without any modifications, the ACT-R model does not predict such spacing effects (Pavlik and Anderson, 2005: 570), so some changes are necessary. The most likely candidate is the decay rate parameter $d$ (see eqn [9]). In order to account for spacing effects, the decay rate has to be made sensitive to the intervals between successive presentations. The formulation that Pavlik and Anderson (2005) used is based on the assumption that the decay rate for the contribution from the $j$-th presentation is a function of the activation at the time of the $j$-th presentation. Thus, eqn [9] is replaced by the following equation for the activation after $n$ presentations:

$$B_n = \ln\left(\sum_{j=1}^{n} t_j^{-d_j}\right) \textit{ with } d_j = ce^{B_{j-1}} + a \qquad [15]$$

If at the start of the $j$-th presentation the activation was high (i.e., the activation after $j$–1 presentations, $B_{j-1}$), $d_j$ will be larger and thus the contribution from that trial at later tests will be lower due to the more rapid decay. Hence, the effect of long spacing intervals (characterized by low activation at the end of the retention interval) will be longer lasting and this more than compensates for their longer retention intervals, thus leading to a spacing effect.

These two examples illustrate the way in which task-specific models are constructed within the ACT-R framework. As mentioned before, ACT-R is an ambitious attempt to provide a unified theory of cognition. As such, restricting the evaluation to just its contribution as a memory model clearly does not do justice to the theory as a whole. However, even though the ACT-R has not been evaluated as extensively as some of the other memory models, the theory has already made a large number of contributions (see Anderson et al., 1998; Pavlik and Anderson, 2005). There have also been extensions of the framework to implicit memory effects, but these need to be investigated more thoroughly to determine whether they are indeed viable explanations of priming effects. A recent extension of the ACT-R framework is the identification of specific modules within ACT-R with specific regions in the brain. Anderson and colleagues (Anderson et al., 2003, 2004, 2005) have shown that the duration of those components can be mapped onto the BOLD response obtained in the associated brain regions (using the assumption that the duration but not the intensity of a specific component is reflected in the BOLD response). This of course opens up a whole new approach to the validation of the general ACT-R theory and also provides a much-needed theoretical framework for the interpretation of neuroimaging data. All in all, then, ACT-R represents an excellent example of the trend toward more general theories that has characterized recent research on mathematical models for memory processes.

## 2.25.3 The SAM and REM Models

### 2.25.3.1 The SAM Model and Related Models

The next model that we will discuss is the SAM model (Raaijmakers and Shiffrin, 1980, 1981b) and a number of related models that have been proposed in recent years. The SAM model (Search of Associative Memory) started out as a model for free recall (Raaijmakers, 1979). It was soon realized that the model could be generalized to paired-associate recall (Raaijmakers and Shiffrin, 1981a) and recognition (Gillund and Shiffrin, 1984). The model was subsequently extended to handle interference and forgetting (Mensink and Raaijmakers, 1988, 1989) and, more recently, spacing effects (Raaijmakers, 2003). Related models in which a semantic memory component was added have been proposed by other researchers, e.g., PIER2 (Nelson et al., 1998) and eSAM (Sirotin et al., 2005). In addition, Shiffrin and coworkers have developed a new model, REM, that is in many ways similar to SAM, but provides a solution to some problems relating to recognition memory, and that has also been extended to semantic and implicit memory paradigms (Shiffrin and Steyvers, 1997; Schooler et al., 2001; Wagenmakers et al., 2004).

The original SAM model was based on a search model proposed by Shiffrin (1970). It shared a number of characteristics with the Atkinson-Shiffrin theory such as the notion of a STS buffer as a model for rehearsal processes and the assumption that storage in LTS is a function of the nature and duration of rehearsal in STS. SAM assumes that when a specific event occurs (this could be anything but in most analyses it is simply the presentation of an item on a study list) various types of information are stored in the memory trace representing that event. Any type of information might be stored in the trace (the memory image, as it is usually called in SAM), but the model uses a classification in item, associative (interitem), and contextual information. Retrieval of information from LTS is a cue-dependent process, i.e., what is retrieved from LTS depends on the information that is present in STS at the time of the retrieval. In applications of SAM to typical memory paradigms such as free recall or recognition, the cues may be words from the studied list, category cues, and contextual cues.

Whether or not a specific memory trace is retrieved depends on the relations between the cues and the information stored in the trace. These relations are defined in a retrieval structure, a matrix that gives the associative strengths between possible cues and the stored memory image. A crucial assumption in SAM is that when several cues are used simultaneously (e.g., context and a retrieved item), the overall strength of the set of cues ($Q_1$, $Q_2$, etc.) to a specific trace is given by the product of the individual associative strengths:

$$A(i) = \prod_{j=1}^{m} S\left(Q_j, I_i\right) \qquad [16]$$

where $A(i)$ is the combined strength or activation of image $I_i$, and $S(Q_j, I_i)$ is the strength of association between cue $Q_j$ and image $I_i$. The most important aspect of this eqn [16] is the assumption that individual cue strengths are combined multiplicatively into a single activation measure. This multiplicative feature focuses the search process on those memory traces that are strongly associated with all cues, the intersection of the sets of traces activated by each cue separately. An important aspect of SAM is that retrieval strategies are implemented in the choice of retrieval cues but once a specific set of retrieval cues is used, the retrieval process is automatic and completely determined by the relations between the retrieval cues and the information stored in memory.

The activations $A(i)$ determine both the probability of retrieval of a memory trace in recall tasks as well as the probability that an item will be recognized as having been presented on the study list. It is assumed that in recall tasks the probability of being able to generate the answer depends on selecting or sampling the correct target trace and on the probability that enough relevant features from the stored trace are activated to enable the reconstruction or recovery of the answer. It is assumed that the system may sample several times before giving up, but if recovery fails once sampled, it will fail again if the same trace is sampled a second time using the same cues.

More specifically, the probability of sampling a trace is assumed to be proportional to the activation strength of the trace:

$$P_S(I_i) = \frac{A(i)}{\sum A(k)} \quad [17]$$

The probability of recovery is assumed to be an exponential function of the summed strengths of the retrieval cues to the sampled image:

$$P_R(I_i) = 1 - \exp\left[-\sum_{j=1}^{m} S\left(Q_j, I_i\right)\right] \quad [18]$$

Combining these assumptions, an equation can be derived that gives the probability of recall for a simple cued recall test in which the same set of cues is used for a maximum of *Lmax* retrieval attempts:

$$P_{recall}(I_i) = \left[1 - (1 - P_s(I_i))^{L_{\max}}\right] P_R(I_i) \quad [19]$$

The above equations apply to cued recall. SAM was, however, initially developed as a model for free recall, which is more complicated since during the search process other list items may be retrieved and these may then be used as new retrieval cues. In SAM it was assumed that during the presentation of the list items, a few items may be simultaneously rehearsed and that storage of context, item, and interitem information was a function of this rehearsal process. That is, the amount of information that is stored for an item was assumed to be a function of the time that that item was rehearsed or the time that a specific pair was simultaneously rehearsed (in case of the interitem associations). For this part of the model, a buffer model similar to that of Atkinson and Shiffrin (1968) was used. At the time of testing, any items still in the buffer are first recalled (unless of course there are no items available anymore in the buffer) and then the process of retrieval from LTS itself starts. Initially, the search process is based solely on the context cues that are available but as soon as a list item is retrieved, that item is used as an additional cue. If this item+context search is not successful (i.e., if there are *Lmax* consecutive retrieval attempts that do not lead to new items being recalled) the system will revert back to using only the context cue. This process continues until no more new items can be recalled (within a reasonable time). For this latter aspect, a stopping criterion was used based on the total number of failed retrieval attempts (*Kmax*), but other stopping rules are also possible (although we have not seen a case where the nature of the stopping rule seems to matter). SAM also assumes that new information may be stored during the retrieval process. That is, if a new item is successfully retrieved, the associative connections between the probe cues and the sampled image are strengthened. Although conceptually simple, it turns out to be virtually impossible to derive analytical predictions for the model for free recall, hence all analyses have been done using Monte Carlo simulations.

Raaijmakers and Shiffrin (1980) reported a large number of such simulation results and showed that the SAM model gave an excellent account of many standard findings from the free recall literature. These included serial position curves, the effects of list length and presentation time, cumulative recall data, the phenomenon of hypermnesia, and many others. As an example, **Figure 3** gives the predictions from SAM and the observed data for the experiment of Roberts (1972) in which presentation time and list length were varied over a wide range.

Of particular interest was the prediction by SAM of the part-list cuing effect (extensively discussed in Raaijmakers and Shiffrin, 1981b). This effect refers to the finding that presenting a random sample from the list items as additional cues did not have the expected positive effect on the recall of the remaining list items as one would have expected based on the notion that subjects use interitem associations during recall. SAM's ability to generate the part-list cuing effect was rather surprising since it ran counter to the then standard interpretation of that effect in terms of inhibitory factors. Subsequent experiments (reported in Raaijmakers and Phaf, 1999) demonstrated the viability of SAM's account of the part-list cuing effect.

SAM assumes that recall and recognition involve the same basic process of activating information. However, when a specific item X is tested for recognition, the response is not based on the retrieval of information from just the trace corresponding to X (although there is no principled reason why it could not be) but on the overall activation of the memory system induced by the retrieval cues. The overall activation is used as the familiarity measure in the

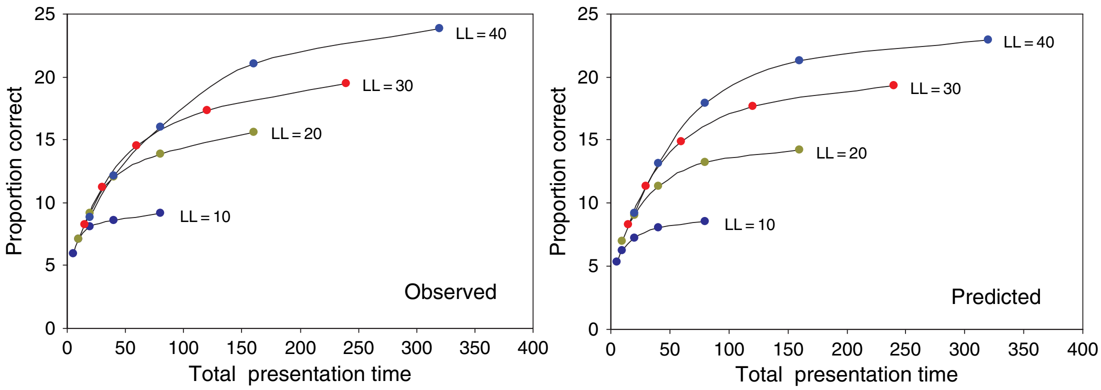

**Figure 3** Observed (left panel, Roberts WA (1972) Free recall of word lists varying in length and rate of presentation: A test of total-time hypotheses. *J. Exp. Psychol.* 92: 365–372) and predicted (right panel) mean number of correct recalls in free recall as a function of presentation time and list length (LL). Predictions are based on the SAM model with parameter values as given in Raaijmakers JGW and Shiffrin RM (1980) SAM: A theory of probabilistic search of associative memory. In: Bower GH (ed.) *The Psychology of Learning and Motivation: Advances in Research and Theory*, vol. 14, pp. 207–262. New York: Academic Press.

standard signal detection model for recognition. This approach to recognition is termed a global familiarity model, in contrast to local familiarity models that are based on the familiarity or activation of the target trace. The global familiarity model is currently the most popular approach to modeling recognition and is used in a variety of models other than SAM (e.g., TODAM, MINERVA2, REM). One obvious advantage of the global familiarity approach is that it provides a simple way to deal with false alarms, the recognition of nonlist items (the distractor items), without having to make any additional assumptions. In the SAM recognition model developed by Gillund and Shiffrin (1984), the global familiarity measure is simply the overall activation in response to the retrieval cues used, i.e., $\sum A(k)$, with $A(k)$ as in eqn [16].

In the SAM model, the role of context cues in episodic memory retrieval is emphasized. Many experiments have shown that testing in a context that is different from the context at the time of encoding leads to a decrease in performance (especially in free recall tasks) compared to testing in the same context. This holds both for changes in the environmental context (e.g., Godden and Baddeley, 1975; Smith, 1979; Grant et al., 1998) and changes in the internal state or context (Eich et al., 1975; Eich, 1980). Mensink and Raaijmakers (1988, 1989) extended this notion to within-session changes in context. They assumed that within an experimental session there are gradual changes in context and that the context that gets stored in a trace is a selection from the currently available context elements. The model that they developed was adapted from Stimulus Sampling Theory (Estes, 1955) and assumed that there was a random fluctuation between a set of available or current context elements and a set of (temporarily) unavailable context elements. Mensink and Raaijmakers (1988) showed how such a notion of context fluctuation in combination with the SAM model for cued recall could account for many of the traditional results in the area of interference and forgetting. Using the same basic model, Raaijmakers (2003) showed that it could also account for standard spacing effects. A related analysis of contextual fluctuation processes as well as an application to free recall was developed by Howard and Kahana (1999; see also Kahana, 1996). Whereas in the original Raaijmakers and Shiffrin (1981b) analysis of free recall, a constant context was assumed during presentation and testing of a single list, Howard and Kahana (1999) made the reasonable assumption that context varies even within a single list and that upon retrieval of a specific trace not just the item information would be retrieved, but also the stored context information. They showed how such a model could account for a number of detailed aspects of recall processes.

Nelson et al. (1998) developed a model (PIER2) related to SAM that they showed could successfully explain a large number of findings on the effects of extralist cues on recall. In these experiments, a list of items is studied; at test, the subjects are given a cue and they are told that the cue item is meaningfully related to one of the list items. The basic idea of PIER2 is that during encoding of a list of words, explicit as well as implicit representations (traces) are formed. The implicit representation is an automatic by-product of the comprehension process. Extralist cued recall may result from retrieving either the explicit or the implicit representation (or both). The PIER2 model focuses on the contribution to recall resulting from the implicit representation. It assumes that during encoding the study or target item as well as its associates are activated and that the activation strengths of both the target item and the associates are a function of their interconnectedness. At the time of testing, when the extralist cue is presented, a sampling function similar to that of SAM is used in which the probability of sampling the target item is proportional to the relative cue-to-target activation strength, relative to the strengths of the connections of the cue to its other associates and the strengths of the connections of the target to its other associates. Thus, the more unique the cue-to-target association (both at the cue side and at the target side) the higher the probability of sampling the (implicit) target representation. Using this sampling model, Nelson et al. (1998) showed that it successfully accounted for many results from previous experiments on extralist cuing.

Even though the SAM model has been quite successful in explaining a large variety of experimental results, the model in its original form fails to account for the list-strength effect (or rather the lack of it) and a number of other results in recognition (see Shiffrin et al., 1990). It soon became clear that in order to be able to explain these results, it would have to be assumed that the extent to which a trace is activated by an unrelated item cue should decrease as the number of features stored in that trace is increased (i.e., as the trace gets stronger). In SAM and most other models, it was assumed that the associative strength was a function of the number of overlapping elements, hence it should either stay the same or increase with the number of features stored.

A solution to this problem was found by adopting a so-called Bayesian or rational approach. In this type of approach (Shiffrin and Steyvers, 1997; McClelland and Chappell, 1998), it is assumed that the system, when confronted with an item that has to be accepted or rejected on a recognition test, makes an optimal decision based on the information that is stored in memory and knowledge of the rules that govern storage of information in memory. In the next section, we will discuss the REM model developed by Shiffrin and Steyvers (1997) as an example of this approach. A similar, independently developed model was presented by McClelland and Chappell (1998). Both of these models are based on the notion of differentiation, i.e., as an item gets stored better, it also becomes easier to differentiate from other items and will less likely be activated by cues representing other items. Although the models are quite similar in spirit (and would be considered equivalent on a purely verbal level), Criss and McClelland (2006) show that the two models are in fact not equivalent and will make different predictions for specific experiments (e.g., associative recognition). However, this analysis is beyond the scope of the present chapter.

### 2.25.3.2 The REM Model

As mentioned before, the REM model (Retrieving Effectively from Memory) is based on the assumption that the memory system behaves as an optimal decision-making system. On a simple recognition test, old and new items are presented and the subject has to decide whether the test item is old or new. REM assumes that the stored memory traces consist of samples of features from the studied items. Features may be stored correctly or incorrectly but as the study time increases, more features will be stored correctly. It is assumed that at test the system matches the features of the test item to each of the traces in memory. For a test item that was indeed on the list, there will of course be a relatively high number of matches and not many mismatches for the trace corresponding to that item. For all other traces (corresponding to the other items on the list) there will be more mismatches. For a distractor test item, all traces will have a relatively high number of mismatches and relatively few matches (since none of these traces corresponds to the test item). Hence, the number of matching and mismatching features gives information about whether the test item was on the list.

It is assumed that the system evaluates the evidence according to standard rules of probability theory and makes an optimal choice based on the available evidence. More specifically, the system chooses whichever response has the higher probability given the observed feature matches and mismatches in all the memory traces. Mathematically, the decision criterion is given by the posterior odds ratio, which according to Bayes' rule may be written as the product of the prior odds and the likelihood ratio:

$$\Phi = \frac{P(old|data)}{P(new|data)} = \frac{P(old)}{P(new)} \times \frac{P(data|old)}{P(data|new)} \qquad [20]$$

It can be shown that in REM, the likelihood ratio is given by the average likelihood ratio for the individual list traces (assume L episodic images are compared to the test probe):

$$\Phi = \frac{1}{L}\sum_j \frac{P(D_j/old)}{P(D_j/new)} = \frac{1}{L}\sum_j \lambda_j \qquad [21]$$

Hence, an old response would be given if $\Phi > 1$. An interesting result from this analysis is that the decision rule turns out to be an example of the global familiarity approach to recognition memory. There are, however, two major differences between the REM and the SAM models for recognition. One is that in SAM the response criterion is basically arbitrary, whereas in REM there is a natural criterion corresponding to a likelihood of 1.0. The other difference is that in REM the activation value $\lambda_j$ may be shown to be a function of both the number of matching and nonmatching features. For a simple version in which we simply count the number of matching and mismatching features, disregarding the exact value of the features (i.e., whether it is a very common or not so common value), it may be shown that the contribution to the overall likelihood for item $j$ is given by:

$$\lambda_j = \left(\frac{\alpha}{\beta}\right)^{m_j}\left(\frac{1-\alpha}{1-\beta}\right)^{q_j} \qquad [22]$$

where $\alpha$ is the probability of a match given storage for the correct trace, $\beta$ is the probability of a match given storage for an incorrect trace ($\alpha$ must obviously be larger than $\beta$), and $m_j$ and $q_j$ are the number of matches and mismatches, respectively, for trace $j$. Thus, the higher the number of matching features, the higher the likelihood, and the higher the number of mismatching features, the lower the likelihood. Earlier we mentioned the need to include information regarding the mismatching features in determining the activation of a trace in order to be able to account for list-strength effects. List-strength effects may be shown by comparing mixed lists composed of both strong and weak items, with pure lists consisting of only strong or only weak items. If there is a list-strength effect, the performance on the weak items in the pure weak list should be better than that on the weak items in the mixed list, and the performance on the strong items should be worse in the pure strong list compared to the mixed list. As shown in Figure 4 (these results were obtained using a simulation program developed by David Huber), the REM model indeed predicts no decrease in recognition performance due to increasing strength of the other list items, although it does predict a decrease as a function of an increase in the number of other list items.

Equation [21] also suggests a similarity between REM and SAM in that the likelihood ratio for a particular trace in REM seems to play a similar role as the activation values in SAM. This suggests that it might be possible to generalize REM to recall paradigms by substituting the likelihood ratios for the activation values. This approach has the desirable feature that most, if not all, of the SAM recall predictions hold for REM as well. Diller et al. (2001) showed that this indeed produces a viable model for

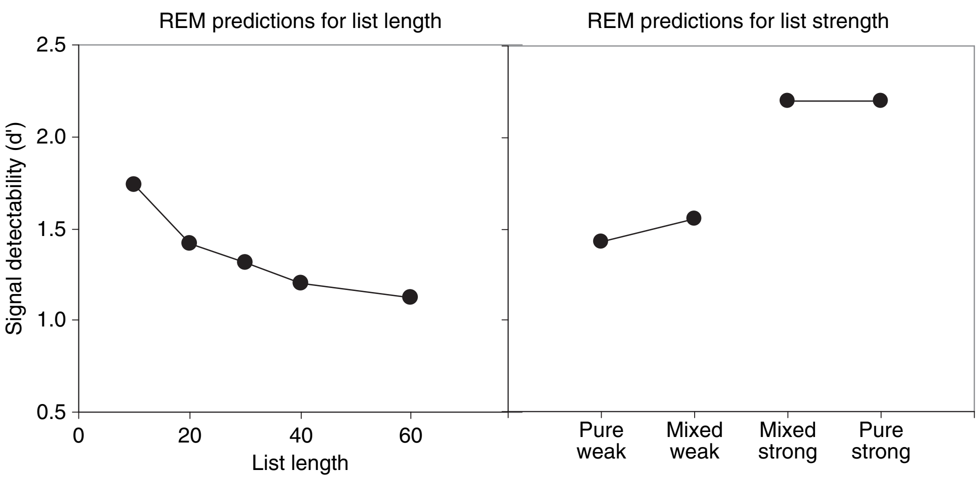

**Figure 4** Predicted values for signal detectability (d′) as a function of list length (left panel) and list strength (right panel) according to the REM model (parameter values: g = 0.4, c = 0.7, u = 0.05; see Shiffrin RM and Steyvers M (1997) A model for recognition memory: REM: Retrieving effectively from memory. *Psychon. Bull. Rev.* 4: 145–166).

recall provided that one raises the likelihood ratios to a constant power. Thus, they defined the probability of sampling trace $i$ as

$$P_S(I_i) = \frac{\lambda_i^\gamma}{\sum \lambda_k^\gamma} \qquad [23]$$

Soon after the REM model for recognition was developed, it was realized that it might be fruitfully generalized to other domains, in particular semantic and implicit memory. In this more general version of REM, it is assumed that when an item is encountered, (a sample of) its features are stored in an episodic trace but also in a lexical/semantic system. Hence, the lexical/semantic trace accumulates information from all prior occurrences and is updated each time the item is presented (see Schooler et al., 2001).

Schooler et al. (2001) developed a REM-based model to account for priming effects in perceptual identification. The model gave a successful account of the results obtained by Ratcliff and McKoon (1997) in the forced-choice identification paradigm. In these experiments, a word (e.g., LIED) is briefly flashed and then masked. The subject is then presented with two alternatives (e.g., LIED and DIED) and has to choose which of these two was the word that was flashed. The critical result in this paradigm is that there is priming (i.e., an increase in the probability of choosing an item that was previously presented on a study list) but only when the two alternatives at the test are perceptually similar (LIED, DIED), but not when they are perceptually dissimilar (e.g., LIED, SOFA). Schooler et al. showed that this pattern of results can be explained in REM by the assumption that a small number of context features are added to the lexical/semantic trace of an item as a result of the prior presentation. These additional context features will obviously have a high probability of matching the later test context, hence will increase (although by a small amount) the number of matching features for the trace corresponding to the primed alternative. The crucial aspect in the REM explanation is that for similar alternatives the outcome of the feature match will often be the same, hence only a relatively small number of perceptual features will be relevant for the decision to choose one or the other alternative. As a result, the additional matches provided by the context features will have a larger effect when the alternatives are perceptually similar than when they are dissimilar.

To see this more clearly, **Figure 5** shows the distributions for the number of critical features for

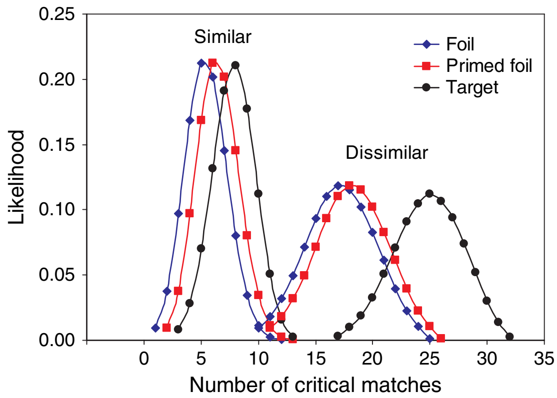

**Figure 5** Predicted likelihood distribution for the number of critical matches for similar and dissimilar choice alternatives according to the REM model of Schooler LJ, Shiffrin RM, and Raaijmakers JGW (2001) A Bayesian model for implicit effects in perceptual identification. *Psychol. Rev.* 108: 257–272.

each of the choice alternatives that match the flashed item. Critical features are features that potentially can make a difference between the two alternatives. Since there are fewer critical features that differentiate similar alternatives, the number of matching critical features will also be lower. Assume that the foil item was presented on the prior study list and that this results in just one additional match due to context overlap between study and test. As shown in **Figure 5**, this additional match will have a clear effect for the similar alternatives: There is much more overlap between the distributions, and hence the probability that the target has more matches compared to the foil will decrease quite a bit. For the dissimilar alternatives, the added match due to context has only a small effect on the probability of choosing the target (the probability of a correct response). Hence, the effect of prior study will be much larger for the similar alternatives compared to the dissimilar ones.

Wagenmakers et al. (2004) presented an application of REM to standard lexical decision tasks in which it was assumed that a lexical decision is based on the evaluation of the likelihood that the presented item corresponds to a word in the lexical system versus a nonword (just as a recognition decision is based on the evaluation that the test item corresponds to an item stored in the episodic system). There is a time-dependent encoding process such that as encoding time increases more and more probe features become available. The likelihood at time $t$ is determined from the features available at that time. The model was evaluated using signal-to-respond tasks and gave a good account for the effects of several major factors such as word frequency, repetition priming, and nonword lexicality.

Raaijmakers (2005) gives an outline of how the REM model may be extended to several other implicit and semantic memory paradigms such as associative priming, semantic categorization tasks, and associative repetition priming. A common feature of all of these applications is that the lexical/semantic system is assumed to be a much more flexible system than in many traditional accounts and that lexical/semantic traces do contain contextual features and hence are sensitive to recent episodes in which the item was presented.

## 2.25.4 Neural Network Approaches

All the approaches that I have discussed thus far do not make specific reference to how the processes that are postulated are actually implemented in the brain. The models in this section on the other hand take the analogy to neural processes in the brain as their starting point. It is assumed that information is distributed over sets of nodes in a neural network rather than as separate traces as in the models discussed thus far. Information is coded not in separate nodes or individual links but in the pattern of strengths over a large number of links or nodes. Hence, each individual node or link participates in the representation of many items or associations. Whenever a specific cue item is presented, the corresponding input nodes are activated and this activation is propagated through a network of links, leading to a specific pattern of activation at the output nodes and this pattern defines the output or the item retrieved from memory. The crucial property of these models (and the one that initially attracted the most attention) is that they provided a mechanistic account of the critical property that distinguishes human memory from other types of memory (such as hard disks), namely its associative character. That is, associative memory systems have the property that if the association *A-B* is stored, presentation of the cue *A* will automatically retrieve *B* without the need to know where *B* (or *A-B*) was stored. In models such as ACT and SAM, this property is assumed, but in neural network models, a computational account is given that generates the associative property, rather than assuming it.

To illustrate this, consider a very simple neural network model in which there is an input layer of neurons and an output layer of neurons and in which each input neuron is connected to each output neuron (e.g., Anderson et al., 1977). Items are represented by vectors, i.e., a series of activation values over the input or output neurons. In order to store the association *A-B*, the connections between the input *A* and the output *B* have to be modified in such a way that presenting *A* at the input side will produce *B* at the output side. This may be accomplished by modifying the connections between the *A* and *B* vectors in such a way that if the *i*-th value of *A* and the *j*-th value of *B* are both high, the connection is made stronger. More generally, if $\mathbf{f_i}$ is the feature vector for item *A* and $\mathbf{g_i}$ is the feature vector for item *B*, then the connections between the input nodes and the output nodes are increased by an amount equal to the product of the feature values. Using vector notation, this is equivalent to the assumption that the changes in the synaptic strengths are modified according to the matrix $\mathbf{M}_i$:

$$\mathbf{M}_i = \mathbf{f}_i\mathbf{g}_i{}' \qquad [24]$$

Thus, if a list of such pairs is studied, the strengths are modified according to the matrix $\mathbf{M}$ with $\mathbf{M} = \sum \mathbf{M}_i$. Presenting an item as a cue to such a system amounts to postmultiplying the matrix $\mathbf{M}$ with the item vector. It is relatively easy to show that in the ideal case where all items vectors are uncorrelated and of unit length, such a model will show the associative property, i.e., on presentation of the item *A* ($\mathbf{f_i}$) the system will generate the associated item *B* ($\mathbf{g_i}$):

$$\mathbf{Mf_i} = \sum \mathbf{M_j f_i} = \sum_{j \neq i} \left(\mathbf{g_j f_j}'\right)\mathbf{f_i} + \left(\mathbf{g_i f_i}'\right)\mathbf{f_i} = \mathbf{g_i} \qquad [25]$$

The example given above is the simplest model of this kind and much more complicated models or networks have been proposed. All of these models, however, share the basic assumption that the associative information is encoded in the links or connections between the neurons. Item information is represented by the pattern or distribution of the activation values at the input and output layers. Note that the same nodes are used to represent all the items: The information is distributed over many nodes. Such models are therefore often called connectionist or distributed memory models. They may contain several layers of neurons with connections between successive layers (see Ackley et al., 1985; Rumelhart et al., 1986). Since the associative property that all of these models share may also be expressed as implying that the model learns to predict the output vector given a specific input vector, it is not surprising that connectionist models have been developed not just to simulate human memory but also to compute any type of predictive relation between a specific input and specific output (i.e., associating a spoken output or phonemes based on the written input text, as in the NETtalk model; Sejnowski and Rosenberg, 1987). These more complex variants do not learn the associations in a single step (as in the simple model described earlier), but require several iterations in which the links between the nodes in the network are gradually changed. Basically what these models do is perform a kind of nonlinear regression using a least-squares fitting procedure to predict the output values given the input values.

Although these models have been quite successful in other domains, their success as a general framework for human memory is more limited. There are a number of features of these models that are problematic when they are used as models for episodic memory.

The most basic problem is known as catastrophic forgetting (McCloskey and Cohen, 1989; Ratcliff, 1990). This property is related to the fact that these models focus on extracting generalized rules from a series of exemplars rather than on storing individual items. The issue is that distributed memory models tend to forget all previously learned information on learning a new set of items. This is most clearly shown in the application of the back-propagation model to a retroactive interference experiment in which two lists are learned in succession (see McCloskey and Cohen, 1989). After learning the second list, humans will show some forgetting for the first list but the forgetting is far from complete. A typical back-propagation model, however, will show complete forgetting of the first list and in fact learning of the second list only starts after the first list has been completely unlearned. Such drastic forgetting is quite different from what is observed in experiments with humans, hence the name catastrophic forgetting. The basic reason for this incorrect prediction is that all the information is contained in the strengths or weights of the links in the network, and since these weights are freely adjusted during second-list learning to optimize second-list performance, there is nothing that prevents the complete forgetting of the first list information. Similar problems for recognition memory performance were demonstrated by Ratcliff (1990), who also showed that the model fails to predict a positive effect of amount of learning on the $d'$ measure for recognition.

It should be noted that these problems are not inherent to distributed memory models but seem to be limited to those connectionist models that assume that learning an item involves an optimization of the weights given to the links in order to tune the network to the information that it is currently being trained on. Murdock (1982, 1993), for example, developed a general framework for memory based on a distributed representation (TODAM, Theory of Distributed Associative Memory) in which item and associative information are added to a single memory vector (similar to the simple vector model described earlier) without any additional tuning. In TODAM, item information is simply added to the trace, while associative information (say the association A–B) is modeled by computing a vector that corresponds to the convolution of the vectors representing **A** and **B** (denoted as $\mathbf{A}^*\mathbf{B}$). Murdock showed that in such a model when A is presented as a cue, B (or at least a noisy version of the **B** vector) may be retrieved by computing the correlation of the **A** vector with the memory vector. TODAM does not suffer from the catastrophic forgetting problem presumably because a second list adds information (and hence noise) to the memory vector but does not destroy the information from the first list.

In order to prevent these problems in connectionist models, changes have to made to the basic structure of such models. One solution is to eliminate the strong version of the distributed memory assumption. For example, it might be assumed that there are a large number of nodes or connections and that learning a particular item or an association uses only a small proportion of these (e.g., so-called sparse distributed networks). Alternatively, it might be assumed that information concerning first-list learning continues to be stored in memory for a relatively long period after the learning of that list (a version of consolidation theory). In this way, the two lists become one list and a compromise is found between first- and second-list performance (see McClelland et al., 1995, for an ingenious version of this approach). Yet another approach is to relax the assumption that specific items are stored in a distributed manner, for example, competitive learning models using a winner-take-all principle in which retrieval results in a single unit are activated (retrieved) or a novelty-detection assumption that enables the system to allocate new items to units not already used to represent other items (e.g. Murre, 1992).

There are other problems that are not as easy to remediate in distributed memory models. For example, Shiffrin et al. (1990) showed that many network models have problems simultaneously predicting the presence of list-length effects and the absence of list-strength effects in recognition memory. Extra items harm performance by changing weights, but strengthening other items also changes the weights and should therefore cause similar harm. As yet, there is no clear solution for this problem within the framework of distributed memory models.

Despite these problems, neural network models continue to have a major influence on memory theories. These models have the advantage of a much closer link to neurobiological approaches and, more importantly, they still provide the only mechanistic explanation for the associative memory property. A nice example of a modern neural network model is the Complementary Learning Systems (CLS) approach proposed by McClelland et al. (1995) and further elaborated by O'Reilly and Rudy (2001) and Norman and O'Reilly (2003). The CLS approach is based on the realization that the memory system must combine two seemingly incompatible functions: Storage of episodic memories and integration of information to enable generalization. The first requires storage of specific, separated traces, whereas the second requires overlapping representations. The phenomenon of catastrophic forgetting shows that standard distributed representations are not a suitable model for episodic memory, although they do allow generalization. The solution in the CLS approach is to assume two separate but interactive systems: A rapidly changing system (assumed to be located in the hippocampal system) and a more slowly changing system (assumed to be cortical or neocortical). The hippocampal system is assumed to employ sparse compressed representations to minimize interference between traces, while the cortical system uses more standard distributed (overlapping) representations. It is assumed that there is a slow consolidation process that transfers information from the hippocampal to the cortical system. During recall, a cue will activate a corresponding pattern in the cortical system and if this pattern is sufficiently close to a stored hippocampal trace, the hippocampal system will settle on that trace, which then sends back activation to the cortical system, leading to the reinstatement of the original event pattern. Catastrophic interference in the neocortical system is avoided by a kind of consolidation process in which storage of new information is interleaved with renewed activation of older information.

McClelland et al. (1995) show how such a model may be used to explain a variety of findings from both human and animal experiments. For example, the fact that amnesic patients are unable to recall recent episodic experiences yet are able to recall older memories and do show implicit memory is attributed to a defect in the hippocampal system coupled with an intact cortical memory system. Norman and O'Reilly (2003) presented simulation results showing that the CLS model gives a good account of recognition memory. For example, the model may predict little or no list-strength effect in recognition if the recognition decision is mostly based on familiarity stemming from the cortical system (rather than on recall based on the hippocampal system). It is not clear, however, how the CLS model would handle both the absence of list-strength effects and the presence of list-length effects in recognition (see Norman and O'Reilly, 2003: 632).

However, even though these newer versions of connectionist modeling provide a solution for a number of the problems that plagued older connectionist models, there are several remaining issues. One is that it is not always clear which aspects of the model are responsible for a specific prediction. Although this is also a concern with other general modeling approaches, the issue is particularly relevant for these models. When a model successfully predicts a specific phenomenon, one also wants to know which aspects of the model are crucial for that prediction and which elements of the model (or the simulation) are incidental. For example, the model may employ a specific learning rule to optimize the weights or a specific equation for the decay of activation values. When one tries to understand why the model predicts the phenomenon, it is important to know whether it would still predict the phenomenon when a different learning rule or a different equation for decay (or perhaps no decay at all) is assumed. Thus, the ability to simulate a specific result does not yet mean that one has an explanation for that phenomenon (see also McCloskey, 1991; see O'Reilly and Farah, 1999, for a contrasting point of view). In many cases (for example, the prediction of the part-list cuing effect in SAM, see Raaijmakers and Phaf, 1999), a substantial amount of work is involved in figuring out why the model makes the prediction, but it is the additional work that ultimately leads to a model-independent explanation of the phenomenon. Such analyses are especially needed when it is difficult for other researchers to run the required model simulations.

## 2.25.5 Models for Serial Order Memory

In this section, I will discuss a number of models that have been proposed to account for memory for serial order information. Such models focus on explaining memory for item and order information in relatively short lists. For example, subjects might be presented with one or more lists of five items and then be given a test in which the items have to be recalled in the correct order, or they might be given the items at test (in a different order) and then asked to provide the correct order of presentation. The empirical evidence for (or against) these models is discussed by Healy and Bonk (*See* Chapter 2.05). We will restrict our discussion to the mathematical formulations that have been used.

A classic approach in this area is Estes' perturbation model (Estes, 1972). In this model, it was assumed that during study, items are associated or linked to their serial positions. However, during the retention interval, the item may shift (perturb) to a neighboring position. If one assumes that movements to an earlier or to a later position are equally likely, then the probability that an item occupies a particular position $n$ at a given time $t$ is given by the following difference equation:

$$P_{n,t} = (1-\theta)P_{n,t-1} + (\theta/2)P_{n-1,t-1} + (\theta/2)P_{n+1,t-1} \quad [26a]$$

For the endpoints we have a slightly different equation:

$$P_{1,t} = (1-\theta/2)P_{1,t-1} + (\theta/2)P_{2,t-1} \quad [26b]$$

for the first position and similarly for the final list position.

These relatively simple equations allow one to calculate the probability distribution for each item on the list. The model predicts better recall for items in the beginning and end positions than for items in the middle of the list since these items will have had less opportunity to perturb. Nairne (1992) obtained data for five-item lists at retention intervals of 30 s, 4 h, and 24 h and showed that the perturbation model gave a good quantitative account of the data. Note that in order to apply the model, one needs to estimate not just the perturbation parameter $\theta$ but also the number of cycles of perturbation (the number of times that eqn [26] is applied). It is easy to see that the model can also handle a number of other findings such as a higher accuracy if there are longer intervals between successive items (longer intervals will lead to less perturbation).

The perturbation model is an example of a bin model in which items are placed in or linked to serial positions rather than to one another. That is, a common view of serial order memory is that order memory is derived from item-to-item associations (the temporal order of a string such as ABCD is remembered through the pairwise associations A-B, B-C etc). What the perturbation model shows is that this type of view is not a necessary one and that an alternative view in which order information is not based on item-to-item associations but on memory for positional information can also give a good account of the data. However, a number of problems have been mentioned in the literature regarding such bin models, the most important one being that these models give no account of the recall of item information (cuing with a specific position automatically leads to recall of the linked item). In addition, it seems to be assumed that at test, the successive bins are always searched in the correct order (a rather strong assumption in the case of somewhat longer lists).

A prime example of a chaining model for serial order memory is the model proposed by Lewandowsky and Murdock (1989). Their model was based on the TODAM framework for memory, one of the distributed memory models discussed earlier. In this application of TODAM, it was assumed that recall starts by using a context cue to generate the first item, and then this item is used as a cue to generate the second item, and so on. A key problem for any type of chaining model is how to proceed if at a particular point no item is recalled. In TODAM, even though the retrieved vector may not enable the recall of a given item (the process of cleaning up the output vector via comparison to a lexicon may not succeed), the retrieved vector may still be used as a further cue.

Finally, Brown et al. (2000) developed a model for serial memory (termed OSCAR) that relies on contextual information to generate temporal information. In their model, context is represented as a series of oscillators that produce a dynamically changing state. The output from the oscillators forms a context vector. The model assumes that the overall context is made up of several such context vectors. During presentation of the list of items, each item vector is associated with the state of each context vector at the time of presentation. Thus, item 1 is associated to context vector 1 at time 1, context vector 2 at time 1, etc. Similarly, item 2 is associated to context vector 1 at time 2, context vector 2 at time 2, etc. All of the item–context associations for each context vector are stored in an association matrix, similar to eqn [24]. At recall, the initial state of the context vectors is reinstated and these are then used to regenerate the context vectors at the following times. To recall the item that was presented at time *m*, context vector 1 at time *m* is multiplied with the memory matrix corresponding to context vector 1 (see eqn [25]), which produces an approximation to item *m*. Similarly, the context vector 2 is used in the same way, also leading to an approximation to item *m*, and so on for all context vectors. Finally, the item in a separately stored vocabulary of items that provides the best overall match to the various approximations of item *m* is then produced as the response. Thus, in this model, recall of a series of ordered items is based on the recall of gradually changing contexts that provide the temporal information for order memory. The OSCAR model is an example of a model for order recall that is based not on interitem associations but on the retrieval of temporal information that is specific to the time that a particular item was studied. The model provides a mechanism for how the system recalls the various contexts as well as the items that were presented. What is not clear, however, is how essential the specific formalization that Brown et al. (2000) used is for the predictions generated by OSCAR (e.g., which properties of the context vectors are essential, and are oscillators really required to enable the model to make these predictions).

## 2.25.6 Concluding Remarks

In the previous sections, I have presented an overview of several global frameworks for human memory. In this section, I return to the question raised in the introduction about what makes such models useful for understanding human memory processes.

Perhaps the most important advantage of having a formal model is that it makes it possible to prove that a specific argument or verbal explanation of a phenomenon is indeed valid (or the reverse: Show that it is not a valid argument). Many striking examples of such results may be found in the literature, for example:

- Batchelder's (1975) demonstration that the results from experiments on all-or-none learning could not be explained as being due to selection effects due to individual differences, as was thought by many proponents of theories in which learning was assumed to be more gradual.
- The demonstration by Hintzman and Ludlam (1980) that a purely exemplar-based classification model (MINERVA) could explain the finding that prototypical information seemed to be forgotten slower than the instances themselves. This finding had been generally interpreted as implying the existence of a prototype representation that was assumed to show a slower decay than the instance representations. The MINERVA model, however, did not contain any prototype representation and yet predicted the observed pattern of forgetting.
- The analysis of the part-list cuing paradigm using the SAM model (Raaijmakers and Shiffrin, 1981b) that showed that the lack of a positive cuing effect was entirely compatible with a model that was strongly based on the use of interitem associations. This analysis led to a new explanation for part-list cuing effects that we would not have thought of prior to running the analyses.

There are many such examples in the literature, and they do not necessarily have to be positive (in the sense of providing a new or alternative explanation). In some cases, computational analyses may show that a model fails to predict a finding that one would have intuitively thought that it should be able to predict. For example, the demonstration by McCloskey and Cohen (1989) of the catastrophic forgetting phenomenon shown by typical connectionist models had a big impact on the field. Similarly, Murdock and Lamon's (1988) demonstration that simple connectionist models failed to predict improved recognition performance with an increasing number of presentations was also initially met with disbelief.

What these examples show is that formal modeling may help to sharpen theoretical analyses by showing which results directly follow from a specific set of assumptions, which results cannot be predicted by the model, and which results may be predicted by the model but only under specific conditions (e.g., specific sets of parameter values). However, in order to be able to draw such conclusions, the modeler should not be content just to show that his or her model can predict the results of a particular set of experiments. This should be considered step one in the analyses and should be followed by additional analyses to determine the robustness of the prediction (does it vary in a qualitative sense when parameters are set to different values) as well as analyses to determine which aspects (assumptions) of the model are really crucial for the prediction. The latter aspect is often left out but is in my view the essence of the modeling approach: Models should not be used as black boxes that in some mysterious way generate a specific pattern of data, but should preferably be used as analytical tools to assist the theoretical analysis of those data (what does it tell us about human memory processes?).

The latter point is related to the view that a model that is applied to a specific experimental paradigm is really a combination of (1) a set of core theoretical assumptions (the general theory), (2) a number of auxiliary assumptions related to the implementation of the model and specific computational aspects (e.g., an assumption that each trial adds the same amount of strength to a trace, or the specific learning rule used in a connectionist model), and (3) a set of task-specific assumptions (say a particular rehearsal strategy that is assumed or the rules that are used in generating an overt response based on the retrieved information). In this view, the ultimate goal of mathematical modeling is not simply fitting a set of data but to provide insight into the basic structure and processes in a particular domain. As such, there is no real difference with non-mathematical approaches. The basic advantage of the modeling approach is that it provides an analytical tool that can be used to experiment in a way that is not possible with verbally stated theories.

Viewed in this way, the progression of simple models that could only be applied to a single type of experiment to the more general approaches that we have discussed in this chapter is a major step toward a more coherent and comprehensive theory of learning and memory processes.

# 2.26 Associative Retrieval Processes in Episodic Memory

**M. J. Kahana**, University of Pennsylvania, Philadelphia, PA, USA

**M. W. Howard**, Syracuse University, Syracuse, NY, USA

**S. M. Polyn**, University of Pennsylvania, Philadelphia, PA, USA

> [Y]ou are wrong to say that we cannot move about in Time. For instance, if I am recalling an incident very vividly I go back to the instant of its occurrence: I become absent-minded, as you say. I jump back for a moment.
>
> H. G. Wells, *The Time Machine*, 1898

In the above quote from Wells' classic science-fiction novel, the protagonist compares his actual travels through time to the mental time travel one experiences through the act of reminiscence. During our childhood, many of us have fantasized about actual time travel. If we could only return to a previously experienced episode of our lives and re-experience that episode in light of our new found knowledge, perhaps that knowledge would lead us to act differently, or simply to appreciate that previous experience in new and different ways.

Although true time travel remains beyond our reach, the act of remembering is a form of time travel that we can exercise at will. Our power to remember previously experienced events can put us back in the approximate mental context of that earlier episode and allow us to interpret that episode in light of our current knowledge. In so doing, we also alter our memory of the episode in permanent ways, such that each remembering brings back not only the original encoding context, but also some elements of the context of previous rememberings.

In 1972, Endel Tulving coined the term episodic memory to refer to the form of memory that allows us to associate the many different types of information constituting an event into a spatiotemporal context and to later use the content of the event to retrieve its context. Episodic memory places us in the memory, marking the memory's position on our personal, autobiographical, timeline. Retrieval of episodic memories constitutes a form of time travel in which we recover the encoding context of the previously experienced event. Other important forms of memory, such as perceptual priming and semantic memory, do not have this feature.

Episodic memory not only supports the vivid recollection of formative life events; it also enables us to remember where we parked our car in the morning, whether we took our medicine, and whom we met at a social engagement. Dramatic failures of these everyday aspects of episodic memory can result from damage to the medial temporal lobe of the brain (Spiers et al., 2001). More subtle impairments of episodic memory accompany the normal aging process (Salthouse, 1991; Kausler, 1994).

Ever since Ebbinghaus carried out his seminal studies in 1885, most laboratory studies of human memory have focused on episodic memory. In these experiments, lists of items[1] constitute sequences of mini-experiences presented in a controlled fashion. Subjects then attempt to recall or recognize the previously studied items under a variety of conditions designed to probe and challenge their memorial abilities.

## 2.26.1 Association and Context

Association has served as the core theoretical construct throughout the history of writings on memory. An association is not observed; rather, it is inferred from the tendency of one item to evoke another. Associations that come to mind quite naturally, like the association of king and queen or of bread and butter, relate to the meaning of the constituent items. This meaning develops through extensive experience, presumably involving the temporal co-occurrence of the items in many different situations. But associations can also be formed between nominally unrelated items in a single exposure. For example, when attending closely to a pair of items presented in temporal proximity (e.g., a name–face pair) we can quickly take hold of the association, at least temporarily. Sometimes, a salient new association may be encoded well enough after a single encounter that it can be recalled, or at least recognized, after a long delay.

The classic laboratory method for studying the encoding and retrieval of episodically formed associations is the paired-associate (or cued-recall) task. In this task, subjects study a list of randomly paired words, name–face pairs, or the like. Later, subjects are presented with one member of each studied pair as a cue to recall its mate. The paired-associate task has subjects explicitly learn associations among items. In the case of words, effective learning of the paired associates depends strongly on the formation of linguistic mediators, the use of imagery, or other strategies that involve elaboration of the meaning of the constituent items (for reviews, see, Paivio, 1971; Murdock, 1974; Crowder, 1976). One may ask whether strategies are strictly necessary for the formation of associations between contiguously presented items. We will return to this question at the end of the present chapter.

The idea of interitem association only takes us so far in thinking about episodic memory. To perform any episodic task one must have some means of distinguishing the current list from the rest of one's experience. For example, if we learn the association between the words *fountain* and *piano* in one setting, and then we later learn the association between *fountain* and *slipper* in another setting, how do we flexibly retrieve either *piano* or *slipper*, and how do we recall the setting in which the word was learned?

The idea that associations are learned not only among items, but also between items and their situational or temporal context was widely recognized in the first half of the twentieth century (Hollingsworth, 1928; Carr, 1931; McGeoch, 1932; Robinson, 1932). This idea formed the basis for Underwood's classic explanation of spontaneous recovery as described in his 1945 dissertation.

Despite its recognition among early memory scholars, the idea of context available at the time was too vague to find favor among the behavioristically oriented learning scholars who dominated in the post-war period (McGeoch and Irion, 1952). Whereas associations could be viewed as an experimentally determined increase in the probability of a stimulus evoking a response, context is not easily tied to experimental manipulations. To scholars of a strictly empirical orientation, the difficulty of controlling and manipulating context, especially internally generated context, greatly limited its utility as an explanatory construct. These scholars feared the admission of an ever-increasing array of hypothesized and unmeasurable mental constructs into the scientific vocabulary (e.g., Slamecka, 1987).

The notion of temporal context regained respectability in the memory literature after the appearance of Gordon Bower's temporal context model in 1972 (Bower, 1972; see also, Bower, 1967). The related notion of temporal coding processes was also emphasized by Tulving and Madigan (1970) in their influential review of the state of the field. According to Bower's model, contextual representations are composed of many features which fluctuate from moment

[1] Although Ebbinghaus used consonant-vowel-consonant (CVC) syllables as stimuli, most modern studies use words due to their relatively consistent interpretation and coding across participants.

to moment, slowly drifting through a multidimensional feature space. Whereas previous investigators had noted the importance of temporal coding (e.g., Yntema and Trask, 1963), Bower's model, which drew heavily on the classic stimulus-sampling theory developed by William K. Estes (1955), placed the ideas of temporal coding and internally generated context on a sound theoretical footing. The Bower–Estes model provided the basis for more recent computational models of temporal context and its central role in episodic memory (Mensink and Raaijmakers, 1988; Howard and Kahana, 2002).

## 2.26.2 Associative Processes in Free Recall

The cognitive revolution of the 1960s brought a shift away from the paired-associate and serial learning tasks which had served as the major experimental approach to the study of human verbal memory until that time. The more cognitively oriented researchers were especially drawn to free recall. In the free recall task, subjects study a sequence of individually presented items. At test, they are simply asked to recall all of the items they can remember in any order they wish.[2] There is no experimenter-imposed structure on the nature of the recall process. By analyzing the order in which subjects recall list items, one can gain considerable insights into the memory processes operating under these relatively unconstrained conditions. In contrast, the paired-associate task imposes a strong, experimenter-defined, organization on the to-be-learned materials: subjects are aware that they must link the paired items at study and that they will later be asked to recall a specific target item in response to a given cue.

The scientific literature on free recall has followed two distinct strands. One strand of research focused on how subjects learn a list over the course of successive study-test trials. In a classic study, Tulving (1962) demonstrated that over repeated trials in which the input sequence is randomized, the sequences of recalled items becomes increasingly consistent from trial to trial. In learning lists of random words, subjects appeared to create a kind of organization of the materials, with the level of recall tracking the degree of organization (see Sternberg and Tulving, 1977, for a review of measures of subjective organization). Earlier work by Bousfield and colleagues (Bousfield, 1953; Bousfield et al., 1954) had shown that when subjects studied lists that included strong semantic associates, their sequence of recalls was organized semantically, a phenomenon termed category clustering. Tulving's work showed that organization was a far more general phenomenon, seen even in lists whose items lacked any obvious categorical or semantic organization. Tulving's work on organization and memory spawned several decades of work aimed at understanding the role of organization in the learning process (see Tulving, 1983, for a review).

The second strand of research on free recall focused on how subjects recalled a list after a single study trial. In his classic analysis of the serial position curve in free recall, Murdock (1962) reported the relation between list position and recall probability. On an immediate recall test, subjects exhibited a striking recency effect, recalling the last few items more frequently than items from earlier list positions. These recency items were typically the first items recalled in the sequence of responses (Deese and Kaufman, 1957; Nilsson et al., 1975). Among the earlier (prerecency) items, subjects exhibited superior recall for the first three or four list items than for items from the middle of the list (the primacy effect).

Murdock varied both list length and presentation rate, and found that both manipulations produced a dissociation between the level of recall of recency and prerecency items. Specifically, he found that increasing list length or speeding the presentation rate resulted in lower recall of early and middle items, but did not affect recall of the more recent items. In addition to list length and study time (presentation rate), other variables that boost recall of prerecency items have little or no effect on recency items. For example, lists of similar words are better recalled than unrelated words (Craik and Levy, 1970), and lists of common words are better recalled than lists of rare words (Sumby, 1963; Raymond, 1969; Ward et al., 2003).[3] In both of these cases, however, the enhanced recall is not seen for the recency items. In contrast, the recency effect is significantly greater for auditorally than for visually presented lists, while modality of presentation has no effect on prerecency items (Murdock and

[2] In 1894, E. A. Kirkpatrick published the first study using the free-recall method. This was the same year that Mary Calkins introduced the paired-associate technique. Because of the unconstrained nature of the free-recall technique, Ebbinghaus (1911) found it to be crude and superficial. However, interest in free recall surged following a series of influential studies published between 1953 and 1962 by Weston Bousfield, James Deese, Ben Murdock, Leo Postman, and Endel Tulving.

[3] In item recognition, normative word frequency has the opposite effect, with rare words being better recognized than common words (MacLeod and Kampe, 1996).

Walker, 1969). Moreover, asking subjects to perform a brief unrelated distractor task at the end of the list (e.g., solving arithmetic problems for 15 s) greatly reduces the recency effect while having no adverse consequences on recall of prerecency items (Postman and Phillips, 1965; Glanzer and Cunitz, 1966). **Figure 1(a)** shows the effect of a brief distractor task on the serial position curve in free recall. These and other dissociations between recency and prerecency led many investigators to embrace the notion of distinct memory systems: a short-term store (STS) responsible for the recency effect, and a long-term store (LTS) responsible for the primacy effect and for the level of recall for prerecency items (Waugh and Norman, 1965; Atkinson and Shiffrin, 1968; Glanzer and Cunitz, 1966).

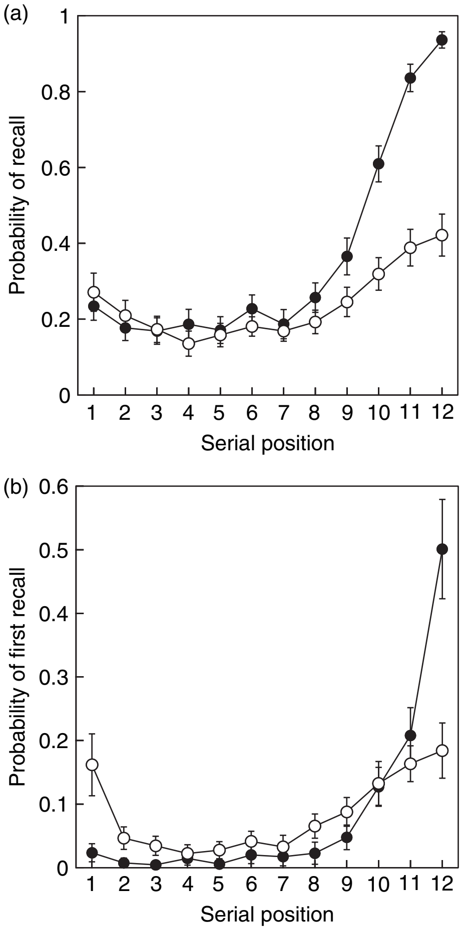

**Figure 1** The recency effect in immediate and delayed free recall. After studying a list of 12 common words, subjects were either asked to recall items immediately (filled circles) or following a 15-s arithmetic distractor task (open circles). (a) Serial position curves. (b) Probability of first recall functions show the probability that the first recalled item was presented in a given serial position. These functions thus illustrate the relative tendency to begin recall with primacy or recency items. Data are from Howard MW and Kahana MJ (1999) Contextual variability and serial position effects in free recall. *J. Exp. Psychol. Learn. Mem. Cogn.* 25: 923–941 (Experiment 1). Error bars denote 95% confidence intervals.

### 2.26.2.1 Retrieval Dynamics in Free Recall

Although traditional serial position-based analyses fueled much of the theoretical debate concerning the memory processing underlying free recall (and for that matter serial recall), such analyses discard information about sequential dependencies in retrieval, information which is crucial for understanding the structure of episodic memory storage, and the process of episodic memory retrieval. By measuring the order in which list items are recalled, we can decompose the retrieval process into a measure of how subjects initiate recall and a measure of how they make transitions among successively recalled items.

As mentioned above, subjects typically initiate recall with one of the final list items. This tendency can be quantified by measuring the probability with which subjects initiate recall at each serial position. **Figure 1(b)**, which shows the probability of first recall as a function of serial position, reveals a strong tendency for subjects to initiate recall with one of the final list items (Hogan, 1975; Laming, 1999). In delayed free recall, this tendency is markedly diminished (Howard and Kahana, 1999). By studying subjects' subsequent recall transitions, one can see that temporally defined, interitem associations exert a strong influence on output order and inter-response times in free recall. These associations are inferred from participants' tendency to successively recall items from nearby list positions. As shown in **Figure 2(a)**, the probability of recalling a word from serial position $i +$ lag immediately following a word from serial position $i$ is a sharply decreasing function of $|\text{lag}|$. Positive values of lag correspond to forward recall transitions; negative values of lag correspond to backward recall transitions.[4] In calculating the conditional response probability as a

[4] For example, if the list had contained the subsequence '*absence hollow pupil*' and a participant recalled *hollow* then *pupil*, the recall of *pupil* would have a lag of +1. If, instead, the participant recalled *hollow* then *absence*, the recall of *absence* would have a lag of −1. In this case, the participant is moving backward in the list. *Absence* followed by *pupil* would yield a lag of +2.

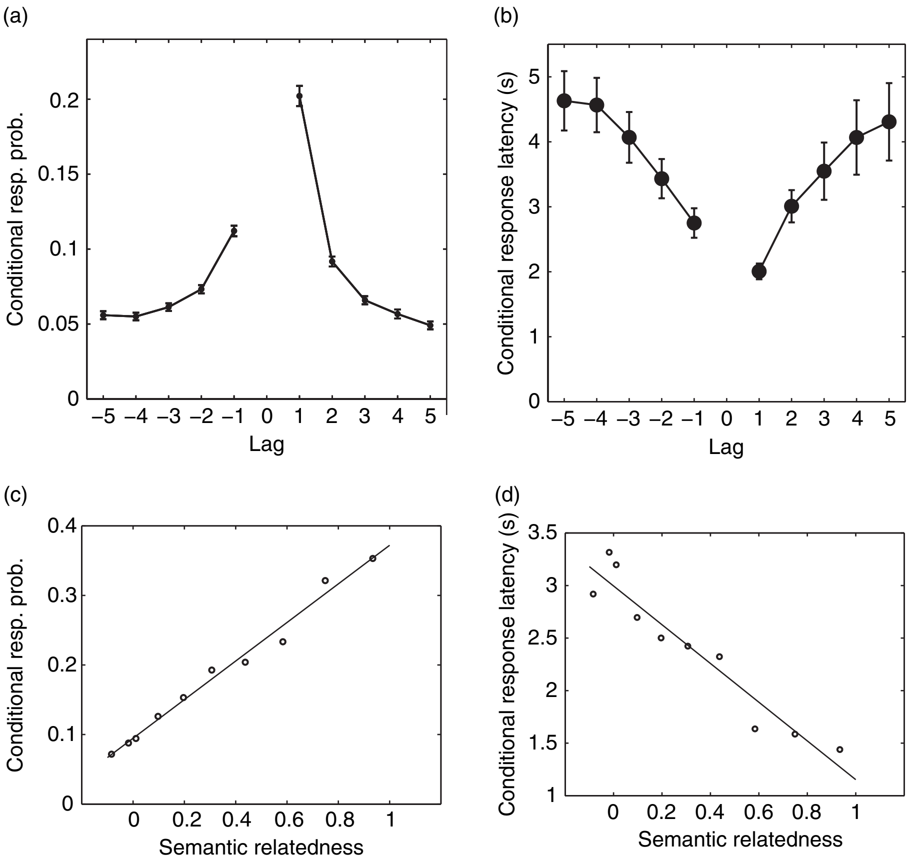

**Figure 2** Associative processes in free recall: effects of temporal contiguity and semantic relatedness. (a) The conditional–response probability as a function of lag (or lag-CRP) shows the probability of recalling an item from serial position $i+\text{lag}$ immediately following an item from serial position $i$. This curve is based on data from 20 experimental conditions (Murdock BB (1962) The serial position effect of free recall. *J. Exp. Psychol.* 64: 482–488; Murdock BB and Okada R (1970) Interresponse times in single-trial free recall. *J. Verb. Learn. Verb. Behav.* 86: 263–267; Murdock BB and Metcalfe J (1978) Controlled rehearsal in single-trial free recall. *J. Verb. Learn. and Verb. Behav.* 17: 309–324; Roberts WA (1972) Free recall of word lists varying in length and rate of presentation: A test of total-time hypotheses. *J. Exp. Psychol.* 92: 365–372; Kahana MJ, Howard MW, Zaromb F, and Wingfield A (2002) Age dissociates recency and lag recency effects in free recall. *J. Exp. Psychol. Learn. Mem. Cogn.* 28: 530–540; Howard MW and Kahana MJ (1999) Contextual variability and serial position effects in free recall. *J. Exp. Psychol. Learn. Mem. Cogn.* 25: 923–941; Zaromb FM, Howard MW, Dolan ED, Sirotin YB, Tully M, Wingfield A, et al. (2006) Temporal associations and print-list intrutions in free recall. *J. Exp. Psychol. Learn. Mem. Cogn.* 32(4), 792–804; Kimball DR and Bjork RA (2002) Influences of intentional and unintentional forgetting on false memories. *J. Exp. Psychol. Gen.* 131: 116–130; Kahana MJ and Howard MW (2005) Spacing and lag effects in free recall of pure lists. *Psychon. Bull. Rev.* 12: 159–164; Kahana MJ, Dolan ED, Sauder CL, and Wingfield A (2005a) Intrusions in episodic recall: Age differences in editing of overt responses. *J. Gerontol. Psychol. Sci.* 60: 92–97). (b) The conditional-response latency as a function of lag (or lag-CRL) shows the mean inter-response time between successive recalls of items from serial positions $i$ and $i+\text{lag}$ (Howard MW and Kahana MJ (1999) Contextual variability and serial position effects in free recall. *J. Exp. Psychol. Learn. Mem. Cogn.* 25: 923–941; Murdock BB and Okada R (1970) Interresponse times in single- trial free recall. *J. Verb. Learn. Verb. Behav.* 86: 263–267; Zaromb FM, Howard MW, Dolan ED, Sirotin YB, Tully M, Wingfield A, et al. (2006) Temporal associations and prior-list intrutions in free recall. *J. Exp. Psychol. Learn. Mem. Cogn.* 32(4): 792–804; Kahana MJ, and Howard MW (2005) Spacing and lag effects in free recall of pure lists. *Psychon. Bull. Rev.* 12: 159–164). Error bars represent 95% confidence intervals across experiments. (c) The conditional-response probability as a function of semantic relatedness (semantic-CRP) reveals that subjects are more likely to recall items that are semantically related to the just-recalled item. Semantic-relatedness was measured using the word-association space technique (Steyvers M, Shiffrin RM, and Nelson DL (2004) Word association spaces for predicting semantic similarity effects in episodic memory. In: Healy AF (ed.) *Cognitive Psychology and its Applications: Festschrift in Honor of Lyle Bourne, Walter Kintsch, and Thomas Landauer*. Washington, DC: American Psychological Association). (d) The conditional-response latency as a function of semantic relatedness (semantic-CRL) shows that subject transitions are made more quickly when they are to related items.

function of lag, or lag-CRP, we estimate the probability of a transition to a given lag by dividing the number of transitions to that lag by the number of opportunities to make a transition to that lag.

### 2.26.2.2 The Contiguity Effect

The analysis of retrieval transitions in free recall reveals a strong tendency for neighboring items to be recalled successively. We refer to this phenomenon, illustrating participants' reliance on temporal associations to guide recall, as the contiguity effect. As shown in **Figure 2(a)**, the contiguity effect exhibits a marked forward bias, with associations being stronger in the forward than in the backward direction. The basic form of the contiguity effect does not appear to depend on experimental manipulations. The lag-CRP functions are virtually identical across manipulations of presentation modality (visual vs. auditory), list length, and presentation rate (Kahana, 1996).

The contiguity effect also appears in the form of shorter inter-response times between recall of items from neighboring list positions. This can be seen in the conditional response latency (lag-CRL) function shown in **Figure 2(b)** (see Kahana and Loftus, 1999, for a further discussion of the accuracy–latency relation). The contiguity effect, as seen in both accuracy and latency data, may reflect a kind of mental time travel undertaken during memory search and retrieval. In recalling an item, the subject may 'travel back' to the time of its presentation, making it more likely that subsequent recalls will come from nearby serial positions.

### 2.26.2.3 The Semantic Proximity Effect

In free recall, participants do not rely solely on newly formed episodic associations; they also make use of their pre-existing semantic associations among list items. We can quantify subjects' use of semantic associations in free recall by computing the conditional probability of a recall transition as a function of an item's semantic relatedness to the just-recalled item (we term this function the semantic-CRP). This approach requires a measure of the semantic relatedness of arbitrary word pairs. To obtain such measures, we turn to computational models of semantic spaces. Landauer and Dumais (1997) developed latent semantic analysis (or LSA); this project involved the statistical analysis of a large text corpus, allowing them to derive a measure of word-relatedness from the tendency for words that share meaning to co-occur in paragraphs. Steyvers et al. (2004) developed a word association space (or WAS) based on the large University of South Florida word association database (Nelson et al., 2004). Both LSA and WAS provide measures of the semantic relatedness for a great many pairs of words in the English language. The measure is quantified as the cosine of the angle between the vectors representing the two words in a high-dimensional space. Completely unrelated words would have $\cos\theta \approx 0$, and strong associates would have $\cos\theta$ values between 0.4 and 1.0. For a more thorough treatment and discussion, see Howard et al. (2007).

The semantic-CRP shows that the stronger the semantic relation between two list words, the more likely it is that they would be successively recalled (**Figure 2(c)**). In addition, the stronger the semantic association between two successively recalled words, the shorter the inter-response time would be between the two words (**Figure 2(d)**). This analysis illustrates the powerful influence of semantic relatedness on recall of randomly chosen word lists. Even when lists lack any strong associates or any obvious categorical organization, recall transitions are driven by the relative semantic strengths among the stored items. Consistent with the findings of category clustering and subjective organization described above, the contiguity effect decreases, and the semantic-proximity effect increases, across learning trials in which the order of word presentation at study is randomized on each trial (Klein et al., 2005; Howard et al., 2007).

### 2.26.2.4 Normal Aging Affects Contiguity but Not Recency

It is well known that older adults perform more poorly on episodic memory tasks than their younger counterparts (Verhaeghen and Marcoen, 1993; Kausler, 1994). The age-related memory impairment is particularly marked in recall tasks that require subjects to use temporally defined associations, such as cued recall and free recall (Naveh-Benjamin, 2000; Wingfield and Kahana, 2002; Hoyer and Verhaeghen, 2006).

The analysis of retrieval transitions, as described above, can be used to directly assess subjects' reliance on temporal associations in free recall. Kahana et al. (2002) examined the difference between recency and contiguity effects in younger and older adults. Half of the subjects in each age group were given an immediate free recall test; the other half were given a delayed free recall test. As expected, younger adults recalled more words on both immediate and delayed tests, and the distractor task attenuated the recency effect for subjects in both age groups. The critical finding was that older adults exhibited a significantly diminished contiguity effect, as seen in their lag-CRP functions (**Figure 3(b)**). In contrast, younger and older adults initiated recall in the same manner; their probability of first recall functions were virtually identical both in the immediate and in the delayed free-recall conditions (**Figure 3(a)**). Although older adults exhibited a markedly reduced contiguity effect, their semantic-proximity effect was unimpaired (unpublished observation). These findings suggest that the mnemonic deficit observed for older adults is largely restricted to the ability to form and/or utilize temporally defined associations. This is consistent with previous reports of age-related deficits in the formation and retrieval of episodic associations (e.g., Naveh-Benjamin, 2000).

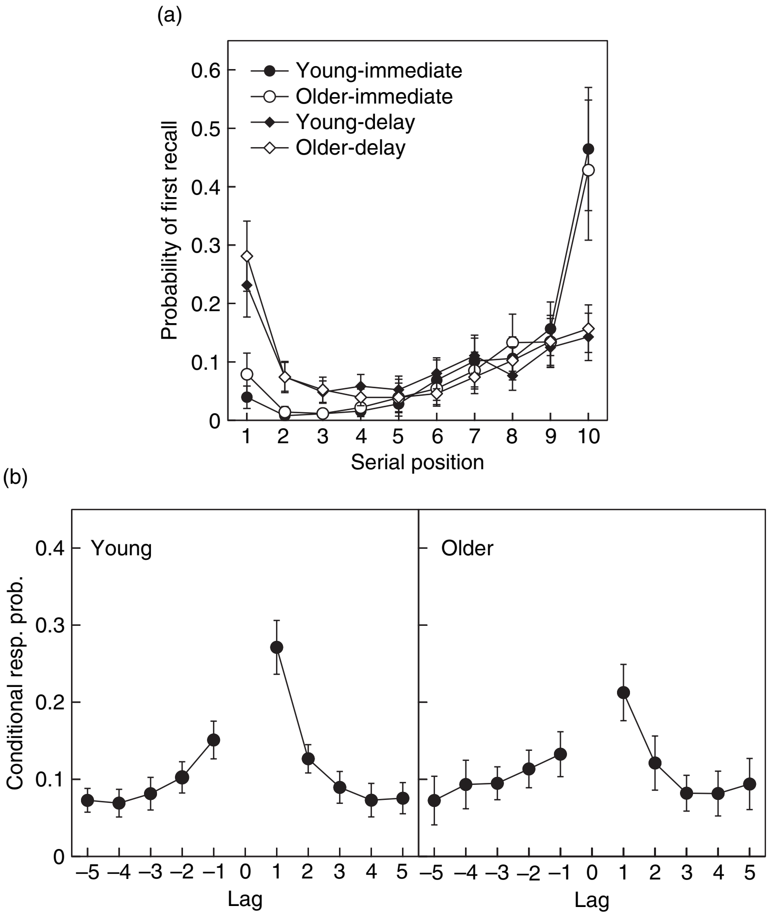

**Figure 3** Selective effect of aging on associative processes in free recall. (a) Probability of first recall from immediate and delayed free recall for younger and older adults. ### 2.26.2.5 Long-Range Interitem Associations

Bjork and Whitten (1974) conducted an experiment which challenged the traditional STS-based account of recency effects in free recall. They were interested in seeing how well subjects could recall a list of word pairs under conditions designed to eliminate between-pair rehearsal. To eliminate between-pair rehearsal, they had subjects perform a difficult distractor task following the appearance of each pair, including the last one. Because the distractor was expected to displace any items in STS, Bjork and Whitten did not expect to find a recency effect. To their surprise, they found a strong recency effect, with the final few pairs being recalled better than pairs from the middle of the list. They called this the long-term recency effect. Their procedure, in which a distractor task is given following every item, including the last, is called continuous-distractor free recall. **Figure 4** illustrates the continuous-distractor free recall procedure alongside the more traditional immediate and delayed free recall procedures.

| Condition | Recency |
|---|---|
| Immediate<br>PEN CAR ROSE ··· BIRD *** | Yes |
| Delayed<br>PEN CAR ROSE ··· BIRD [1+2=] *** | No |
| Continuous distractor<br>PEN [6+2=] CAR [3+7=] ROSE [1+1=] ··· BIRD [2+5=] *** | Yes |

**Figure 4** Illustration of immediate, delayed, and continuous-distractor paradigms. The row of asterisks indicates the start of the recall period.

The long-term recency effect has now been replicated many times using both single words and word pairs, and across delays ranging from tenths of seconds (Neath, 1993) to days (Glenberg et al., 1983). The magnitude of the long-term recency effect depends critically on both the duration of the distractor given after the last word (the retention interval) and on the duration of the distractor intervening between list words (the interpresentation interval). For a given retention interval, increasing the interpresentation interval results in more recency and better recall of the final item.

Kahana (1996) interpreted the contiguity effect as evidence for associations formed in STS. If associations are formed between items that are active together in STS (as postulated by Glanzer, 1972; Raaijmakers and Shiffrin, 1980), then this would predict the contiguity effect because nearby items spend more time together in STS than remote items. However, because a long interitem distractor should displace items in STS, the contiguity effect should be significantly attenuated in continuous-distractor free recall.

Howard and Kahana (1999) tested this hypothesis by measuring the contiguity effect in continuous-distractor free recall. **Figure 5(a)** illustrates the contiguity effect for interpresentation intervals ranging from 0 s (standard delayed free recall) to 16 s. As can be seen, the contiguity effect was relatively constant across this range of interpresentation intervals. This result is quantified in **Figure 5(b)** by fitting a power function ($P = a|\text{lag}|^{-b}$) to each participant's lag-CRP curve and using the $b$ parameter as an estimate of the contiguity effect (the $a$ parameter determines the overall scale of

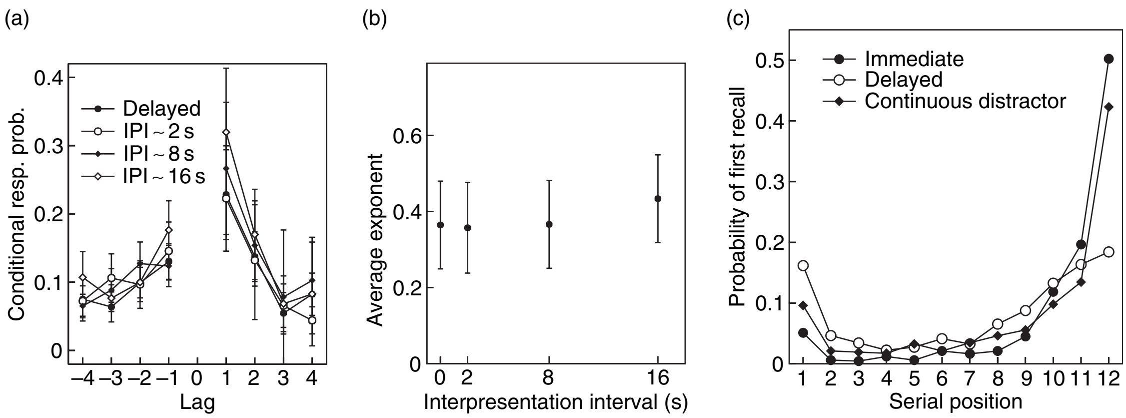

**Figure 5** Long-range contiguity and recency effects. (a) Lag-CRP as a function of the length of the distractor task in continuous-distractor free recall. (b) To quantify the contiguity effect, power functions were fit to the lag-CRP curves for each participant in each condition. Error bars represent 95% confidence intervals. (c) The probability of first recall functions for immediate, delayed, and continuous-distractor free recall (Howard and Kahana, 1999).

the function). Insofar as the contiguity effect is insensitive to the absolute delay between list items, it exhibits an approximate time-scale invariance. Although 16 s of a distractor had virtually no impact on the contiguity effect, the same amount of distractor activity presented at the end of the list was sufficient to eliminate the end-of-list recency effect (**Figure 5(c)**).

As shown in **Figure 5**, the contiguity effect persists even when the study items are separated by 16 s of a demanding distractor task. However, recent work shows that the contiguity effect is evident on even longer time scales. Howard et al. (2008) presented subjects with a series of lists for free recall. At the conclusion of the session, subjects were given a surprise final free recall test in which they were instructed to remember as many words as possible from the 48 study lists in any order. Howard et al. (2008) measured the contiguity effect in this final free recall period both for transitions within a list as well as between lists. They found that transitions between nearby lists were more frequent than transitions between lists that were farther apart in the experiment. This contiguity effect extended about ten lists, or several hundred seconds, extending the range over which contiguity effects are observed in free recall by a factor of ten. Moreover, this paradigm offers several potential advantages over continuous-distractor free recall. In continuous distractor free-recall, subjects have an incentive to try and rehearse items across the distractor intervals. Because the subject is only asked to recall the most recent list in the Howard et al. (2008) study, and intrusions from prior lists are scored as errors, there is no strategic reason for subjects to rehearse across lists in anticipation of the surprise final free recall test. In continuous-distractor free recall, the consistency of associations across delay intervals was inferred from observing lag-CRP curves across conditions that differed in their IPI. It is conceivable that this was due in part to different strategies across experimental conditions. In contrast, in the Howard et al. (2008) study, both within-and across-list associations were observed simultaneously during the final free recall period.

#### 2.26.2.6 Interim Summary

We have shown how both temporal contiguity and semantic relatedness strongly predict the order and timing of subjects' responses in the free-recall task. The contiguity effect (**Figure 2(a, b)**) illustrates how episodic associations are graded, exhibiting power-function decay with increasing lag. Recall of an item has a tendency to evoke not only adjacent list items, but other nearby items as well. In addition, episodic associations appear to be asymmetrical, favoring retrieval of items in the forward order.

Whereas the previous two characteristics of episodic association can be accommodated within the view that neighboring items become associated when they cooccupy a short-term buffer (or working memory system), analyses of episodic association in continuous-distractor free recall show that the contiguity effect persists across time scales. That is, using a distractor task to temporally segregate list items does not disrupt the associative mechanism. Moreover, contiguity can even be observed in recall transitions among items studied as part of different lists, separated by several minutes. The tendency for an item to evoke a nearby item thus depends on the relative spacing, not the absolute spacing, of the list items.

A critical question for memory theory is whether the contiguity effect is specific to free recall, or whether similar associative processes operate in other memory tasks. It is possible that some of the phenomena described in the preceding section are a consequence of specific strategies that subjects use in the free-recall paradigm. In particular, by allowing participants to recall items in any order, we may be observing participants' biases in favoring particular kinds of transitions (e.g., forward over backward, adjacent over remote) rather than revealing the underlying associative structure. This criticism is blunted by our finding that the lag-CRP and lag-CRL functions vary little across experiments that differ significantly in their methodologies, even including the introduction of a long interitem distractor (see **Figure 5**). Nonetheless, it is important to take a broader look at the question of associative processes in episodic memory. In the next section, we show how associative processes can be seen in the pattern of subjects' errors in free recall, serial recall, and cued recall. We then examine the question of associative processes in item recognition. The final section of this chapter discusses these empirical data in terms of the major theories of associative processes in episodic memory.

### 2.26.3 Memory Errors Reveal Associative Processes

The study of the errors made in a variety of memory tasks shows that even when the memory system goes awry and produces a response that is incorrect in the context of a given experiment, the processes generating this error appear to be influenced by the same factors that guide correct responses. In this section, we consider how subjects' recall errors reveal characteristics of the associative processes operating in free recall, serial recall, probed recall, and cued recall tasks.

### 2.26.3.1 Prior-List Intrusions in Free Recall

It is well known that incorrect recalls (intrusions) often arise due to the semantic relations between studied and nonstudied items. For example, after studying a list of items that include the semantic associates of a critical word, participants often incorrectly recall that critical word even though it was not presented on the list (Deese, 1959; Roediger and McDermott, 1995; Roediger et al., 1998; Gallo and Roediger, 2002). Although semantic association is a major determinant of false recall, episodic memory processes also appear to play an important role. For example, in free recall of randomly arranged word lists, prior-list intrusions – incorrect recalls of words that were presented on an earlier list – are often more frequent than extralist intrusions – incorrect recalls of words that were not presented during the course of the experiment. This suggests that the recent study of an item increases the probability that it will be (incorrectly) recalled. Moreover, prior-list intrusions exhibit a strong recency effect, being most likely to come from the list immediately preceding the target list (Murdock, 1974; Zaromb et al., 2006); the number of prior-list intrusions coming from earlier lists decreases sharply (see **Figure 6(a)**).

In a recent study, Zaromb et al. (2006) asked whether contiguity-based associations would also tend to induce false recall. They conducted several free-recall experiments in which some items in a given list had also appeared on earlier lists. In all cases, participants were instructed to recall only the items from the most recently presented list. By creating lists that contained mixtures of novel items and items repeated from earlier lists, Zaromb et al. found that recalls of repeated items were more likely to be followed by prior-list intrusions than were recalls of novel items. This finding would emerge if temporal associations forged on prior lists compete with the associations formed in the current list, and if these older associations occasionally win in the competition. As further support for the role of contiguity-based associations, Zaromb et al. found that repetition-evoked prior-list intrusions came from the same prior lists as the repetitions themselves, and from positions near the repetitions in those lists. When subjects committed two same-list prior-list intrusions in succession, those intrusions tended to come from neighboring positions in their original list, exhibiting a temporal contiguity effect similar to that seen for correct recalls (see **Figure 6(b)**).

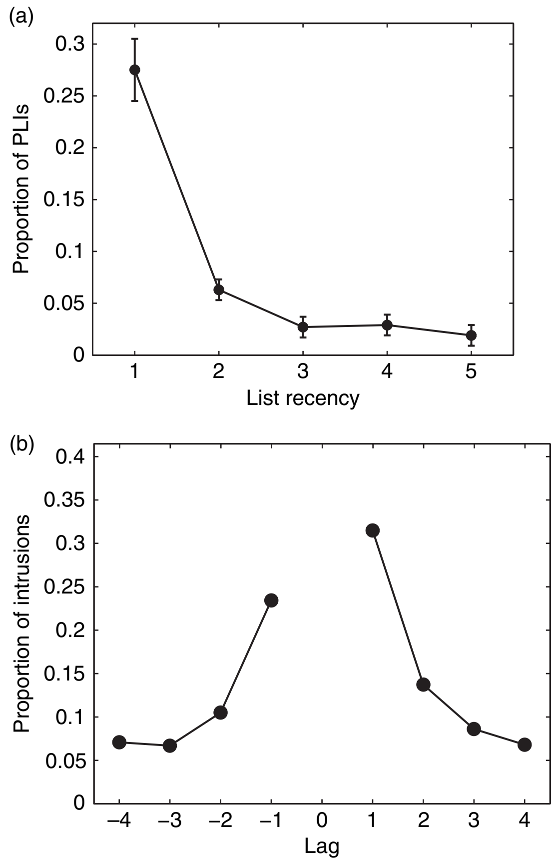

**Figure 6** Effects of recency and contiguity on intrusions in free recall. (a) Prior-list intrusion (PLI) recency effect. Proportion of intrusions coming from one to five lists back. In calculating these PLI-recency functions for items originally presented one to five lists back, we excluded the first five trials from the analysis. That is because PLIs from five lists back could only occur on trials 6 and later. (b) Successive PLIs that came from the same original list tend also to come from neighboring positions in their original list. Thus, temporally defined associations influence PLIs in free recall (Zaromb et al., 2006).

### 2.26.3.2 Intrusions in Serial and Probed Recall

We next consider the effect of contiguity on retrieval in serial-order memory. In a serial-recall task, participants are instructed to recall the list items in order of presentation, rather than in any order as in free recall. In requiring ordered recall, the serial-recall task demands that subjects store information not only about which items were on the list, but also about their order. Thus, the serial-recall task exerts greater control over the manner of encoding and retrieval than does free recall.

Although subjects can only make one correct response in a given output position, they can commit many different types of errors. The orderly pattern of subjects' errors in serial recall can teach us a great deal about the underlying processes. For example, it is well known that when recalling an item in the wrong position this item tends to be misplaced near the correct (target) position (e.g., Lee and Estes, 1977). This finding has also been documented extensively in reordering tasks, where subjects are given all of the target items and asked to place them in their correct studied order (e.g., Nairne, 1990a, 1990b).

The traditional method for measuring error gradients is to plot the probability of an item studied in serial position $i$ being recalled in position $i+$ lag. This approach works especially well in reordering tasks where all the items are placed in some position. With longer lists, where only some of the items are recalled, it is especially important to correct for the availability of different lags, as we have done in our lag-CRP analysis of free recall. For these lag-CRP analyses, we compute the probability of recalling an item from position $i$ in position $i+$ lag conditional on the possibility that an item could be placed in position $i+$ lag (for example, we make sure that the item from that position has not already been recalled). **Figure 7(a)** shows an analog of the lag-CRP derived from errors observed during serial recall (Kahana and Caplan, 2002). In addition to revealing the tendency for errors to come from nearby list positions, this curve shows a clear asymmetry effect, with errors in the forward direction being significantly more likely than errors in the backward direction.[5] Thus, the temporal gradient of errors in serial recall is strikingly similar to the temporal gradient of correct responses observed in free recall (see Klein et al., 2005, for a direct comparison of free recall and serial recall).

The analysis of errors in serial recall is complicated by the fact that each response depends on the sequence of prior responses (Giurintano, 1973). An alternative approach to measuring serial-order memory is to present subjects with a single item from a previously studied list and ask them to recall the item that preceded or followed the probe item (Murdock, 1968; Woodward and Murdock, 1968). Analysis of error gradients obtained in forward and backward probed recall provide an even cleaner test of the asymmetry effect observed in both free and serial recall. **Figure 7(b)** shows error gradients in a probed recall study reported by Kahana and Caplan (2002). The top panel shows that when subjects were given item $i$ and asked to recall item $i+1$, responses tended to come from nearby positions, with a forward bias ($i+2$ is more likely than $i-1$). The bottom panel of **Figure 7(b)** shows that when subjects were probed in the backward direction (i.e., given item $i$ and asked to recall item $i-1$), the same forward asymmetry was obtained (see also Raskin and Cook, 1937).

### 2.26.3.3 Intrusions in Paired-Associate Recall

The preceding section documented two characteristics of errors in serial recall and in probed recall of serial lists: (1) subjects' intrusions tend to be items studied near the position of the target item and (2) subjects' error gradients exhibit a forward asymmetry, with errors being more likely to be items following than items preceding the target item. The temporal gradient of retrieval transitions in free recall as seen in the lag-CRP, and the gradient of subjects' intralist intrusion errors in both serial and probed recall could reflect a common methodological aspect of these tasks. In both free and serial recall tasks, the to-be-learned items constitute an unbroken series such that storing and retrieving associations among neighboring items is useful for performing the task. An important exception to this is continuous-distractor free recall, in which list items are separated by a demanding distractor task. Nonetheless, even in continuous-distractor free recall, subjects may be motivated to make associations between neighboring items.

Paired associate memory provides an interesting contrast to both free and serial recall. In the standard paired-associate procedure, subjects are asked to learn a list of nonoverlapping pairs of words. Following this study phase, subjects are cued for recall of specific pairs (either in the forward or the backward order). Unlike free and serial recall, in which subjects must learn an entire list, subjects in the paired-associate task have no reason to learn associations other than those binding the items within

[5] As with the lag-CRP analysis of free recall, this analysis corrects for the number of available to-be-recalled items.

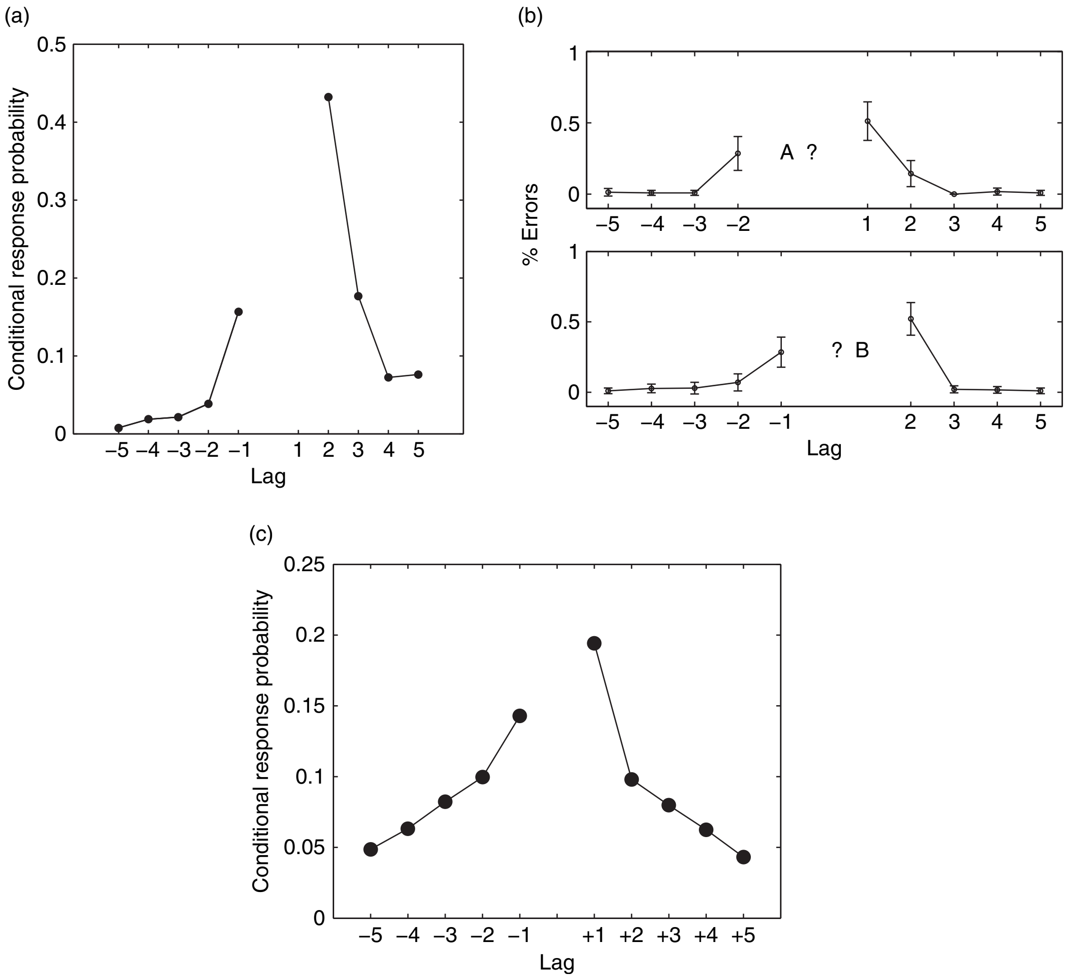

**Figure 7** Intrusions reveal associative tendencies in serial-recall, probed-recall, and cued-recall tasks. (a) Lag-CRP analysis of errors in immediate serial recall. Correct responses (lag of +1) were excluded from this analysis. (b) Conditional error gradients in forward (top) and backward (bottom) probed recall; subjects are given item $i$ as a cue for item $i+1$ (upper panel), or $i-1$ (lower panel), and they recall some other item $i+$ lag. Data are from Trial 1 of Kahana and Caplan's second experiment (Kahana MJ and Caplan JB (2002) Associative asymmetry in probed recall of serial lists. *Mem. Cognit.* 30: 841–849). (c) Following study of 12 randomly chosen noun-noun pairs, subjects were given a standard cued recall test. The probability of incorrectly recalling a word from pair-$j$ in response to a cue word from pair-$i$ decreased with increasing lag, measured in pairs. (Davis OC, Geller AS, Rizzuto DS, and Kahana MJ (2008) Temporal associative processes revealed by intrusions in paired-associate recall. *Psychon. Bull. Rev.* 15(1): 64–69).

each studied pair. Recall is strictly cued by the experimenter so there is no benefit to recalling any item other than the one being probed. Whereas associations in both free and serial recall have a strong forward bias, associations in paired-associate tasks are generally symmetric, with nearly identical recall rates for forward and backward probes (for reviews see Ekstrand, 1966; Kahana, 2002). This surprising result led Gestalt psychologists to propose an *associative symmetry hypothesis* (Köhler, 1947; Asch and Ebenholtz, 1962). According to this hypothesis, associations are learned by incorporating the representations of the constituent items into a new holistic representation. Formalized in computational models, this hypothesis implies that the strengths of forward and backward associations are approximately equal and highly correlated (Rizzuto and Kahana, 2001; Kahana, 2002; Caplan et al., 2006; Sommer et al., 2007).

In light of the distinct features of the paired-associate task, one may wonder whether subjects form temporal associations beyond those required to learn the pairings set forth in the experiment. Davis et al. (2008) addressed this question by examining subjects' pattern of intralist intrusions in paired associate recall. In a cued recall task, there are a number of types of errors a subject could make. Intralist intrusions are incorrect responses where the subject recalls an item from a different pair than the cue came from. Davis et al. (unpublished data) hypothesized that if a common associative process underlies all recall tasks, intralist intrusions would be more likely to come from neighboring list pairs. Consistent with CRP analyses from other paradigms, Davis et al. conditionalized the probability of committing an intrusion from a given lag on the availability of the pair at that lag. Although intralist intrusions constituted only 5% of subjects' responses, these intrusions exhibited a strong tendency to come from neighboring pairs. This can be seen in **Figure 7(c)**, which shows that the conditional probability of an intralist intrusion decreased monotonically with the number of pairs (lag) separating the intrusion from the probed item. This effect was not limited to an increased tendency to commit intrusions from adjacent pairs; even when adjacent pairs were excluded, a regression analysis demonstrated that the across-pair contiguity effect was highly reliable.

Because the order of test was randomized with respect to the order of study, there was no reason for subjects to adopt a strategy of learning interpair associations. Indeed, such a strategy would have been counterproductive insofar as it would induce high levels of associative interference between pairs (Primoff, 1938). As such, these findings of associative tendencies in subjects' intralist intrusions suggest that these temporally defined associations arise from a basic and most likely obligatory memory process that causes items studied in nearby list positions to become associatively connected.

This spectrum of findings reveals that free recall is not alone in providing evidence for the centrality of contiguity effects in human memory. All of the major recall paradigms – free recall, serial recall, and paired-associates learning – show graded effects of temporal contiguity; in many cases these effects are revealed in the patterns of errors made by subjects. Taken together, these findings allow us to glimpse the workings of a general-purpose 'engine of association' that is tapped by all of these varied tasks. Furthermore, the observation of long-range contiguity, both in free recall and in subjects' intrusions in paired-associate recall, challenges the view that intentional encoding is necessary for the formation of contiguity-based associations.

## 2.26.4 Associative Processes in Item Recognition

Theories of item recognition and cued recall typically assume that these two tasks are based on distinct and possibly independent sources of information (Murdock, 1982; Gillund and Shiffrin, 1984; Kahana et al., 2005b) According to these theories, item recognition relies on item-specific information, whereas recall tasks rely on associative (or relational) information (Humphreys, 1978; Hunt and McDaniel, 1993). This view is supported by experimental dissociations between item recognition and free recall (e.g., the word frequency effect; Kinsbourne and George, 1974) and by the finding that words that are recallable often cannot be recognized, and vice versa (e.g., Tulving and Thompson, 1973; Tulving and Wiseman, 1975).

Despite these differences between recall and recognition, both tasks assess memory for an event encoded within a temporal context. Given the ubiquitous character of the contiguity effect across all of the major recall paradigms, it is natural to ask whether contiguity exerts some influence on retrieval in item recognition, at least under conditions where subjects' recognition judgments are accompanied by a feeling of recollection. More specifically, one might hypothesize that recognizing an item as having been previously studied would partially reinstate the item's encoding context, which in turn might facilitate subsequent recognition of neighboring items.

To test this hypothesis, Schwartz et al. (2005) manipulated the serial lag between successive memory probes in an item recognition study that used landscape photos as stimuli. The recognition test was a sequence of test probes that included the old items from the list intermingled with an equal number of new items that served as lures. Subjects pressed one of six keys in response to each probe, rating their confidence that it was seen before from 1 (sure new) to 6 (sure old). A recognition test might include the subsequence of test probes ($\ldots O_{23}$, $N$, $O_{12}$, $O_7$, $N$, $N$, $O_{39}, \ldots$), where $N$ denotes a new item and $O_x$ denotes an old item from position $x$ in the study list. The lag between two successive old items ($\ldots O_i$, $O_j \ldots$) is just the distance, $j - i$, between the items on their initial presentation.

Suppose that recognition of a test item, $O_i$, brings forth the mental state – or temporal context – that prevailed when $O_i$ was first encoded. Suppose further

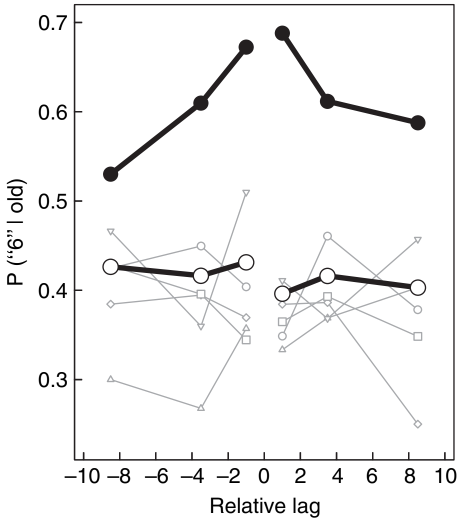

**Figure 8** Contiguity effects in item recognition are specific to highest-confidence responses. Probability of a highest confidence (6) response to an old-item test probe as a joint function the relative lag of, and the response given to, the preceding old-item probe. Large filled circles represent 6 responses to the prior test probe. Open symbols represent one of the other five possible prior responses; downward-facing triangles, boxes, triangles, upward-facing diamonds, and circles represent responses 1–5 respectively. Large open circles collapse data over responses 1–5. Data are from Schwartz et al. (2005). Shadows of the past: Temporal retrieval effects in recognition memory. *Psychol. Sci.* 16: 898–904.

that this retrieved mental state contributes to the retrieval environment that determines subsequent recognition judgments. Then, if the very next test item is $O_j$, we would predict that memory for $O_j$ should be enhanced when lag $= j - i$ is near zero.

The data in **Figure 8** show that when two old items are tested successively, memory for the second is better if it was initially presented in temporal proximity to the first. This tendency, however, was wholly attributable to cases in which the first item received a highest-confidence response. These highest-confidence old responses may be considered to reflect successful recollection of specific attributes of the encoding episode, whereas lower-confidence old responses are assumed to reflect the familiarity of an item whose attributes are not recollected (Yonelinas, 1999; Sherman et al., 2003). Schwartz et al. (2005)'s observation of contiguity effects in item recognition suggests that recollection of an item not only retrieves detailed information about the item tested, but also retrieves information about the item's neighbors.

We have now seen that the contiguity effect appears in all of the major episodic memory paradigms, including free recall, serial recall, probed recall, paired-associates, and even item recognition. The ubiquitous nature of this phenomenon implores us to search for an explanation in terms of fundamental principles of memory function. This search is the topic of the next section.

## 2.26.5 Theories of Episodic Association

Four major theories have been proposed to account for associative processes in episodic memory: (1) associative chaining, (2) associations formed in working memory (or buffer theory), (3) hierarchical associations (or chunking theory), and (4) contextual retrieval theory. In this section, we examine the implications of each of these four theories for the key empirical findings concerning contiguity-based associations in episodic memory.

Chaining theory, which originates in the writings of the associationists (e.g., Herbart, 1834) and in the early experimental work of Ebbinghaus, (1885/1913), assumes that when the memorial representations of two items become simultaneously active, or become active in rapid succession, the items' representations become associated in the sense that activation of one will evoke the other. A key feature of chaining is that associations are formed on the basis of temporal contiguity at study and that an item's representation is assumed to remain active only until the occurrence of the next item in the list.

Buffer models elaborate the basic chaining idea to include a mechanism that maintains an item's representations in the system past its actual presentation, allowing direct interitem associations to be created between items that are presented further apart in time (remote associations). Whereas classic chaining models assume that only two items are simultaneously active, buffer models allow for a larger number of items to be maintained in an active state and provide rules that determine when an item enters and leaves the active state (i.e., the buffer; Raaijmakers and Shiffrin, 1981).

Hierarchical associative models are based on the idea that multiple items can become unitized into a higher-order, conjunctive, representation which is distinct from any of the constituent items. These models have been particularly useful in describing the process of serial learning and serial recall (Johnson, 1972; Martin and Noreen, 1974; Lee and Estes, 1977; Murdock, 1995b, 1997). They assume that associations between items are mediated by a higher-level (super-ordinate) representation.

Finally, contextual retrieval theory assumes that items are associated with a time-varying representation of spatiotemporal/situational context (Estes, 1955; Bower, 1972; Burgess and Hitch, 2005). Successively presented items are associated with this context representation, which then can be used as a cue to retrieve those item representations during the recall period. Importantly, associations arise when items retrieve their encoding context, which in turn cues neighboring items (Howard and Kahana, 2002).

Although we consider each of these major theories in turn, they are not mutually exclusive. In some cases, modern theories of episodic memory make use of more than one of the ideas presented above. For example, some modern buffer models also use a representation of temporal context to differentiate items on the current target list from items on previous lists (Mensink and Raaijmakers, 1988; Sirotin et al., 2005).

As we see it, any theory of associative memory retrieval needs to account for (at least) seven critical behavioral findings regarding temporal-associative processes. The first of these is the contiguity effect – the tendency for neighboring items to be recalled successively. The second critical finding is the asymmetry effect – the tendency for subjects to make transitions to items studied in subsequent list positions. This forward asymmetry is remarkably robust in free recall, being observed in every dataset that reports output order effects. The third critical finding is the long-range contiguity effect – the observation of contiguity effects in continuous-distraction free recall and in a final free-recall task. This finding illustrates how episodic associations are not limited to successively studied items, or even to items studied within a short time period. Rather, contiguity-based associations appear to span many intervening items. The fourth critical finding is that when items are repeated across lists, prior-list intrusions in free recall tend to come from serial positions close to the original presentation (Zaromb et al., 2006). This illustrates the tendency for associations formed on prior lists to influence memory for the current list. Fifth, the tendency for intrusions in serial-recall and probed-recall paradigms is to come from list positions close to the target item. This tendency also exhibits a forward asymmetry effect, where errors tend to be items from subsequent list positions. Sixth, the tendency is for intrusions in paired-associate paradigms to come from neighboring pairs. Although this effect exhibits some forward asymmetry, memory for the items within a pair is strikingly symmetric, with recall accuracy being nearly identical for forward and backward probes (Ekstrand, 1966; Kahana, 2002). Finally, the seventh critical finding is the observation of a contiguity effect in an item recognition task (though this effect appears to be limited to probe items that receive highest confidence old responses). In the sections below, we review the ability of the four major theories of episodic association to account for these findings.

In addition to the temporally defined associative processes reviewed above, a parallel set of findings concerns recency-sensitive processes in memory retrieval. Murdock (1974) summarizes the literature on primacy and recency effects in immediate recall and recognition tasks. Briefly, recency is the most prominent feature of the serial position curves obtained in free recall, paired-associate recall, probed recall, and item recognition. In serial recall, the primacy effect is more prominent than the recency effect. This is largely due to the fact that serial recall requires that subjects initiate recall at the start of the list. Although within-list recency effects in recall tasks are largely attenuated by an end-of-list distractor, recency returns in continuous-distractor free recall (Bjork and Whitten, 1974; Glenberg et al., 1980; Howard and Kahana, 1999). Recency is also observed over much longer time scales than the presentation of a single list, as evidenced by the observation that prior-list intrusions tend to come from recent lists (Murdock, 1974; Zaromb et al., 2006). Similarly, on a final free recall test, subjects are far more likely to recall items from recently studied lists (Craik, 1970; Tzeng, 1973; Glenberg et al., 1980; Howard et al., 2008). Thus, any theory of episodic memory must be able to accommodate recency across very long time scales. Whereas immediate recency effects have often been attributed to the operation of a short-term store, or buffer, longer-range recency effects are often attributed to a contextual coding process. A critical question is whether these recency effects have a common basis or whether they arise from distinct mechanisms (Greene and Crowder, 1984; Raaijmakers, 1993; Davelaar et al., 2005).

### 2.26.5.1 Chaining Theory

According to early conceptualizations of chaining theory, studying an item leads to the creation or strengthening of forward and backward connections

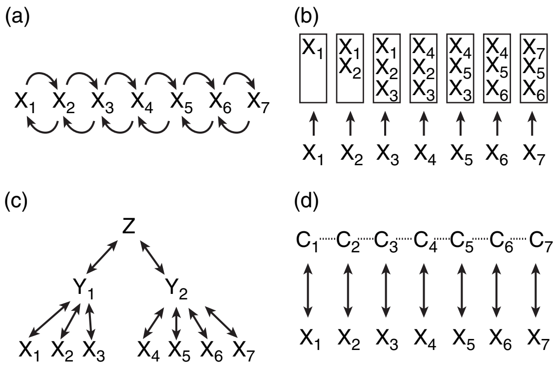

**Figure 9** Illustration of the four types of memory models. (a) Chaining Theory. Each item is associated with its immediate neighbors. (b) Buffer Theory. Items are inserted into a fixed-capacity buffer and reside there until displaced. (c) Hierarchical Association Theory. Conjunctions of items are used to create higher-level representations, which are associated with the original items. (d) Contextual Retrieval Theory. A slowly changing context representation is associated with each of the items.

to the immediately preceding item, with associations being stronger in the forward direction (**Figure 9(a)**). As this classic version of chaining theory has often been associated with behaviorism and its rejection of mentalistic constructs, chaining has been a frequent source of ridicule at the hands of cognitively oriented theorists.

Modern chaining theories (e.g., Lewandowsky and Murdock, 1989; Chance and Kahana, 1997) improve on earlier conceptualizations in a number of critical ways. First, modern chaining theories represent each item as a collection of abstract features or attributes rather than as a single node. Second, associations are conceptualized as networks of connections between the processing units that represent the attribute values. These associative networks can be seen as representing a new entity rather than simply linking two preexisting knowledge structures. The associative retrieval process is thus able to recover a partial representation of an item and use that representation as a cue for subsequent recalls. In addition, the attribute representation of items provides a natural way of characterizing the similarities among item representations. By capturing the similarities among items, chaining models can simulate critical aspects of the behavioral data, such as the effect of semantic similarity on recall.

Lewandowsky and Murdock (1989) used the mathematical operations of convolution and correlation to simulate the chaining of associations among item representations in memory. This mathematical approach has also been used by Murdock and his colleagues to simulate data on free recall (Metcalfe and Murdock, 1981), paired associates, and item recognition (Murdock, 1982, 1992). Similar models have also been developed using Hebbian weight matrices to store associations (Humphreys et al., 1989; Rizzuto and Kahana, 2001; Kahana et al., 2005b).

**Table 1** illustrates chaining theory's predictions regarding the seven critical findings reviewed above. It is not surprising that chaining theory predicts a contiguity effect in both immediate and delayed free recall (Kahana, 1996). Although most theories do not make explicit accounts of latency, it would be relatively straightforward to model the effect of contiguity on latency by using the strength of association to drive a diffusion model (e.g., Ratcliff, 1978).

Chaining theory is consistent with the idea that associations learned on earlier lists can induce subjects to commit intrusions when those earlier items are repeated in the target list. Further, when intrusions beget intrusions, chaining theory predicts that those intrusions should exhibit similar contiguity effects within the prior list that they came from (Zaromb et al., 2006). However, to accurately simulate the relatively modest interlist effects observed in the data, chaining theory must be augmented with a list context representation that is used to focus retrieval on the items in the target list (e.g., Sirotin et al., 2005).

Chaining theory can accommodate the forward asymmetry of the contiguity effect by differentially weighting the storage of forward and backward associations. This is not easily accomplished within the convolution-correlation formalism of Murdock and colleagues, but it can be easily implemented in a Hebbian matrix model (Pike, 1984; Kahana, 2002). Even so, employing differential weighting of forward and backward associations does little to explain the phenomenon.

The standard version of chaining theory assumes that associations are forged among neighboring items. One can extend the standard chaining model to produce the gradient of remote associations seen in the contiguity-effect in free recall by modeling the rehearsal process. When presented with an item for study, subjects often think about that item in relation to recently studied items. This rehearsal process will cause the functional order of study to differ from the nominal order of presentation (Brodie and Murdock, 1977; Tan and Ward, 2000), resulting in the remote

**Table 1** The ability of four major theories of association to account for contiguity phenomena across memory tasks.

| Theory | Contiguity | Asymmetry | Long-range contiguity | Prior-list intrusions | Probed recall intrusions | Across-pair intrusions | Contiguity in item recognition |
|---|---|---|---|---|---|---|---|
| Chain | ✓ | * | × | ✓ | ✓ | ✓ | * |
| Buffer | ✓ | * | × | ✓ | ✓ | ✓ | * |
| Vertical | ✓ | * | × | ✓ | ✓ | * | * |
| Context | ✓ | ✓ | ✓ | ✓ | ✓ | ✓ | ✓ |

The ✓ symbol means that the model can account for the data without modification. The * symbol means that the model requires some modification from the standard version to account for this data-point (see text for elaboration of each case). The × symbol means that the model is unable to account for this data-point.

associations of the kind seen in Figure 2(a). The standard approach to modeling rehearsal in free recall is to assume that rehearsal is controlled by a working memory buffer that actively maintains (and rehearses) a small number of items (e.g., Raaijmakers and Shiffrin, 1980). We discuss the predictions of these so-called buffer models in the next subsection.

The more serious challenge to chaining theory comes from the observation of preserved long-range contiguity effects in free recall. It is hard to envision how chaining models would explain the approximate time-scale invariance of the contiguity effect, as shown in Figure 5(b). Nearest-neighbor chaining theory, even when augmented with a rehearsal buffer and a list-context representation, would predict a diminished contiguity effect when subjects perform a demanding distractor task following each study item. For chaining theory to explain the long-range contiguity effect in continuous-distractor free recall, one would have to assume that remote associations extend through distractor intervals and even across entire lists. To explain the gradient of intrusions observed in recall of paired-associates (Figure 7(c)), one would need to assume that remote associations automatically link items that were studied in nonadjacent pairs.

The finding of associative effects in item recognition is also not easily explained by chaining theory, as it would require associations to be automatically formed between items even when there is no task demand to do so. If chained associations were automatically formed between neighboring items, and if compound cueing operates at retrieval (e.g., McKoon and Ratcliff, 1992), then chaining theory should be able to predict the associative effects seen in Figure 8.

It would be misleading to imply that chaining theory should be evaluated solely on the basis of the select phenomena highlighted in Table 1. In the domain of serial recall, where chaining theories have been most thoroughly investigated, the basic chaining model offers strikingly counterfactual predictions concerning subjects' recall errors, particularly in lists that incorporate repetitions of identical or similar items (Ranschburg, 1902; Lashley, 1951; Crowder and Melton, 1965; Crowder, 1968; Henson et al., 1996; Henson, 1998; Kahana and Jacobs, 2000).

### 2.26.5.2 Working Memory Buffers and Dual Store Theory

Chaining theory makes the implicit assumption that the just-presented item is somehow maintained long enough to become associated with the current item. In essence, the just-presented item must be maintained in some type of working memory buffer. Dual-store memory models, such as the Atkinson–Shiffrin model and its more modern descendant, the SAM retrieval model, elevate the working memory buffer to a far more prominent role (Raaijmakers and Shiffrin, 1980; Sirotin et al., 2005). These models assume a working memory buffer that is capable of holding multiple items during list presentation. Any items residing in the buffer at the time of test may be recalled without a lengthy search process. Moreover, the rules that determine how items enter and leave the buffer can be designed to simulate the process of strategic rehearsal, thus enabling the models to account for aspects of free-recall data that are believed to depend on the pattern of rehearsals that occur during list presentation (Rundus, 1971; Brodie and Murdock, 1977; Tan and Ward, 2000; Laming, 2006). The critical assumption for our purposes is that items that are co-resident in the buffer become associated, and the size of the buffer determines the range of remote associations among items (see Figure 9(b)).

The SAM retrieval model, and its latest variant, eSAM, offers the most comprehensive model of free recall currently available (Raaijmakers and Shiffrin, 1980; Sirotin et al., 2005). The model's ability to explain a wide range of data, including findings concerning semantic organization effects, comes at the expense of a greater number of assumptions and mechanisms that are built into the model. For example, the eSAM model incorporates associations between items that share time in the buffer (essentially chaining) as well as associations between a time-varying list context signal and items. These associations reside in an episodic memory matrix that is distinct from a semantic memory matrix which is also used in retrieval. eSAM (and SAM) include a dynamical probabilistic recall process which keeps track of which items have already been recalled given a particular set of cues. Finally, a postretrieval recognition test is used to determine whether a retrieved item should be recalled or rejected due to its weak strength to the current list context.

It is important to note that buffer models such as those described by Davelaar et al. (2005) and Sirotin et al. (2005) have been shown to account for a very wide range of recall phenomena. For example, buffer models provide a natural explanation for the striking recency effect observed in immediate free recall and its marked attenuation following a brief interval of distracting activity. Because retrieval of items remaining in the buffer produces the recency effect in immediate recall tasks, buffer-based models can also neatly explain the numerous dissociations between recall of recency and prerecency items, as well as dissociations between immediate and continuous distractor free recall (Davelaar et al., 2005). Although they cannot easily account for long-range contiguity effects, buffer models still represent an important benchmark in the episodic memory literature.

### 2.26.5.3 Hierarchical Association Theory

Hierarchical models of association (e.g., Johnson, 1972; Lee and Estes, 1977; Murdock, 1995a, 1997; Anderson and Matessa, 1997; Anderson et al., 1998) attempt to explain how subjects unitize (or chunk) groups of items to create new conjunctive representations in memory. Whereas both chaining and buffer models define associations as directly linking neighboring items, hierarchical models assume that associations are mediated by a superordinate representation that provides access to two or more neighboring items. An item can be used to retrieve the superordinate representation (or chunk) which in turn can retrieve the other items associated with it. This kind of hierarchical associative structure is illustrated in **Figure 9(c)**.

Hierarchical theories of association have been largely motivated by the observation that practiced subjects tend to rhythmically group items during serial learning (e.g., Müller and Pilzecker, 1900). Because it is difficult to study subjects' grouping strategies in an unconstrained learning situation, researchers have devised methods to encourage specific grouping strategies whose consequences can be reliably measured. Such experimenter-imposed grouping is typically achieved by inserting pauses at regular intervals during list presentation.

There are four major consequences of experimenter-imposed grouping. First, consistent grouping leads to better serial recall, with the highest levels of recall observed for group sizes of three or four items (Wickelgren, 1967). Second, the grouping effect is largest for auditorally presented lists (Ryan, 1969). Third, grouping leads subjects to recall items in the correct within-group position but in the wrong group (Johnson, 1972; Brown et al., 2000). Fourth, subjects inter-response times during recall are longer at group boundaries (Maybery et al., 2002). These and related findings inspired the development of hierarchical associative models which have been applied with great success to data on serial recall (e.g., Estes, 1972; Lee and Estes, 1977; Murdock, 1993, 1997).

Hierarchical, or vertical, associations can be used to create representations that bridge time, which would help to explain some of the critical findings listed in **Table 1**. If the model is able to make a higher-level bridging representation associating successively presented items, then it can capture the contiguity effect. It is less clear whether a model like this can capture the asymmetry effect (Murdock, 1995b). Long-range contiguity effects pose a greater challenge, as they would require hierarchical representations to be robust to distraction, and to keep building up across lists. Hierarchical associations may be able to capture the contiguity effect in recognition, but this would require that the hierarchical representations are formed when there is no task demand to do so.

The preceding discussion refers to a type of hierarchical representation that bridges representations that are separated in time; however, another class of hierarchical models forms higher-level representations that bridge various simultaneously active lower-level representations. In particular, the connectionist model of episodic memory introduced by McClelland et al. (1995), and further developed by Norman and O'Reilly (2003) posits that the hippocampus serves as the locus of a higher-level representation that represents the conjunction of all of the features activated in the various cortical areas that project to it. This hippocampally based episodic representation is associated with all of these lower-level features such that the later activation of a subset of those features allows the episodic representation to be retrieved; it then projects out to the cortical areas and reactivates the full set of originally active features.

### 2.26.5.4 Contextual Retrieval Theory

The effective use of memory depends on our ability to focus retrieval on those memories learned within a given spatiotemporal context (e.g., Carr, 1931; McGeoch, 1932). According to temporal-context models, the memory system associates each studied item with the contextual features present at the time of encoding. At the time of test, the current state of context is a good retrieval cue for recently studied memories (Bower, 1972; Howard and Kahana, 2002). Because retrieval results from a competition among activated memory traces, one observes recency both in immediate and in continuous-distractor free recall (Bjork and Whitten, 1974; Crowder, 1976; Howard and Kahana, 1999).

Howard and Kahana (2002) proposed an extension of the classic Estes-Bower context theory that was designed to explain the observation of long-range contiguity effects. According to their temporal context model (TCM), recall of an item results in a partial reinstatement of the context that was present when that item was studied. This retrieved context then serves as a retrieval cue for other items with a similar context at study, which are most likely to be items from nearby serial positions, thus yielding the contiguity effect.

TCM provides a natural explanation for the robust contiguity effects found in continuous-distractor free recall, as retrieval transitions are driven by the relative similarity between the temporal contexts of different list items. As long as a similar duration of distracting activity separates each item from its neighbors, TCM predicts that the transitions among neighboring list items will be largely independent of the absolute temporal separation of the items in the list.

According to TCM, context is a vector that changes gradually as a result of items being activated in semantic memory. TCM provides a formal mathematical model of how temporal context evolves as a consequence of item encoding and retrieval. It also describes an associative architecture, implemented as a neural network, that links both items to context and context to items.

A given state of temporal context will cue recall items via the context-to-item associative network. Consistent with Tulving's notion of encoding specificity (Tulving, 1983), the optimal cue for an item is the context in which it was encoded. Because context changes gradually, the state of context at the time of test will overlap most strongly with the contexts associated with recent items. This gives rise to the recency effect seen in all episodic memory tasks. Primacy is accommodated within TCM by assuming that early list items receive more rehearsals and/or increased attentional resources (Brodie and Murdock, 1977; Tan and Ward, 2000).

Just as contextual states can retrieve items in semantic memory, so too can items retrieve their associated contextual states. In TCM, it is this process of contextual reactivation that drives the evolution of the context vector itself. Contiguity effects arise because the retrieved contextual states overlap with the encoding context of nearby items. For a more complete treatment, the reader is referred to Howard and Kahana (2002) and Howard et al. (2006). For a discussion of a potential mapping between TCM and the structure and function of the medial temporal lobe, see Howard et al. (2005).

According to TCM, the forward-bias in the contiguity effect arises because recall of an item retrieves both the context stored during list presentation (which is similar to both the prior and subsequent list items) and the pre-experimental contextual states associated with the item. Because the pre-experimental contextual states associated with an item is added to the context vector at the time of the item's encoding, that part of the retrieved context is similar to the contextual states associated with subsequent list items but not prior list items. Thus, the context retrieved by an item includes a symmetric component (the contextual state associated during list presentation) and an asymmetrical component (the pre-experimental contextual states). The combination of these two components produces the forward asymmetry seen in the contiguity effect (**Figure 2(a)**).

Retrieved context is one way that contiguity effects could arise across wide-ranging time scales, such as those observed in continuous-distractor free recall, final free recall, and recall of paired-associates. Dennis and Humphreys (2001) suggested that temporal context may underlie recognition judgments as well. In this case, one might predict that high confidence yes responses reflect successful retrieval of context. The contiguity effect seen in item recognition (Figure 8) could arise if the retrieved contextual representation of an item combined with the subsequent test probe.

## 2.26.6 Conclusions and Open Questions

The evidence we have reviewed shows how retrieval of episodic memories is a cue-dependent process that reflects the temporal contiguity and the semantic relatedness of the cue and the target items. Analyses of retrieval transitions in free recall demonstrate that both temporal and semantic factors have a dramatic effect on retrieval. Although subjects may recall items in any order they wish, the recall of a given item is predictable on the basis of its semantic relatedness and temporal contiguity to the just recalled item.

The contiguity effect, as seen in Figure 2(a), exhibits a strong forward asymmetry, with recall transitions being nearly twice as likely in the forward than in the backward direction. This tendency to make forward transitions contrasts with the overall tendency to begin recall at the end of the list (Kahana, 1996). Contiguity and asymmetry are ubiquitious in free recall. The basic lag-CRP and lag-CRL curves have the same form for lists of different lengths and presentation rates, for different presentation modalities, for different word frequencies, etc. Although reduced for older adults, the contiguity and asymmetry effects have the same basic form across age groups.

The contiguity effect is not limited to free recall; rather, it is a nearly universal characteristic of retrieval in episodic memory. Contiguity is seen in the pattern of correct recalls, inter-response times, and intrusions in free recall, and in the memory errors seen in probed recall, serial recall, and paired-associate recall. Even in item recognition, contiguity appears when subjects respond with high confidence.

One of the most striking and theoretically significant features of the contiguity effect is its persistence across time scales. In free recall, the contiguity effect is not reduced when list items are separated by 16 s of distractor activity. In recall of paired associates, contiguity appears in subjects' tendency to recall items from nearby pairs, thus demonstrating that contiguity does not depend on subjects intention to learn the association between neighboring items.

Four major theories have been proposed to explain episodic associations: Chaining theory, buffer theory, hierarchical association theory, and retrieved context theory. Whereas all of these theories can account for the basic contiguity effect, retrieved context theory offers the only adequate account of the long-range contiguity effect. Retrieved context theories, such as TCM, provide a basis for synthesizing the associative effects observed across all of the major episodic recall and recognition paradigms. In TCM, associative effects appear because retrieved context of a given item overlaps with the encoding context of nearby items. This approach constitutes a departure from traditional accounts of association, such as those assuming direct interitem associations (chaining or buffer theory) or those that assume hierarchial associative structures.

Although the presence of contiguity across time scales supports the contextual retrieval account of episodic association, it does not preclude the operation of other factors as suggested by the alternative theories. For example, it is possible to envision a hierarchical associative model or a buffer-based associative model that also includes a contextual retrieval mechanism.

Despite the enormous strides in our understanding of episodic association, a number of intriguing puzzles remain to be solved. One unsolved puzzle concerns the asymmetric nature of episodic associations. Although the forward asymmetry is a striking feature of associations in free recall, serial recall, and probed recall, the data do not reveal striking asymmetries in all episodic tasks. Moreover, recall of individual paired associates is almost perfectly symmetrical, with subjects exhibiting nearly identical rates of forward and backward recall, and with forward and backward recall being highly correlated at the level of individual pairs (Kahana, 2002).

Perhaps the most important of these puzzles is the question of how the rich structure of semantic associations in human memory could arise simply due to the repeated presentation of related items in temporal proximity. Computational models of semantic memory, such as LSA (Landauer and Dumais, 1997) and the topics model (Griffiths and Steyvers, 2002, 2003) provide some clues as to how such a reconciliation might be possible. LSA and the topics model extract information about the temporal contexts in which words appear to estimate their meaning. Specifically, in these models, temporal context is defined as a passage of text. The hyperspace analog of language (HAL, Lund and Burgess, 1996) and BEAGLE (Jones and Mewhort, 2007) models define temporal context as a sliding window of a fixed number of words. This suggests the possibility of a unification of computational models of semantic memory and models of episodic memory based on contextual retrieval (Dennis and Humphreys, 2001; Howard and Kahana, 2002), in that each process may rely on the presence of a slowly-drifting source of contextual information.

# 2.27 Episodic Memory: An Evolving Concept

**K. K. Szpunar and K. B. McDermott**, Washington University, St. Louis, MO, USA

## 2.27.1 Introduction

Although the term episodic memory did not exist until about 35 years ago, it captures much of what philosophers, psychologists, and lay people have meant by memory or remembering. Episodic memory – or the recollection of events from one's personal past – is therefore one of the most fundamentally important concepts in the study of human memory. It is the capacity for episodic memory that enables one to recollect the multitude of details surrounding one's most cherished moments.

A challenge inherent in writing a review chapter on episodic memory is that it is not a static term; the essence of the term episodic memory has morphed and broadened considerably over the short time of the term's existence. It should be no surprise, then, that different empirical evidence has been brought to bear on the different meanings. A further twist is that a single person, Endel Tulving, both introduced the term (in 1972) and has modified its meaning many times in the years since. As a result, his theorizing and adaptation of the concept has spawned much of the relevant literature, and this chapter draws very heavily upon his work and emergent ideas.

We have chosen the following approach in organizing this chapter. We begin by attempting to identify a few of the historical landmarks or prominent features proposed in the conceptual development of episodic memory. We then choose two topics to consider in some depth. Specifically, we consider evidence supporting the proposition that episodic memory is a distinct memory system, different from other types of memory. We then consider research bearing on the suggestion that episodic memory may represent only one facet of a more general cognitive capacity that enables mental time travel into both the subjective past and future.

## 2.27.2 Historical Landmarks

### 2.27.2.1 A Taxonomic Distinction: Episodic and Semantic Memory

The concept of episodic memory was formally introduced in a seminal chapter by Tulving (1972), who drew a distinction between memory for specific events (episodic memory) and memory for general knowledge and facts (semantic memory). For example, remembering that the word elephant had been present in a list of previously studied words, recounting the events surrounding the day of one's college graduation, or reminiscing about the most recent Christmas dinner with a family member would be considered instances of episodic memory. Knowing that elephants live in Africa, the name of the college one attended, and that a family gathering typically implies a special occasion would be classified as examples of semantic memory (*See* Chapter 2.28).

In 1972, Tulving explained that laboratory studies of human memory had long been concerned with episodic memory. That is, most experiments were of the same general design: Present events for study and then measure how well they are remembered at a later time. At this time, episodic memory was associated with a certain type of task: Those that required recall or recognition of a prior episode.

Although episodic and semantic memory are both declarative (i.e., may be articulated) and can be differentiated from memory that cannot be expressed in terms of representational information (i.e., procedural memory, or memory of how to perform a skill, see Squire, 1987), there exists a fundamental and straightforward distinction between episodic and semantic memory: Episodic memory involves remembering an episode from one's past that is specific to time and place, whereas semantic memory involves general knowledge that is not associated with specific episodes.

Tulving summarized his seminal 1972 chapter as having made "a case for the possible heuristic usefulness of a taxonomic distinction between episodic and semantic memory and two parallel and partially overlapping information processing systems" (Tulving, 1972: p. 401). At the time, the episodic/semantic distinction was offered as a proposal that the two types of memory may be separable. As will be seen, the concept of episodic memory quickly grew to denote more than its originally intended meaning. The taxonomic distinction between episodic and semantic memory, however, is a central feature of the original conceptualization that has stood the test of time. Indeed, this distinction has been adopted by the field and is in widespread use.

Before proceeding further, it is worth considering the similarities and differences between the term episodic memory and a few other, related terms. Autobiographical memory refers to personal memories of one's own life. These can be of two types: episodic or semantic. Consider the following examples: Remembering the first day of grammar school would rely upon episodic memory, whereas knowing the name of one's grammar school relies upon semantic memory. Both examples, however, represent autobiographical (self-related) memory. We should acknowledge, though, that researchers define autobiographical memory in different ways, so not all would agree with this classification scheme. Explicit memory is another term related to episodic memory. Explicit memory is a term often used as a heuristic for the type of memory used on an explicit test of memory; an explicit test is one in which a person is asked to willfully attempt to retrieve the past. Explicit memory can be contrasted with implicit memory, which is the unintentional manifestation of memory (e.g., if you were to read this chapter a second time, it would likely be read faster).

### 2.27.2.2 Subjective Awareness

The role of subjective awareness in memory has long been a topic of interest for the field (e.g., feeling-of-knowing judgments, tip-of-the-tongue states; for a historical review see Metcalfe, 2000). In 1983, Tulving published *Elements of Episodic Memory*, in which he explicitly applied such ideas to his own work. In that volume, Tulving proposed that memories for personal episodes are characterized by a strong feeling of re-experiencing the past. In contrast, Tulving argued that retrieval of general knowledge from semantic memory lacked this phenomenological quality. That is, although someone may know a fact (e.g., that St. Louis is the site of a famous arch) and is aware that he or she acquired knowledge of this fact in the past, one does so in a way that does not necessitate re-experiencing the instance in which the fact had been learned.

Tulving further argued that the feeling of re-experiencing a previously encountered event is the *sine qua non* of episodic memory. He outlined a general framework (General Abstract Processing System, or GAPS; **Figure 1**) by which to understand the act of remembering from episodic memory (Tulving, 1983). The GAPS framework was intended to highlight many issues associated with retrieval from episodic memory. We focus here on how this framework predicts the emergence of subjective awareness (or recollective experience, as it was referred to in 1983). As can be seen in **Figure 1**, an encoded event is converted into a latent memory trace (or engram;

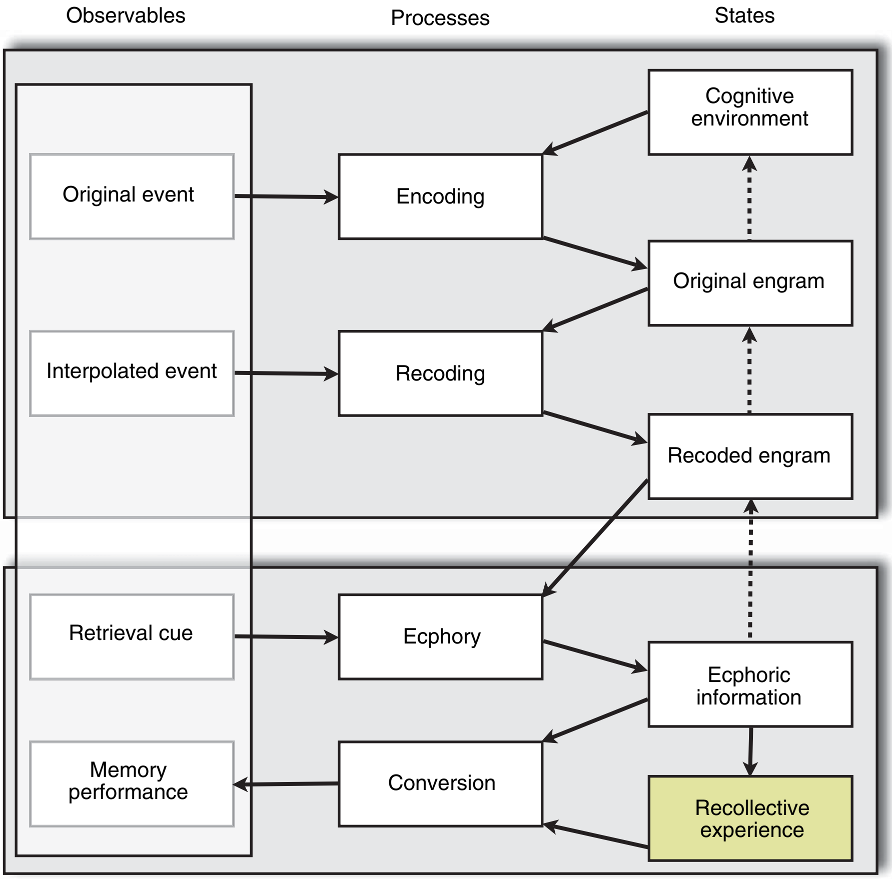

**Figure 1** General Abstract Processing System: A conceptual framework for understanding retrieval from episodic memory. Adapted from Tulving E (1983) *Elements of Episodic Memory.* New York: Oxford University Press.

Semon, 1904). However, it is unlikely that the event will be remembered exactly as it had originally occurred. For instance, the latent engram related to that event is subject to recoding (e.g., by virtue of related interpolated events). The recoded engram then interacts with a retrieval cue to produce ecphory: The evocation of information from a latent engram into an active state (Semon, 1904; Tulving and Madigan, 1970; Tulving, 1976; Schacter et al., 1978). That is, the synergistic product of the memory trace and the retrieval cue determine the nature of what is remembered (ecphoric information; *See* Chapter 2.16; Tulving, 1982), which in turn determines recollective experience. Accordingly, the rememberer will become aware of the encoded event to the extent that ecphoric information is representative of the original episode. At this time, no data were presented that directly assessed a participant's recollective experience for the contents of his or her memory.

On the basis of the notable absence of phenomenological data from the majority of verbal learning experiments (but see Metcalfe, 2000, who discusses various exceptions), Tulving (1983) suggested that students of psychology had not yet begun the study of episodic memory. Of course, this claim directly contradicts his previous (Tulving, 1972) assertion, which he declared in 1983 to have been "not very well thought out" (Tulving, 1983: p. 9). Prior research had assumed a correlation between a learner's behavioral response and subjective awareness. That is, if a learner was able to recall or recognize having previously encountered a given stimulus item (e.g., a word from a previously presented list) it was assumed that he or she mentally re-experienced the original event. It is now well-established that there is no direct correlation between behavior on a memory test and the cognitive processes underlying that behavior (Schacter, 1987; Tulving, 1989a; Jacoby, 1991; Roediger and McDermott, 1993; Toth, 2000; *See*

Chapter 2.33). Tulving (2002b) reflected on this issue by pointing out that episodic memory is concerned with what happened where and when. Typical verbal learning experiments assessed the what aspect but left when and where unqueried.

With this problem in mind, Tulving (1985b) devised a research paradigm designed to illustrate that a learner in a memory experiment does not necessarily remember the instance in which he or she experienced an event that he or she knows occurred in the past. This procedure was a starting point for exploring the nature of subjective awareness.

### 2.27.2.3 The Remember/Know Paradigm

The remember/know paradigm was introduced as a tool for investigating a learner's subjective awareness of a prior study episode (Tulving, 1985b), although current procedures have been modified somewhat from the original implementation (see Rajaram, 1993). For the most part, a remember/know experiment takes the form of the typical laboratory memory experiment. Learners study a set of stimulus materials at time one (e.g., a list of words) and take a memory test on those materials at time two. The innovation that Tulving introduced was to ask learners at the time of the memory test whether they actually remembered the exact prior occurrence of a given study item (e.g., the word ocean), or whether they just knew that the item had been presented, but could not remember the precise instance of its original presentation (Tulving, 1985b; Gardiner, 1988; Rajaram, 1993; Gardiner and Richardson-Klavehn, 2000; *See* Chapter 2.17).

Tulving (1985b) showed that learners could easily make these mental distinctions and that both remember and know responses were present during tasks that previously had been thought to tap episodic memory (i.e., recognition, cued recall, and even free recall). This important finding suggested that learners had two routes by which to recover the contents of a past study episode. Remembering was identified as the hallmark of episodic memory and was further associated with a unique mental state called autonoetic (self-knowing) awareness, implying a feeling of personally re-experiencing the past. Knowing was associated with semantic memory and noetic (knowing) awareness, a mental state lacking the feeling of personally re-experiencing the past. Further, memory tasks were found to vary in the degree to which they relied upon remembering, with free recall demonstrating the greatest level of remember responses (i.e., the greatest reliance on episodic memory). Hence, an important conclusion here is that no memory test is a pure measure of episodic memory, and tests designed to assess episodic memory differ in the degree to which they rely on the construct, with none achieving a pure assessment of episodic memory.

It is interesting to note that the subjective (autonoetic) awareness that Tulving had identified as a central component of episodic memory was similar to what pioneers of memory research had in mind when discussing remembering. For instance, William James (1890) wrote of remembering as, "a direct feeling; its object is suffused with a warmth and intimacy to which no object of mere conception ever attains" (James, 1890: p. 239). Hermann Ebbinghaus, (1885) adopted a generally understood conceptualization of memory that had been put forth by John Locke, defining remembering as the emergence of a sought after mental image that is "immediately recognized as something formerly experienced" (Ebbinghaus, 1885: p. 1). According to Locke, memory was the power of the mind "to revive perceptions, which it has once had, with this additional perception annexed to them, that it has had them before" (Locke, 1975: p. 150).

### 2.27.2.4 Retrieval Mode

Aside from the subjective awareness (or lack thereof) thought to accompany memory retrieval, Tulving (1983) outlined various other features by which he distinguished episodic from semantic memory (see also Tulving, 2005). At the time, the listing of differences was meant as a starting point for discussion, rather then any acknowledgment of hard-set facts. Importantly, the features on which episodic and semantic memory were hypothesized to differ were divided into three categories, each separately focusing on the information handled by episodic and semantic memory, their operations, and their applications. The main point of these subcategories was to emphasize that the distinction between episodic and semantic memory was more than just a difference in the type of information under consideration.

For instance, Tulving (1983) made a distinction regarding the manner in which access is gained to episodic and semantic knowledge. According to Tulving, access to information from episodic memory is deliberate and requires conscious effort. Conversely, semantic knowledge may be accessed in a relatively automatic fashion. For instance, stimuli in the environment are immediately interpreted on the basis of semantic knowledge. When reading a novel, the meanings of words come to mind with relative ease. However, it is only when one is in a particular state of mind that is focused on their personal past that the same stimulus may remind one of a particular episode. For example, single words have been shown to act as effective cues for the retrieval of personal autobiographical memories (Crovitz and Schiffman, 1974; Robinson, 1976); this is only the case, however, when participants are specifically instructed to use those words as retrieval cues. This state in which one focuses attention on their past and uses incoming information as cues for past experiences is referred to as retrieval mode (Tulving, 1983; Lepage et al., 2000). A potential exception to this rule involves spontaneous conscious recollection, wherein personal memories suddenly come to mind. One common example is the evocation of an emotional memory (e.g., one's first kiss) by a particular piece of music (see Berntsen, 1996, 1998). Similar examples have been offered in the prospective memory literature (McDaniel and Einstein, 2000; Einstein et al., 2005).

Tulving (1983) argued that retrieval mode constituted a necessary condition for retrieval from episodic memory but admitted, "we know next to nothing" about it (Tulving, 1983: p. 169). In terms of the behavioral literature on the topic, the same statement holds true today. Although subsequent research on the topic has illuminated the nature in which the presence/absence of retrieval mode may be manipulated in the context of a memory experiment (e.g., retrieval intentionality criterion, Schacter et al., 1989), we have not learned much more about the state itself.

Recent advances in neuroimaging techniques (see section titled "Functional neuroimaging") have revived interest in the study of retrieval mode. For example, Lepage et al. (2000) suggested that brain regions showing similar patterns of brain activity during either successful or failed attempts of episodic retrieval (relative to a control task that does not engage episodic retrieval processes) can be taken as neuroanatomical correlates of retrieval mode. Reviewing the relevant literature, Lepage et al. identified six frontal lobe regions (mostly right lateralized) that appear to become active whenever participants attempt to retrieve past information, regardless of whether they are successful or not. Thus, the underlying nature of retrieval mode has not yet been delineated, but neuroimaging techniques may prove useful in approaching this issue.

### 2.27.2.5 Subjective Awareness, Self, and Time

As we have mentioned, the concept of episodic memory has been considerably refined over the years. According to Tulving's most recent conceptualization, episodic memory is a recently evolved, late-developing, and early-deteriorating past-oriented memory system, more vulnerable than other memory systems to neuronal dysfunction, and probably unique to humans. It makes possible mental time travel through subjective time, from the present to the past, thus allowing one to re-experience, through autonoetic awareness, one's own previous experiences (Tulving, 2002b: p. 5).

Thus far we have highlighted subjective (autonoetic) awareness as the defining feature of retrieval from episodic memory. Equally important are concepts of self and subjective time (Tulving, 2002a,b). That is, episodic memory requires the capacity to represent a psychologically coherent self that persists through subjective time, whose past experiences are recognized as belonging to the present self (self-contiguity; Klein, 2001). Klein (2001; see also Klein et al., 2004) argues that a breakdown of self-contiguity disrupts the ability to represent past and present mental states as being aspects of the same personal identity, thus leaving an individual incapable of identifying a current mental state as one that was previously experienced. Klein (2001) reviews compelling evidence to support this claim. For example, individuals with schizophrenia – a population characterized by impairments in self-contiguity – have profound deficits in episodic memory (McKenna et al., 1994).

### 2.27.2.6 The Episodic Memory System

As can be seen by the 2002 definition (quoted in the previous section), episodic memory grew to encompass much more than the type of memory that allowed one to recall or recognize prior events. It became a hypothetical neurocognitive memory system that is characterized, relative to other memory systems, by its unique function and properties (Tulving, 1984, 1985a; Sherry and Schacter, 1987; Schacter and Tulving, 1994). Of course, this basic idea was foreshadowed somewhat by the earlier description (even in the 1972 description regarding partially overlapping processing systems), but the earlier emphasis had been on the basic taxonomic distinction and not on the much more bold claim that it is a memory system.

What exactly is a memory system, and what might the criteria be for establishing one? These questions have spurred a great deal of controversy, much of which appeared in the context of the emerging literature on implicit memory in the late 1980s and early 1990s (Tulving, 1985a; Sherry and Schacter, 1987; Roediger et al., 1990, 1999; Schacter and Tulving, 1994; Buckner, 2007). Some theorists were concerned that the lack of stringent criteria would lead to a proliferation of putative memory systems, many of which were probably not well justified. We wish to sidestep that general debate here; our view is that although the criteria for establishing a memory system are not well-specified (and are often not met even when specified), there is nonetheless strong evidence that episodic memory represents a fundamentally different kind of memory than semantic memory and that the hypothesis that it is indeed a distinct memory system is certainly viable. Here we choose to focus on what was meant by this claim that episodic memory should be considered a memory system and review some of the evidence bearing on the claim.

First, the episodic memory system enables its owner to process (i.e., encode, store, and retrieve) personally experienced episodes. In this way, it allows one to accomplish a feat not possible without the system. Secondly, episodic memory can be differentiated from semantic memory on a variety of dimensions (Tulving, 1972, 1983). We have already addressed one of these dimensions at length, namely the conscious awareness that characterizes episodic (autonoetic awareness) relative to semantic (noetic awareness) memory. Hence, episodic memory has a set of properties that differentiate it from other systems.

It is important to note that the episodic memory system is hypothesized to be related to and have evolved from phylogenetically earlier systems, including semantic memory (Tulving, 1985b, 1995). That is, the ability to consciously re-experience a specific event from the past may have grown out of a more general ability to use the past in an informative fashion, albeit one lacking a sense of subjectively reliving the event (see **Figure 2**). The episodic memory system "depends upon but goes beyond the capabilities of the semantic system. It could not operate in the absence of the semantic system" (Tulving, 1989b: p. 362). Of course, the evolutionary relation between episodic memory and semantic memory is not subject to laboratory investigation. As will be seen, a similar relation appears to exist in the course of ontogenetic development, though, whereby episodic memory emerges in the presence of fully functioning semantic memory.

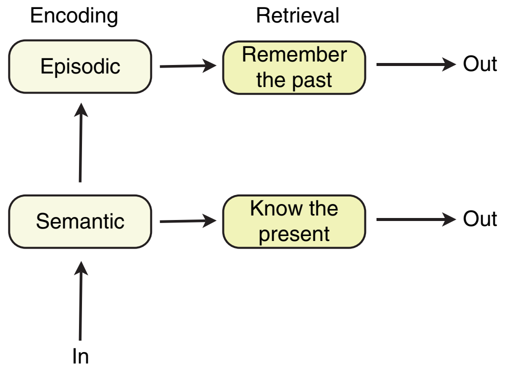

**Figure 2** Sketch of the relations between semantic and episodic memory. Information can be encoded into semantic memory independent of episodic memory but must be encoded into episodic memory through semantic memory. Encoded and stored information is potentially available for retrieval from one of the two systems or from both of them. Adapted from Tulving and Markowitsch (1998).

In the following section, we present evidence from neuropsychology, functional brain imaging, and developmental psychology consistent with the idea that episodic memory may in fact represent a viable neurocognitive system or is at least functionally dissociable from semantic memory.

## 2.27.3 Converging Evidence for the Episodic Memory System

The idea that episodic memory might represent a distinct memory system emerged largely out of the behavioral psychological literature, where it was shown that a particular independent variable might affect performance on one measure or set of measures (e.g., measures thought to draw largely upon episodic memory) but not affect performance (or affect performance in the opposite direction) on different measures, thought to draw largely on semantic memory. For example, level of processing during encoding affects the likelihood of later remembering but not knowing (when the remember/know paradigm is used; see Yonelinas, 2002, for review). Perhaps the most compelling evidence for the idea comes from brain-based studies, particularly neuropsychological studies. Here it can be shown that some patients lose the ability to use episodic memory while retaining other classes of memory, including semantic memory. Following, we review some of this evidence.

### 2.27.3.1 Neuropsychology

Neuropsychological observations of brain-damaged individuals have contributed a great deal to our understanding of the organization of human memory in the brain. Perhaps the most famous contribution is that of Scoville and Milner (1957), who reported the case of patient HM. HM incurred dense amnesia following a bilateral resection of the medial temporal lobes. Since then, a great deal of converging evidence from neuropsychological observations of human patients, neurological experimentation using animal subjects, and more recent advances in functional brain imaging techniques has corroborated Scoville and Milner's original observation: The medial temporal lobes play an important role for memory (for an early reference, see Bekhterev, 1900).

Of particular interest, Scoville and Milner (1957) classified the impairment observed in patient HM as one of declarative memory. That is, no distinction was made between episodic and semantic memory. Of course, this is not surprising given that the distinction was not introduced to the neuropsychological community for another 30 years (Tulving, 1985b; although see Nielsen, 1958, for a foreshadowing of the distinction). Another potential reason the distinction was not made is because it was not readily apparent. HM's surgical resection encompassed large portions of the medial temporal lobes, including, but not limited to, the hippocampal formation. It has recently been considered that hippocampal damage is particularly associated with deficits of episodic memory, whereas semantic memory problems arise as a result of adjacent cortical damage (Mishkin et al., 1997; Aggleton and Brown, 1999). Accordingly, both episodic and semantic memory may have been damaged in patient HM.

Vargha-Khadem and her colleagues have recently reported on a set of three amnesic patients, each of whom sustained bilateral pathology restricted to the hippocampus following an anoxic episode in early life (ranging from birth to 9 years; Vargha-Khadem et al., 1997). Unlike most amnesic patients, their ability to acquire knowledge remains intact. As a result, all three patients have been able to progress through the educational system with little trouble. However, all three are severely impaired in their ability to recall events, even those that occurred minutes previously. These cases represent a clear dissociation between episodic and semantic memory function in the presence of brain damage restricted to the hippocampus.

Although dissociations between episodic and semantic memory are rarely clear-cut, there do exist many case reports in which one is relatively more impaired than the other. Most such cases have reported greater deficits of episodic memory relative to semantic memory (e.g., Cermak and O'Connor, 1983; Calabrese et al., 1996; Kitchener et al., 1998; Levine et al., 1998; Viskontas et al., 2000), although the reverse pattern also occurs (e.g., Grossi et al., 1988; De Renzi et al., 1997; Yasuda et al., 1997; Markowitsch et al., 1999). The reversed pattern (i.e., greater impairment of semantic than episodic memory) is not well accommodated by the idea that episodic memory requires semantic memory to operate.

It is important to note that these case studies are characterized by various etiological factors and resulting patterns of brain impairment that are not restricted to the medial temporal lobes. In general, there is good reason to believe that the operations of various memory systems (including episodic and semantic) depend upon highly distributed and interacting regions of the brain (Mesulam, 1990; Nyberg et al., 2000). For instance, although the role of hippocampus is well established, deficits of episodic memory are also highly correlated with frontal lobe pathology (e.g., Ackerley and Benton, 1947; Freeman and Watts, 1950; Stuss and Benson, 1986; Wheeler et al., 1997).

As an example of relative impairment of episodic memory, consider patient ML (Levine et al., 1998). Following a severe closed-head injury, patient ML became amnesic for pretraumatic events. Although ML retained the capacity to recount many autobiographical facts, he was unable to re-experience any specific event associated with them. For instance, ML could recount the name of a high school teacher perfectly well but was unable to recollect any experience associated with that individual. In brief, the episodic component of patient ML's autobiographical memory was missing. His pathology was restricted to right ventral frontal lobe, including the unicinate fasciculus, a band of fibers connecting frontal and temporal cortices. Patient ML is one of many brain-damaged patients who have lost much of their episodic and semantic memory, with no accompanying anterograde (posttrauma) amnesia.

That is, these patients are able to learn new information. With respect to these patients' retrograde (pretrauma) memory problems, semantic memory typically recovers, while episodic memory remains largely impaired.

As an example of disproportionate impairment of semantic memory, consider the report by Grossi et al. (1988) of a student who lost her ability to reproduce factual knowledge that she had learned prior to her injury. For instance, she was unable to recount various facts learned in school, although she could remember specific meetings with instructors. Summarizing over many such observations, Kapur (1999) concluded that, "loss of factual, semantic memories is readily dissociable from loss of memory for personally experienced events" (p. 819).

Perhaps the most well-documented example of a dissociation between episodic and semantic memory is a patient known as KC, who has been investigated by Tulving (1985b) and his colleagues at the University of Toronto. At the age of 30, patient KC sustained damage to several regions of his brain (including the medial temporal lobes) following a closed-head injury from a motorcycle accident (Rosenbaum et al., 2000, 2005). As with many amnesic patients, neuropsychological testing revealed that KC had retained many of his cognitive capacities. For instance, his intelligence and language faculties remain largely unaffected; he can read and write; he is able to focus and pay close attention to a conversation; he is capable of performing a wide variety of mental tasks, including visual imagery; and his short-term memory is normal.

KC also knows many details about his personal past. Among other things, he knows the names of many of the schools that he attended, the address of his childhood home, the make and color of his former car, and the location of his family's summer home. That is, KC's semantic knowledge of information acquired prior to the brain trauma remains largely intact. Nonetheless, KC cannot remember a single personal episode associated with this knowledge. For instance, although he can readily describe the process of changing a flat tire, he cannot remember ever having performed this task. In fact, KC cannot remember a single episode from his lifetime. This lack of episodic memory extends to highly emotional events; KC has no recollection regarding the untimely death of his brother or a bar fight that left him with a broken arm.

Given the diffuse nature of KC's brain pathology, it remains unclear what the precise cause of the clear dissociation between episodic and semantic memory might be, although strong arguments can be made regarding damage to regions of KC's medial temporal lobes (e.g., Vargha-Khadem et al., 1997; Klein et al., 2002) and frontal cortex (see Wheeler et al., 1997). Regardless, the story of patient KC is a remarkable one and suggests that there may emerge a biological dissociation between episodic and semantic memory.

As a whole, these studies show that various forms of deficits can be found with respect to episodic and semantic memory. Note, however, that there has not yet been successful resolution of how the current concept of episodic memory could accommodate finding a properly functioning episodic memory system occurring in a person with semantic memory deficits. Nonetheless, the more general finding that episodic and semantic memory can be dissociated not just as a function of independent variables but also in neuropsychological patients is consistent with the idea that episodic memory should be considered a memory system.

### 2.27.3.2 Functional Neuroimaging

There now exist seemingly countless neuroimaging studies of episodic memory. Here we identify a few general patterns that indicate a brain-based dissociation between episodic and semantic memory. We have found it necessary to be brief, and we suggest that the interested reader seek some of the in-depth reviews that detail the wealth of studies that have shaped our understanding of episodic memory and how it is represented in the brain.

Traditional psychological studies and (especially) lesion studies do not allow the easy separation of retrieval from storage. In neuroimaging studies, however, retrieval effects can arguably be better isolated. Here we focus primarily on retrieval from episodic memory for a couple reasons. First, the encoding of information into episodic memory seems to rely largely upon retrieval of information from semantic memory (Tulving et al., 1994; see also Prince et al., 2007). Storage is a phase not well studied with the methods under consideration here. Finally, retrieval has been argued to be the foundation for understanding memory; indeed, Roediger (2000) entitled a chapter "Why retrieval is the key process in understanding human memory."

Functional neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), allow neuroscientists to examine the healthy human brain at work.

When participants engage in a given cognitive task, PET or fMRI provide information about the level of cerebral blood flow (PET) or blood oxygenation level (fMRI) localized in the brain regions recruited for the task. Such metabolic changes correlate highly with underlying neuronal activity and thus provide important insights into the brain structures that might underlie specific cognitive tasks.

One challenge in conducting brain-imaging research lies in experimental design. In the typical design, metabolic changes associated with two cognitive tasks are contrasted with one another in hopes of isolating the neural correlates of the cognitive process of interest. Researchers attempt to contrast a pair (or in some cases a set) of tasks that are highly similar to one another but that vary on one key dimension. Note that such a contrast highlights differences between tasks but (in the absence of a third, low-level baseline task) is unable to address areas of common activation.

For instance, in order to identify the neural correlates associated with retrieval from episodic memory, studies have contrasted a task that draws upon episodic memory with a second retrieval task that does not involve the reinstatement of specific spatial-temporal details (e.g., retrieval of general knowledge, which draws upon semantic memory). Although one may be certain that one task reasonably depends more on episodic memory and the other more on semantic memory, neither task is a direct window into the type of memory it is designed to reflect; confidence is gained, however, when results replicate across studies and tasks. This approach makes testable the assumption made by Tulving that retrieval from episodic memory relies upon semantic memory but adds to it certain other processes or brain regions. It is therefore possible to see whether episodic memory seems to rely upon the same brain regions as semantic memory with the addition of others.

With the neuropsychological studies just reviewed in mind, one could make some predictions with respect to how episodic and semantic memory might differ. Relative to some lower-level baseline task, semantic and episodic memory would be expected to reveal very similar activity. To the extent that episodic memory indeed builds upon semantic memory, any differences seen would be expected to be in the direction of greater activity for episodic than semantic memory. Specifically, retrieval from episodic memory would be expected to rely more upon hippocampus (and potentially surrounding structures) than would semantic memory.

In general, neuroimaging studies of episodic memory do not line up perfectly with the neuropsychological studies, and the precise reasons behind this situation are still unclear (Buckner and Tulving, 1995). One way in which the data are consistent with the theory is that in general, activation for retrieval from semantic and episodic memory tasks is very similar, with many (but certainly not all) differences tending to go in the direction of episodic retrieval. One puzzling finding is that the hippocampus is not reliably seen as particularly active during retrieval from episodic memory, especially as typically studied, with verbal materials (Fletcher et al., 1997; Schacter and Wagner, 1999). However, neuroimaging studies of episodic memory using autobiographical memories as the content of retrieval, rather than word lists learned in the laboratory, do overlap nicely with lesion studies (e.g., hippocampal activity is commonly reported in neuroimaging studies of autobiographical memory retrieval). Thus, questions regarding the differences obtained using differing methodologies may ultimately need to focus on the tasks being used in conjunction with the method of inquiry.

Direct comparisons of tasks designed to rely on episodic and semantic memory have not been reported as often as one might think (but for some examples see Shallice et al., 1994; Fletcher et al., 1995; Nyberg et al., 1996; McDermott et al., 1999a,b). Those who have done so show that regions within frontal cortex are more active for episodic than semantic memory. In the early 1990s (when the literature was based largely on PET methodology), retrieval-related activation in frontal cortex was almost always right-lateralized in or near Brodmann Area (BA) 10 (for a review see Buckner, 1996); more recent studies using fMRI tend to show bilateral or left-lateralized activity here. Following this relatively unanticipated finding, much work has been devoted to attempting to identify the processing underlying these prefrontal regions involved in episodic retrieval. Some hypotheses regarding the processes include retrieval mode (the mental set of attempting to retrieve the past, LePage et al., 2000), retrieval success (McDermott et al., 2000), postretrieval processing (a set of processes following the initial recovery of information in the retrieval phase; see Rugg and Wilding, 2000), or the amount of retrieval effort extended (Schacter et al., 1996). Different regions certainly contribute to different processes, but it is not yet clear which regions are contributing which processes (or even if the correct processes have been identified). A precise understanding of the situation awaits further work.

Another somewhat surprising finding is the role parietal cortex appears to play in episodic memory. Contrasts of episodic memory tasks with semantic memory tasks tend to activate regions within bilateral inferior parietal cortex (within BA 40) and within medial parietal cortex (precuneus and posterior cingulate/retrosplenial cortex, e.g., McDermott et al., 1999b), and contrasts of episodic retrieval with other comparison tasks have elicited similar findings, which have led to recent attempts to identify the role of parietal cortex in memory (Shannon and Buckner, 2004; Wagner et al., 2005). Although the possible importance of parietal cortex in episodic retrieval was at the time unanticipated from the lesion literature, a closer look at the lesion literature shows that lesions on medial parietal structures can indeed produce what has been called retrosplenial amnesia (Valenstein et al., 1987).

Of historical importance is an early generalization in functional imaging studies of human memory, which suggested an apparent asymmetry between episodic encoding and retrieval processes: Hemispheric Encoding/Retrieval Asymmetry (HERA; Tulving et al., 1994). In general, episodic encoding was thought to be more strongly associated with left frontal lobe activity (than right), whereas episodic retrieval was more strongly associated with right frontal lobe activity (than left). Because episodic encoding is believed to involve a high degree of semantic elaboration of incoming information, semantic retrieval has also been associated with left frontal lobe activity. As reviewed above, most researchers would probably argue that the more profitable approach is to attempt the ascription of processes to specific cortical regions (rather than making broad generalizations to larger regions of cortex, e.g., the role of the right frontal lobe). Nonetheless, the HERA idea was influential in the late 1990s and served as a guiding framework for a number of studies.

In this short review, we have necessarily omitted many relevant issues from consideration. Among those are fMRI studies of remembering and knowing (e.g., Henson et al., 1999; Eldridge et al., 2000; Wheeler and Buckner, 2004) and studies from the tradition of autobiographical memory (see Maguire, 2001 for review). Further, event-related potential (ERP) studies anticipated the importance of parietal cortex in retrieval (Rugg and Allan, 2000) and some of the differences seen in remembering and knowing.

To summarize, initial contrasts of episodic and semantic memory were expected to elucidate the role of the hippocampus in episodic memory. Although some studies showed such activation, many did not. Attention then turned to the role of frontal cortex in remembering (with an accompanying new look at the neuropsychological literature). Most recently, the role of parietal cortex has become of great interest. The questions being asked are essentially of the flavor of which regions contribute which processes. In our view, this approach is the best one to take at this point (see, too, Roediger et al., 1999). Neuroimaging studies have not well adjudicated the question of whether episodic memory is a memory system but have clarified thinking with respect to how (in process terms) episodic and semantic memory differ and what the neural substrates of those different processes might be. Note that this review has focused on studies that are somewhat relevant to the question of whether episodic memory can be thought of as a memory system dissociable from semantic memory; other related issues (e.g., a comparison between remembering and knowing or between successful and unsuccessful retrieval attempts) have not been addressed, as we see them as less critical to the question under consideration here (although they address fundamentally important issues in the topic of remembering).

### 2.27.3.3 Development of Episodic Memory: The Magic Number 4 ± 1

Episodic memory is a late-developing memory system that emerges in the context of an already existing ability to draw upon the past in an informative fashion. Beginning at an early age, children are able to acquire vast amounts of knowledge from their surroundings. For instance, within the first few years of life, a child will have learned and retained the meanings of thousands of words and detailed knowledge pertaining to the identities of various objects in their environment. This early accumulation and utilization of knowledge is best characterized in terms of semantic memory. That is, although children know about many things that they have learned in the past, the capacity to reliably remember specific events does not emerge until approximately 4 years of age.

As with various other developmental milestones, episodic memory emerges in a gradual manner. Specifically, although most 3 year olds have great difficulty with tasks that are believed to require episodic memory, there do appear glimpses that this capacity is beginning to manifest itself. For instance, by the age of

3 years, many children are capable of reporting the content of an event that they had previously witnessed in the laboratory (Howe and Courage, 1993; Bauer et al., 1995; Bauer and Werenka, 1995). However, the descriptions are typically vague, and it is difficult to know whether these children remember the precise episodes they describe, or whether they just know about them.

Johnson and Wellman (1980) have presented data suggesting that the ability to discriminate between the mental states of remembering and knowing does not emerge until the age of 5 years. In their study, few 4 year olds, some 5 year olds, and most first-grade children demonstrated an understanding of the distinction. This finding is consistent with the claim that children under the age of 4 years are likely relying upon semantic memory when reporting on events from their past.

A great deal has been learned about the emergence of episodic memory through the use of source memory tests (Johnson and Raye, 1981; Johnson et al., 1993). Not only do such tests require the participant to remember the content of a prior study episode, but the participant must also remember the context (e.g., when, where, etc.) in which that content was learned. Source memory tasks are believed to be good tests of episodic memory in that a correct response requires the reinstatement of specific spatial–temporal aspects of the originally encoded event. Studies that have adapted the source memory paradigm for use with children are consistent in their findings: The capacity for episodic memory appears to emerge around the age of 4 years.

In a particularly clear demonstration, Gopnik and Graf (1988) had 3-, 4-, and 5-year-old children learn the contents of a drawer under one of three conditions. The children were told about the contents of the drawer, were allowed to see the contents of the drawer for themselves, or were given hints so they could infer the contents of the drawer. During a later test, the researchers were interested in the children's ability to answer two questions: What was in the drawer, and how do you know? With regard to the first question, retention of the contents of the drawer was comparable across all age groups. All children knew what they had seen. This was not the case when the children were required to discriminate the source of their knowledge. Although the 5-year-old children made few mistakes in describing the manner in which they had learned about the contents of the drawer, the 3 year olds performed at chance levels (see also Wimmer et al., 1988; O'Neill and Gopnik, 1991). That is, only the 5-year-old children remembered the circumstances under which they had seen the contents.

This basic finding has been replicated many times (e.g., Lindsay et al., 1991; Taylor et al., 1994; see Wheeler, 2000b; Drummery and Newcombe, 2002, for a review). In general, 3 year olds show initial signs of a developing episodic memory system, but for the most part they have great difficulty when they are required to report specific details of past occurrences. By the age of 5 years, most children appear to possess fully functioning episodic memory, although this capacity is likely to continue to develop thereafter (for related discussion, see Nelson, 1984; Gopnik and Slaughter, 1991; Flavell, 1993; Howe et al., 1994; Perner and Ruffman, 1995; Wheeler et al., 1997; Wheeler, 2000a,b; Tulving, 2005; Piolino et al., 2007). With respect to the purposes of our present discussion, children of all ages (except those younger than 8 months; Wheeler, 2000b) possess intact semantic memory, the context in which episodic memory develops.

## 2.27.4 Episodic Memory and Mental Time Travel

Finally, we consider the most recent conceptual development regarding episodic memory, namely, its relation to mental time travel. The idea, initially delineated by Tulving (1985a), is roughly that humans (and perhaps only humans) possess the ability to mentally represent their personal past and future (see also Suddendorf and Corballis, 1997; Tulving, 2002a). That is, just as we can vividly recollect our personal past, we can also, with a seemingly equal level of vividness and efficacy, mentally represent personal future scenarios (episodic future thought).

Beginning with the pioneering work of Hermann Ebbinghaus (see also Nipher, 1876), students of psychology and neuroscience have expended more than 100 years of thought and careful experimentation toward an understanding of human memory. However, there has been surprisingly little inquiry into episodic future thought. According to Tulving and his colleagues, both capacities represent an important component of autonoetic consciousness, which is the ability to "both mentally represent and become aware of subjective experiences in the past, present, and future" (Wheeler et al., 1997: p. 331).

Next, we review evidence suggesting that the capacity for episodic future thought (Atance and

O'Neill, 2001) is intricately related to the ability to vividly recollect one's past. Specifically, it has been argued that impairments to both capacities co-occur following brain damage (Tulving, 1985; Klein et al., 2002), that both share similar neural networks (Okuda et al., 2003; Addis et al., 2007; Szpunar et al., 2007), and that both appear rather late in ontogenetic development (Busby and Suddendorf, 2005).

### 2.27.4.1 Neuropsychology

For an example of selective damage, consider again patient KC. Along with a selective deficit of episodic memory, KC is unable to project himself mentally into the future. When asked to do either, he states that his mind is "blank"; when asked to compare the kinds of blankness in the two situations, he says it is the "same kind of blankness" (Tulving, 1985: p. 4).

A similar profile is exhibited by patient DB, studied by Klein and colleagues (Klein et al., 2002); DB experienced an anoxic episode following cardiac arrest and can no longer recollect his past, nor can he project himself into the future. Interestingly, Klein et al. revealed that DB was able to think about the past and future in a nonpersonal (semantic) manner. That is, while DB could not report any of what he had personally experienced in the past or any of what he might experience in the future, he could report general facts related to the past, along with what might generally occur in the future (e.g., concerns about global warming).

Hassabis et al. (2007) replicated and extended these findings in a more systematic fashion. In that study, the authors presented a set of five amnesic patients with brain damage localized to the hippocampal formation. Each of these patients is densely amnesic for personal episodes but retains intact semantic memory. To test whether the profound deficit of episodic memory was accompanied by a deficit in episodic future thought, the authors tested the patients' ability to form mental images of novel future experiences. Specifically, the patients were presented with a series of 10 cues and asked to imagine themselves in the context of either novel (e.g., castle) or familiar (e.g., possible event over next weekend) settings. Relative to those of control subjects, the patients' images were "fragmentary and lacking in coherence" (Hassabis et al., 2007: p. 1728).

The aforementioned case studies represent only a few of many reports about amnesic patients. Most other investigations into the phenomenon of amnesia have, for the most part, focused on the memory problems inherent in such patients. For instance, many others have been interested in investigating the relative effects of brain damage on episodic versus semantic memory (Kapur, 1999; Wheeler and McMillan, 2001). Thus, it remains uncertain whether comparable impairments in backward- and forward-going aspects of mental time travel are common in all such patients.

Nevertheless, there do exist prior reports describing amnesic patients as living in the permanent present (Barbizet, 1970; see also Lidz, 1942), and cases similar to the ones mentioned above have been reported (Stuss, 1991; Dalla Barba et al., 1997; Levine et al., 1998). In addition, there exist extensive reviews of case study reports on patients with frontal lobe damage (e.g., Luria and Homskya, 1964; Luria, 1969). One common characterization of these patients is that they seem to be detached from the past and unconcerned about matters related to their personal future (Ackerley and Benton, 1947; see also Freeman and Watts, 1950; Ingvar, 1985; Fuster, 1989; Wheeler et al., 1997; Wheeler, 2000a).

### 2.27.4.2 Functional Neuroimaging

The psychological study of episodic future thought has been attempted only sporadically (D'Argembeau and Van der Linden, 2004, 2006; Szpunar and McDermott, in press), and the search for its neural substrates has begun only very recently. Note that we draw an important distinction between episodic future thought and more general thoughts of the future, such as planning, which has received extensive attention in the literature and is thought to rely heavily on regions within frontal cortex (Stuss and Benson, 1986; Shallice, 1988; Fuster, 1989). The set of procedures under examination here – comprising episodic future thought – are arguably a necessary precursor to planning; without the ability to envision oneself spending a weekend with friends on the ski slopes, for example, it is unlikely that one would plan the weekend.

Consider a recent PET study by Okuda et al. (2003). Participants were asked to speak aloud for 1 min about their near future (the next few days), far future (next few years), near past (recent few days), and far past (last few years). Activity during these states was compared to each other and to a fifth, baseline state, which involved talking about the meaning of various words. Two regions in anteromedial frontal cortex and medial temporal cortex were more active for the future conditions than the past conditions; other regions (in nearby medial frontal and medial temporal cortex) exhibited the opposite effects (more activity for past conditions relative to future). The authors suggested that remembering the past and planning for the future likely share common neural correlates and that it may be necessary for past experiences to be reactivated in order to facilitate an effective plan for future events (see too Burgess et al., 2000). Their data suggest that specific regions within frontal and medial temporal cortex might be suited for these functions. Although quite interesting, these data are of questionable relevance to the topic under consideration because in speaking about the future, the participants in this study tended not to focus upon specific future episodes but instead spoke about intentions, conjectures, and schedules. In contrast, these aspects were not much present when speaking about the past (i.e., the past tended to focus on specific episodes). In the other two studies to be considered, participants were asked to focus on specific episodes (either episodes that might take place in the future or ones that indeed took place in the past).

Szpunar et al. (2007) used fMRI to identify brain regions that might be important for representing oneself in time and then to examine those regions to see whether or not they are similarly engaged by past and future thought. In order to accomplish this goal, participants were asked to perform a set of three tasks. In all of these tasks, participants viewed a series of event cues (e.g., birthday party) and were asked to envision a specific scenario in response to the cues. In one task, the instructions were to recollect a personal memory of that kind of event (e.g., a specific previous birthday party). The second task instructed subjects to use the cue to think of a specific future scenario involving the cue. Activity common to both tasks (i.e., a conjunction of the past and future tasks) was contrasted with a third task that involved many of the processes common to past and future thought (e.g., mental construction of lifelike scenarios) but that lacked a sense of representing oneself in time. Specifically, the control task required participants to use the cue as a starting point for imagining former U.S. President Bill Clinton in a specific scenario. Bill Clinton was chosen because pretesting showed that he is easy to visualize in a variety of situations.

As can be seen in **Figure 3**, several regions in the brain's posterior cortex were similarly engaged during personal past and future thought, but not during the control task. These regions were located in the occipital cortex, the posterior cingulate cortex, and the medial temporal lobes. Previous research had shown that these regions are consistently engaged during tasks such as autobiographical memory (Svoboda et al., 2006) and mental navigation of familiar routes (Ghaem et al., 1997; Mellet et al., 2000;

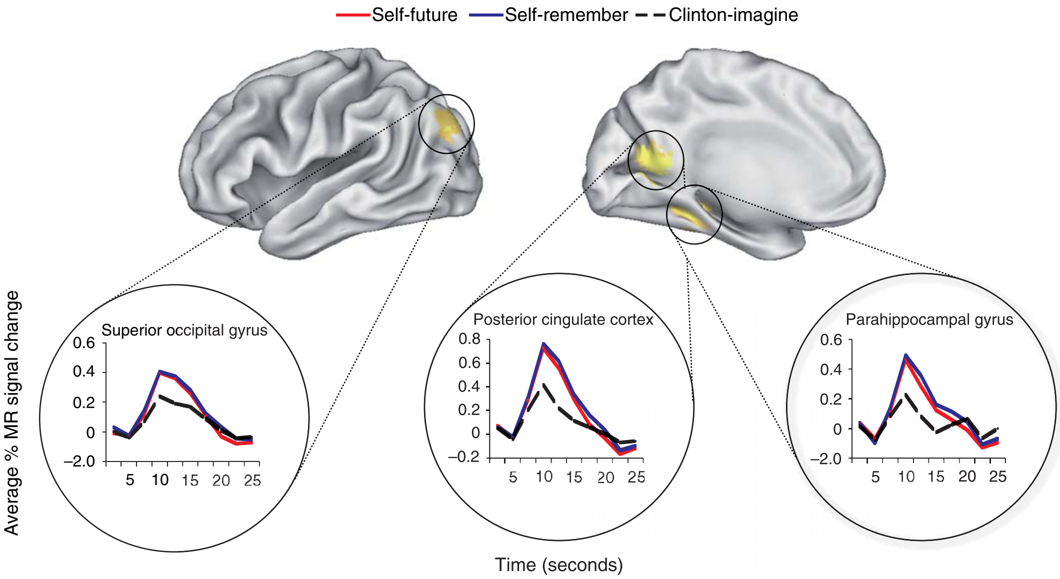

**Figure 3** Percent signal change for brain regions exhibiting indistinguishable patterns of activity across time while participants envisioned their personal future and recollected the past. Imagining a familiar individual in similar scenarios resulted in a pattern of activity different from both the past and future tasks. Regions appear within superior occipital gyrus, posterior cingulate cortex, and parahippocampal gyrus. Data from Szpunar, Watson, and McDermott (2007).

Rosenbaum et al., 2004), which encourage participants to recount previously experienced settings (Aminoff et al., 2007). Szpunar et al. hypothesized that asking participants to envision a personal future scenario likely required similar processes. That is, in order to effectively generate a plausible image of the future, participants reactivate contextual associations from posterior cortical regions (cf., Bar and Aminoff, 2003; Okuda et al., 2003; Bar, 2004). Postexperiment questionnaires indicated that participants did tend to imagine future scenarios in the context of familiar settings and people.

A similar pattern of fMRI data has been presented by Addis et al. (2007), who parsed episodic future thought and remembering into two separate phases: construction and elaboration. That is, subjects were given cues (e.g., car) and asked to envision themselves in the future or to remember a past event. Once the event was in mind, they were to press a button and to then keep thinking about the event for the remaining time of the 20 s. They then rated the level of detail, the emotional intensity, and the perspective (first person or third person) before moving to the next trial. Of most interest to the present discussion is the construction phase (in part because the activity during the elaboration phase could not be separated from the activity during the three subsequent rating phases). Relative to baseline tasks that involved sentence generation and imagery, constructing the past and future episodes led to equivalent activity in a set of posterior cortical regions similar to those reported by Szpunar et al. (2007).

In light of such findings, Schacter and Addis (2007a) have proposed what they call the constructive episodic simulation hypothesis. They argue that one important function of retaining personal memories is the ability to sample their contents in mentally constructing (predicting) novel future scenarios (see also Szpunar and McDermott, in press). That past and future thought are so closely related provides insight into why certain populations who lack access to specific personal details of their past (e.g., brain damaged amnesic patients) are also unable to imagine specific personal future scenarios.

Finally, it should be noted that although this is a very recently emerging topic of interest, we anticipate that the above-mentioned studies will act as a catalyst for future research. Several early concept papers and reviews on the topic have also been put forth (Buckner and Carroll, 2007; Miller, 2007; Schacter and Addis, 2007a; Szpunar and McDermott, 2007). There is a recent but clear trend in thinking about episodic memory to include episodic future thought.

### 2.27.4.3 Development of Episodic Future Thought

A small but growing line of research suggests that the ability to project oneself into the future emerges in concert with the ability to vividly recollect the past. For instance, Busby and Suddendorf (2005) have shown that it is not until about the age of 5 years that children are able to accurately report what they will or will not do in the future (i.e., tomorrow), as well as what they have or have not done in the past (i.e., yesterday). Many of these studies have focused on requiring children to predict future states (e.g., Suddendorf and Busby, 2005) and have revealed both that the emergence of this capacity is not based simply on semantic knowledge related to the future event (Atance and Meltzoff, 2005) and that it is not dependent on language (Atance and O'Neill, 2005).

## 2.27.5 Is Episodic Memory Uniquely Human?

Perhaps the most intensely debated topic regarding episodic memory is whether this capacity, and mental time travel more generally, is uniquely human. There is no dispute that nonhuman animals possess memory. For example, consider a dog that buries a bone in the backyard and retrieves it the following day. How does the dog accomplish this task? Perhaps the animal mentally travels back in time, as we might. Alternatively, the animal may simply know that the backyard is somewhere where things are buried and may be able to make use of salient cues to locate the object it desires. Or the animal may know exactly where the bone is without remembering the episode in which it was placed there. We suspect most dog owners would suggest that the animal surely remembers where it had buried the bone and would likely be willing to offer many other examples to support the claim. But is this what happens?

As it turns out, this is a very difficult question to answer. If we assume that subjective (autonoetic) awareness is the central component of episodic memory, then we are not able to get very far. Much of the evidence for the concept of autonoetic awareness comes by way of verbal reports regarding the subjective state experienced during the act of remembering the past (e.g., remembering vs. knowing). Because we cannot directly ask a nonhuman animal to describe its mental state, the prospect of identifying autonoetic awareness in other species is dim (Clayton et al., 2005). This state of affairs has led some to argue that there should be other means by which to investigate episodic memory in nonhuman animals.

Clayton et al. (2003) suggest that one alternative is to characterize episodic memory in terms of the spatial–temporal information that is encoded about an earlier event (what, where, and when) and the nature by which this information is represented (i.e., as an integrated whole) and utilized. The authors argue that animal studies must consider these behavioral criteria if they are to demonstrate convincing evidence of episodic memory in nonhuman animals. Clayton et al. further review prior attempts using primates, rats, and other animals that fall short of meeting these criteria.

Clayton, Dickinson, and their colleagues have presented several impressive demonstrations of an integrative memory capacity in the western scrub jay (e.g., Clayton and Dickinson, 1998, 1999). In their studies, the scrub jays are given the opportunity to cache both preferable but perishable (e.g., wax worms) and nonpreferable but less perishable (e.g., nuts) foodstuffs (see **Figure 4**). Given that the scrub jays' preferred snack will perish sooner, the birds must remember not only what they stored and where they stored it, but also when the foodstuff had been stored. Although the scrub jays will prefer to search for their favored treat, there is little point if that snack is no longer edible. It appears that the scrub jays are able to integrate these aspects of the original caching episode and search accordingly. That is, the scrub jays are able to appropriately adjust recovery attempts of the differentially perishable caches depending on how long ago they had stored the food items.

**Figure 4** A western scrub-jay caching wax worms.

Even such convincing evidence of an integrated spatial–temporal memory of the past leaves open questions regarding the mental life of this species of bird. As a result, Clayton et al. (2003; Clayton and Dickinson, 1998) refer to this capacity as episodic-like memory, while others question whether this feat represents episodic memory or some other mechanism that may be driven by specific learning algorithms (Suddendorf and Busby, 2003; Suddendorf, 2006; see also Tulving, 2005).

Tulving (2005) has suggested that although mental states cannot be reported by other species, they may in fact be inferred, particularly in the context of mental time travel into the future (e.g., Emery and Clayton, 2001; Dally et al., 2006). Specifically, Tulving argues that comparative studies of episodic memory per se may be futile, in that demonstrations of episodic-like memory in other species may be explained away by simpler mechanisms that need not evoke episodic memory in its true sense (involving autonoetic consciousness). However, it may be possible to construct a situation in which an animal's future-directed behavior may not be attributed to other, simpler means.

Achieving such a situation, however, is no simple matter. A great deal of evidence suggests that even our nearest primitive relatives are incapable of truly future-oriented behavior (for reviews see Roberts, 2002; Suddendorf and Busby, 2003). According to the Bishof-Kohler hypothesis, an animal's foresight is necessarily restricted because it cannot anticipate future needs (for a more in-depth discussion see Suddendorf and Corballis, 1997). For instance, although chimpanzees display preparatory behaviors for future food consumption, it is unclear whether such behaviors indicate foresight beyond the near future (e.g., Boesch and Boesch, 1984; Byrne, 1995). Based on a review of the relevant literature, Roberts (2002) also concluded that higher-order primates appear to be "stuck in time."

Future studies will require clever experimental designs that will allow researchers to examine whether a particular species is able to plan for the future in a manner that is not instigated or maintained by its present motivational state, and in the absence of any immediate benefits associated with a future-directed action (see Mulcahy and Call, 2006; Raby et al., 2007). As it stands, the capacity to mentally represent the personal past and future has only been convincingly demonstrated with human beings (usually over the age of 4 years). Although future research will provide us with a better understanding as to how unique this capacity is to humans, it will likely remain that this capacity holds a special status for humankind (Suddendorf and Corballis, 1997; Tulving, 2002a).

## 2.27.6 Concluding Remarks

As with all concepts of scientific inquiry, episodic memory is an evolving one that is largely shaped through the intricate relationship between data, theory, and available methods of inquiry. The concept of episodic memory started out as a taxonomic distinction that might possess some heuristic usefulness for future research. It has now expanded to encompass a dissociable system of the human brain that enables its owner to accomplish a feat (i.e., becoming autonoetically aware of episodes from one's past) that could not otherwise be possible. Currently, episodic memory represents a concept of great interest to many fields (e.g., clinical psychology, comparative psychology, developmental psychology, experimental psychology, functional brain imaging, neuropsychology, and psychopharmacology). There is little doubt that the continuing accumulation of data from these various areas of research, together with their unique methods of inquiry and furthering technological advancements, will ensure that researchers on the topic will continue to ask new and exciting questions.

# 2.28 Semantic Memory

**D. A. Balota and J. H. Coane**, Washington University, St. Louis, MO, USA

Semantic memory entails the enormous storehouse of knowledge that all humans have available. To begin with, simply consider the information stored about the words of one's native language. Each of us has approximately 50,000 words stored in our mental dictionary. With each entry, we also have many different dimensions available. For example, with the word 'dog' we have stored information about how to spell it, how to pronounce it, its grammatical category, and the fact that the object the word refers to typically has four legs, is furry, is a common pet, and likes to chase cats (sometimes cars, squirrels, and other rodents), along with additional sensory information about how it feels when petted, the sound produced when it barks, the visual appearance of different types of dogs, emotional responses from past experiences, and much, much more. Of course, our knowledge about words is only the tip of the iceberg of the knowledge we have available. For example, people (both private and public) are a particularly rich source of knowledge. Consider how easy it is to quickly and efficiently retrieve detailed characteristics about John F. Kennedy, Marilyn Monroe, Bill Clinton, a sibling, parent, child, and so on. Indeed, our semantic, encyclopedic knowledge about the world appears limitless.

One concern reflected by the examples above is that semantic memory seems to be all inclusive. In this light, it is useful to contrast it with other forms of memory, and this is precisely what Tulving (1972) did in his classic paper distinguishing semantic and episodic memory. According to Tulving, semantic memory "is a mental thesaurus, organized knowledge a person possesses about words and other verbal symbols, their meaning and referents, about relations among them, and about rules, formulas, and algorithms for the manipulation of these symbols, concepts and relations" (1972, p. 386). In contrast, episodic memory refers to a person's memory for specific events that were personally experienced and remembered. So, the memory for the experience of having breakfast yesterday (e.g., where one was seated, how one felt, the taste of the food, who one was with) would fall under the umbrella of episodic memory, but the fact that eggs, cereal, and toast are typical breakfast foods reflects semantic knowledge. However, as we shall see, there is some controversy regarding where episodic memory ends and semantic memory begins. Indeed, we would argue that semantic memory penetrates all forms of memory, even sensory and working memory (Sperling, 1960; Tulving and Pearlstone, 1966; Baddeley, 2000), because tasks that are assumed to tap into these other types of memory often are influenced by semantic memory.

So, what is indeed unique about semantic memory, and how has this area of research contributed to our understanding of learning and memory in general? One issue that researchers in this area have seriously tackled is the nature of representation, which touches on issues that have long plagued the philosophy of knowledge or epistemology. Specifically, what does it mean to know something? What does it mean to represent the meaning of a word, such as DOG? Is it simply some central tendency of past experiences with DOGS that one has been exposed to (i.e., a prototype DOG), or is there a limited list of primitive semantic features that humans use to capture the meaning of DOG, along with many other concepts and objects? Is the knowledge stored in an abstracted, amodal form that is accessible via different routes or systems, or is all knowledge grounded in specific modalities? For example, the meaning of DOG might be represented by traces laid down by the perceptual motor systems that were engaged when we have interacted with DOGs in the past.

In this chapter, we attempt to provide an overview of the major areas of research addressing the nature of semantic memory, emphasizing the major themes that have historically been at the center of research. Clearly, given the space limitations, the goal here is to introduce the reader to these issues and provide references to more detailed reviews. The vast majority of this work emphasizes behavioral approaches to the study of semantics, but we also touch upon contributions from neuropsychology, neuroimaging, and computational linguistics that have been quite informative recently. We focus on the following major historical developments: (1) the nature of the representation, (2) conceptual development and learning, (3) insights from and limitations of semantic priming studies, (4) interplay between semantic and episodic memory tasks, and (5) cognitive neuroscience constraints afforded by comparisons of different patient populations and recent evidence from neuroimaging studies. For further discussion of this latter area, the interested reader should see Chapter 2.29.

## 2.28.1 Nature of the Representation

Although the question of how one represents knowledge has been around since the time of Aristotle, it is clear that cognitive scientists are still actively pursuing this issue. One approach to representation is that we abstract from experience a prototypical meaning of a concept, and these ideal representations are interconnected to other related representations within a rich network of semantic knowledge. This is the network approach. Another approach is that there is a set of primitive features that we use to define the meaning of words. The meanings of different words and concepts reflect different combinations of these primitive features. This is a feature-based approach. Historically, the distinction between these two approaches has been central to research addressing the nature of semantic memory.

## 2.28.2 Network Approaches

One of the first landmark studies of knowledge representation came from computer science and was based on the important dissertation of A. M. Quillian. Quillian (1968) developed a model of knowledge representation called the Teachable Language Comprehender. A goal of this model was to formulate a working program that allowed efficient access to an enormous amount of information while minimizing redundancy of information in the network. Quillian adopted a hierarchically organized network, a portion of which is displayed in **Figure 1**. As shown, there are two important aspects to the network: nodes and pathways. The nodes in this network are intended to directly represent a concept in semantic memory, so for example, the word BIRD has a node that represents BIRDNESS. These nodes are interconnected in this network via labeled pathways, which are either 'isa' directional pathways or property pathways. Specifically, one can verify that BIRDS are indeed ANIMALS by finding an isa pathway between BIRDS and ANIMALS. Likewise, one could verify that 'A ROBIN BREATHES' by finding the isa pathway between robin and bird, and between bird and animal, and then accessing the property pathway leading to BREATHES from ANIMALS. In this sense, the model was quite economical, because most properties were stored only at the highest level in the network in which most of the lower exemplars included that property. For example, BREATHES would only be stored at the ANIMAL level, and not at the BIRD or CANARY level, thereby minimizing redundancy (and memory storage) in the network. Quillian also recognized that some features may not apply to all exemplars below that level in the network (e.g., ostriches are birds, and birds fly), so in these cases, one needed to include a

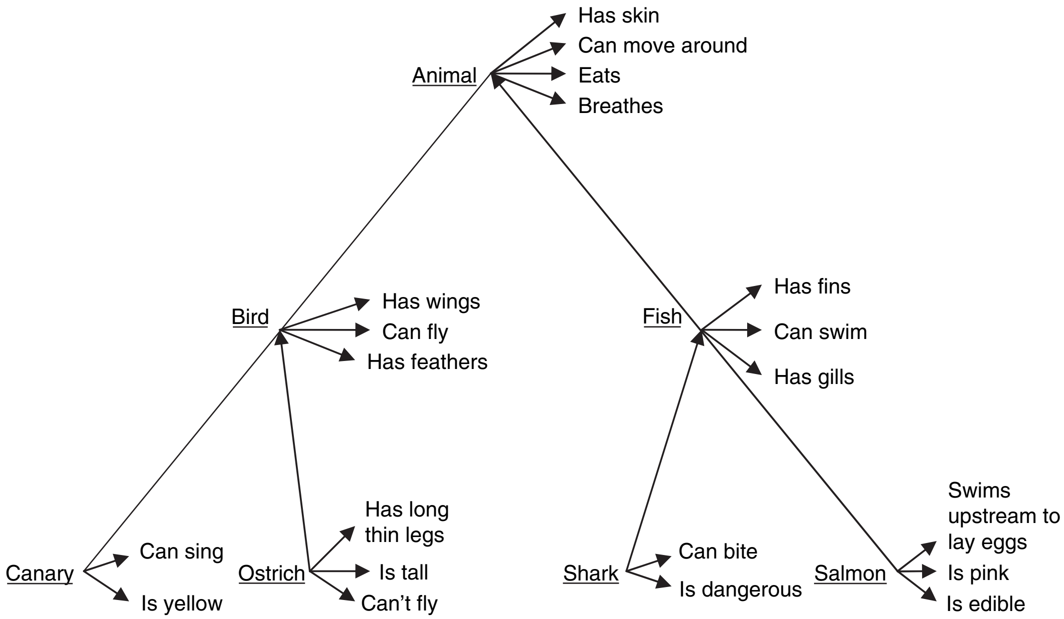

**Figure 1** Hierarchically arranged network. Taken from Collins A and Quillian MR (1969) Retrieval time from semantic memory. *J. Verb. Learn. Verb. Behav.* 8: 240–247.

special property for these concepts (such as CAN'T FLY attached to OSTRICHES).

The economy of the network displayed in Figure 1 does not come without some cost. Specifically, why would one search so deeply in a network to verify a property of a given concept, that is, why would one have to go all the way to the ANIMAL concept to verify that 'CANARIES BREATHE'? It seems more plausible that we would have the property BREATHES directly stored with the CANARY node. Of course, Quillian was not initially interested in how well his network might capture performance in humans, because his goal was to develop a computer model that would be able to verify a multitude of questions about natural categories, within the constraints of precious computer memory available at the time.

Fortunately for cognitive psychologists, Quillian began a collaborative effort with A. Collins to test whether the network model developed by Quillian could indeed predict human performance on a sentence verification task, that is, the speed to verify such sentences as 'A CANARY IS A BIRD'. Remarkably, the Collins and Quillian (1969) study provided evidence that appeared to be highly supportive of the hierarchically organized network structure that Quillian independently developed in artificial intelligence. Specifically, human performance was nicely predicted by how many 'isa' and 'property' pathways one needed to traverse to verify a sentence. The notion is that there was a spreading activation retrieval mechanism that spread across links within the network, and the more links traversed the slower the retrieval time. So, the original evidence appeared to support the counterintuitive prediction that subjects indeed needed to go through the 'CANARY IS A BIRD' link and then the 'BIRD IS AN ANIMAL' link to verify that 'CANARIES BREATHE', because this is where BREATHES is located in the network.

The power of network theory to economically represent the relations among a large amount of information and the confirmation of the counterintuitive predictions via the sentence verification studies by Collins and Quillian (1969) clearly encouraged researchers to investigate the potential of these networks. However, it soon became clear that the initial hierarchically arranged network structure had some limitations. For example, the model encountered some difficulties handling the systematic differences in false reaction times, that is, the finding that correct 'false' responses to 'BUTTERFLIES ARE BIRDS' are slower than responses to 'SPIDERS ARE BIRDS.' Importantly, there was also clear evidence of typicality effects within categories. Specifically, categories have graded structure, that is, some examples of BIRD, such as ROBINS, appear to be better examples than other BIRDS, such as OSTRICHES.

There were numerous attempts to preserve the basic network structure of Collins and Quillian (1969), and indeed, some general models of cognitive performance still include aspects of such network structure. Collins and Loftus (1975) took a major step forward when they developed a network that was not forced into a hierarchical framework. This is displayed in **Figure 2**. As shown, these networks are basically unstructured, with pathways between concepts that are related and the strength of the relationship being reflected by the length of the pathways. Collins and Loftus further proposed that the links between nodes could be dependent on semantic similarity (e.g., items from the same category, such as DOG and CAT, would be linked), or the links could emerge from lexical level factors, such as cooccurrence in the language. Thus, DOG and CAT would be linked because these two items often occur in similar contexts. Because the strength of spreading activation is a function of the distance the activation traversed, typicality effects can be nicely captured in this framework by the length of the pathways. Of course, one might be concerned that such networks are not sufficiently constrained by independent evidence (i.e., if one is slow the pathway must be long). Nevertheless, such networks have been implemented

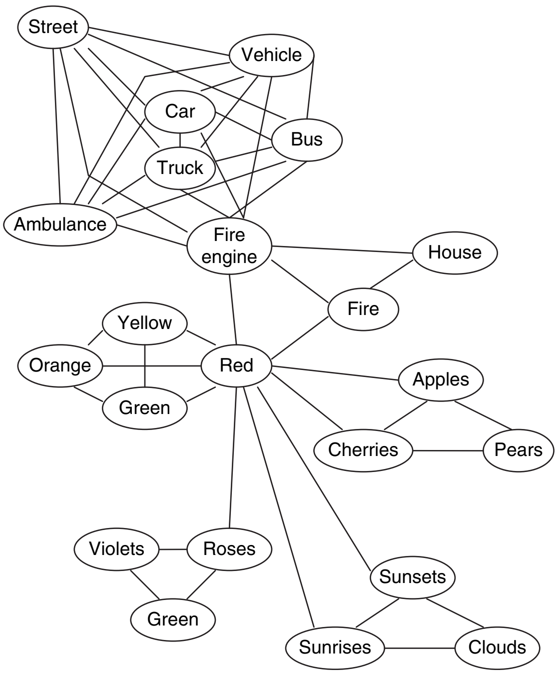

**Figure 2** Semantic network. From Collins AM and Loftus EF (1975) A spreading-activation theory of semantic processing. *Psychol. Rev.* 82: 407–428.

to capture knowledge representation in both semantic and episodic domains (see Anderson, 2000).

More recently, there has been a resurgent interest in a type of network theory. Interestingly, these developments are again driven from fields outside of psychology such as physics (see Albert and Barabasi, 2002) and biology (Jeong et al., 2000). This approach is very principled in nature in that it uses large existing databases to establish the connections across nodes within a network and then uses graph analytic approaches to provide quantitative estimates that capture the nature of the networks. In this light, researchers are not arbitrarily constructing the networks but are allowing the known relations among items within the network to specify the structure of the network. This approach has been used to quantify such diverse networks as the power grid of the Western United States and the neural network of the worm, *C. elegans* (Watts and Strogatz, 1998). Once one has the network established for a given domain (i.e., providing connections between nodes), one can then quantify various characteristics of the network, such as the number of nodes, the number of pathways, the average number of pathways from a node, and the average distance between two nodes. Moreover, there are more sophisticated measures available such as the clustering coefficient, which reflects the probability that two neighbors of a randomly selected node will be neighbors of each other. In this sense, these parameters quantify the characteristics of the targeted network. For example, when looking at such parameters, Watts and Strogatz (1998) found that naturally occurring networks have a substantially higher clustering coefficient and relatively short average distances between nodes compared with randomly generated networks that have the same number of nodes and average connectivity between nodes. This general characteristic of networks is called 'small world' structure. These high clustering coefficients may reflect 'hubs' of connectivity and allow one to access vast amounts of information by retrieving information along the hubs. In popular parlance, such hubs may allow one to capture the six degrees of separation between any two individuals that Milgram (1967) proposed and that has been popularized by the game "six degrees of separation with Kevin Bacon".

What do worms, power grids, and parlor games have to do with semantic memory? Steyvers and Tenenbaum (2005) used three large databases reflecting the meaning of words to construct networks of semantic memory. These included free-association norms (Nelson et al., 1998), WordNet (Miller, 1990), and Roget's Thesaurus (1911). For example, if subjects are likely to produce a word in response to another word in the Nelson et al. free-association norms, then a connection between the two nodes was established in the network. Interestingly, Steyvers and Tenenbaum found that these semantic networks exhibited the same small world structure as other naturally occurring networks; specifically, high-clustering coefficients and a relatively small average path distance between two nodes. As shown in **Figure 3**, if one moves along the hub of highly interconnected nodes, an enormous amount of information becomes readily available via traversing a small number of links.

Of course, it is not a coincidence that naturally occurring networks have small world structure. The seductive conclusion here is that knowledge representation has some systematic similarities across domains. Indeed, Steyvers and Tenenbaum (2005) and others have suggested that such structure reflects central principles in development and representation of knowledge. Specifically, Steyvers and Tenenbaum argue that as the network grows, new nodes are predisposed to attach to existing nodes in a probabilistic manner. It is indeed quite rare that a new meaning of a word is acquired without it being some variation of a preexisting meaning (see Carey, 1978). Hence, across time, nodes that are added to the network will be preferentially attached to existing nodes. This will give rise to a high degree of local clustering, which is a signature of small world network structure. We return to the issue of how concepts develop in a later section.

It is noteworthy that Steyvers and Tenenbaum (2005) have also provided empirical support from their network analyses. For example, they have found that word frequency, or the degree to which a word is encountered in language, and age of acquisition, defined as the average age at which a child learns a given word, effects in naming and lexical decision performance naturally fall from this perspective. Naming and lexical decision are two of the most commonly used word recognition tasks used in research investigating the nature and structure of semantic memory. In naming (or speeded pronunciation), a participant is asked to read a presented stimulus aloud as quickly as possible, whereas in lexical decision, he or she is asked to indicate whether a letter string is a real word or a pseudoword (i.e., a string of letters that does not correspond to the spelling of a real word). In both tasks, the primary dependent measure is response latency. The general assumption is that the speed required to access the pronunciation of a word or to recognize a string of letters reflects processes involved in accessing stored

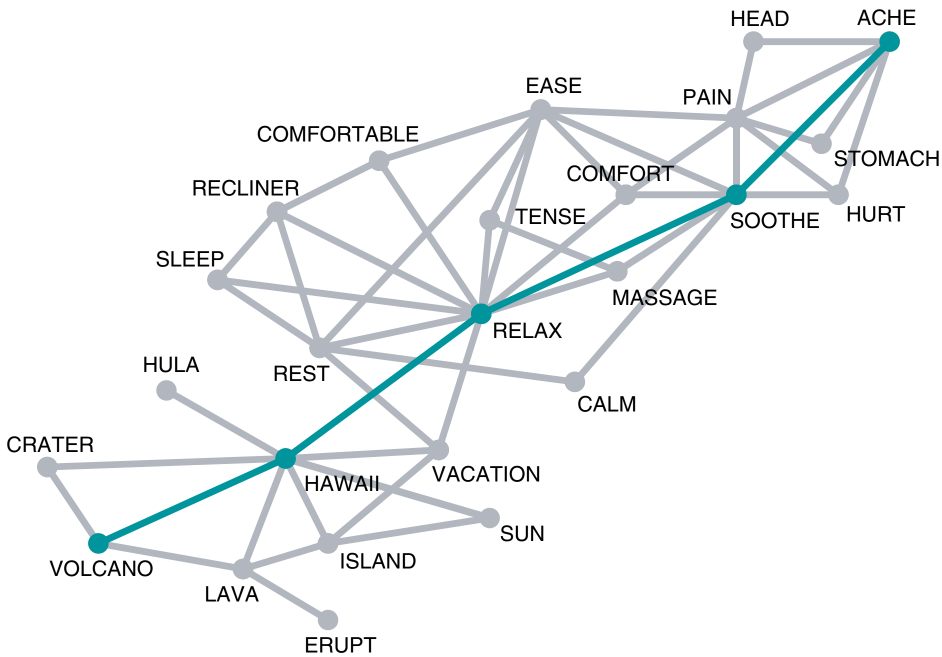

**Figure 3** Segment of small world semantic network. Courtesy of Marc Steyvers.

knowledge about that word. Interestingly, Steyvers and Tenenbaum found a reliable negative correlation between number of connections to a node (semantic centrality) in these networks and response latency, precisely as one might predict, after correlated variables such as word frequency and age of acquisition have been partialed out (also see Balota et al., 2004). Clearly, further work is needed to empirically confirm the utility of these descriptions of semantic structure and the mechanisms by which such networks develop over time. However, the recent graph analytic procedures have taken a significant step toward capturing semantic memory within an empirically verified network.

## 2.28.3 Feature Analytic Approaches

An alternative to concepts being embedded within a rich network structure is an approach wherein meaning is represented as a set of primitive features that are used in various combinations to represent different concepts. Of course, this issue (distributed representation of knowledge, by way of features, vs. a localist representation, via a node to concept relationship) is central to attempts to represent and quantify learning and memory in general. We now turn to a review of the feature-based approaches in semantic memory.

The original Collins and Quillian (1969) research generated a great deal of attention, and soon researchers realized that categories reflected more graded structures than was originally assumed. Specifically, some members of categories are good members (ROBIN for BIRD), whereas other members appear to be relatively poor members (VULTURE for BIRD) but are still definitely members of the category (see Battig and Montague, 1969; Rosch, 1973). In addition, there was a clear influence of goodness of an exemplar on response latencies in the sentence verification task described above. Specifically, good exemplars were faster to verify than poor exemplars, referred to as the typicality effect. The Collins and Quillian hierarchical network model did not have any obvious way of accommodating such degrees of category membership.

Smith et al. (1974) took a quite different approach to accommodate the results from the sentence verification task. They rejected the strong assumptions of network theory and proposed a model that emphasized the notion of critical semantic features in representing the meaning of a word. So, for example, the word BIRD might be represented as animal, two legged, has wings, sings, is small, flies, and so on. There is no hierarchical organization within this model, but concepts reflect lists of critical features. They also distinguished between two classes of features, defining features and characteristic features. Defining features are the necessary features that an exemplar must have to be a member of a category. So, for example, all birds must eat, move, lay eggs, and so forth. On the other hand, characteristic features are features that most, but not all, exemplars have, such as small, flies, sings.

The second important aspect of the Smith et al. (1974) perspective is the emphasis on the decision processes engaged in the classic sentence verification task (see Atkinson and Juola, 1974; Balota and Chumbley, 1984, for similar decision models applied to short-term memory search and lexical decision, respectively). In verifying a sentence such as 'A ROBIN IS A BIRD,' subjects first access all (both defining and characteristic) features associated with ROBIN and all features associated with BIRD. If there is a high degree of overlap in the features, that is, above some criterion, the subject can make a fast 'yes' response. This would be the case in 'A ROBIN IS A BIRD,' since both defining and characteristic features provide a high degree of overlap. On the other hand, some exemplars of a given category may overlap less in characteristic features such as in 'AN OSTRICH IS A BIRD'. Although ostriches are clearly birds, they are not small and do not fly, which are characteristic features of birds. Hence, in such cases, the subject needs to engage in an additional analytic checking process in which only the defining features are compared. This additional check process takes time and so slows response latencies. Hence, the model can naturally capture the typicality effects mentioned above, that is, robins are better exemplars of birds than ostriches, because robins can be verified based on global overlap in features, whereas ostriches must engage the second, more analytic comparison of only the defining features, thereby slowing response latency.

In addition to accounting for typicality effects, the feature analytic model also captured interesting differences in latencies to respond 'no' in the sentence verification task. Specifically, subjects are relatively fast to reject 'A CARP IS A BIRD' compared with 'A BUTTERFLY IS A BIRD.' Carps do not have many overlapping features with birds, and so the subject can quickly reject this item, that is, there is virtually no overlap in features. However, both butterflies and birds typically have wings, are small, and fly. Hence, the subject must engage the additional check of the defining features for 'BUTTERFLY IS A BIRD,' which ultimately leads to slower response latencies, compared with the sentence 'A CARP IS A BIRD.'

Although there were clear successes of the Smith et al. (1974) feature analytic approach, there were also some problems. For example, the model was criticized for the strong distinction between characteristic and defining features. In fact, McCloskey and Glucksberg (1979) provided a single process random walk model that accommodated many of the same results of the original Smith et al. model without postulating a distinction between characteristic and defining features. According to the random walk framework, individuals sample information across time that supports either a yes or no decision. If the features from the subject and predicate match, then movement toward the yes criterion takes place; if the features do not match, then movement toward the no criterion takes place. This model simply assumed that the likelihood of sampling matching feature information for the subject and predicate is greater for typical members than nontypical members, and therefore the response criterion is reached more quickly for typical than nontypical members, thus producing the influence on response latencies. The distinction between single- and dual-process models is a central issue that pervades much of cognitive science.

A second concern about the Smith et al. (1974) model is that they did not directly measure features but, rather, inferred overlap in features based on multidimensional scaling techniques, in which an independent group of subjects simply rated the similarity of words used in the sentence verification experiment. In this way, one could look at the similarity of the words along an N-dimensional space. Interestingly, Osgood et al. (1957) used a similar procedure to tackle the meaning of words in their classic work on the semantic differential. Osgood et al. found that when subjects rated the similarity across words, and these similarity ratings were submitted to multidimensional scaling procedures, there were three major factors that emerged: Evaluative (good–bad), potency (strong–weak), and activity (active–passive). Although clearly this work is provocative, such similarity ratings do not provide a direct measure of the features available for a concept. So, if there are indeed primitive features, it seems necessary to attempt to more directly quantify these features.

McRae and colleagues have been recently attempting to provide such constraints on feature analytic models (McRae et al., 1997; Cree et al., 1999; Cree and McRae, 2003; McRae, 2004; McRae et al., 2005). The goal here is to develop a feature-based computational model implemented in an attractor network capable of capturing the statistical regularities present in semantic domains. The general notion underlying attractor network models is that knowledge is distributed across units (which might be thought of as features) and that the network settles into a steady pattern of activity that reflects the representation of a concept. The conceptual representations that form the basis of semantic knowledge in the model are derived from feature norming data. To collect norms, groups of participants are asked to list features for a number of concepts (e.g., for DOG, participants might list BARKS, FURRY, CHASES CATS, etc.). McRae and colleagues propose that when participants are asked to list features of various basic-level category exemplars (e.g., DOG and APPLE are basic-level concepts from the superordinate category of MAMMALS and FRUIT, respectively), the resulting lists of features reflect the explicit knowledge people have of these concepts. Importantly, McRae does not claim that the nature of the representation consists of a feature list; rather, he argues, the features are derived from repeated multisensory interactions with exemplars of the concept, and in a feature listing task, subjects temporarily create an abstraction for the purpose of listing features that can be verbally described. Currently, feature norming data are available for 541 concrete objects, representing a wide variety of basic-level concepts. Importantly, the model can account for many empirical observations in semantic tasks, as discussed below.

The major assumption implemented by McRae and colleagues' model is that semantic knowledge, as represented by feature lists, involves the statistical averaging of feature correlations among members of similar categories. Features are correlated if they co-occur in basic-level concepts. For example, HAS FUR is highly correlated with HAS FOUR LEGS, as these two features cooccur in numerous exemplars of the mammal category. However, HAS FUR and HAS WINGS have a low (almost nonexistent) correlation, as these two features do not co-occur frequently. The argument is that individuals are highly sensitive to the regularity of the correlations, which are tapped by semantic tasks. As demonstrated by McRae et al. (1999), the strength of the feature correlations predicted feature verification latencies in both human subjects and model simulations, with stronger correlations yielding faster response latencies than weaker correlations when the concept name was presented before the feature name (e.g., DOG-FUR). In addition, the correlation strength interacted with stimulus onset asynchrony (the time between the onset of the concept name and the onset of the feature name, SOA). Specifically, the effect of feature correlations was larger at shorter SOAs, with only high correlations predicting response latencies. However, at longer SOAs, even weakly correlated features influenced response times, indicating that, as more time was allowed for the effects of correlated features to emerge, even the more weakly correlated feature-concept pairs benefited from the shared representation. In another series of studies, McRae et al. (1997) reported that the strength of feature correlations predicted priming for exemplars from the living things domain but not for exemplars from nonliving things domains, for which priming was instead predicted by individual features. This finding is consistent with evidence that, compared to living things, nonliving things tend to have a lower degree of correlated features (also see section 2.28.8.1).

Several interesting extensions of McRae and colleagues' work on the role of features in organizing semantic knowledge have been recently reported. Pexman et al. (2002) examined the role of the number of features associated with a concept and found that items with more features were responded to faster in both naming and lexical decision tasks after a number of other variables known to influence visual word recognition latencies had been factored out. Pexman et al. (2003) reported similar results in a semantic categorization task and in a reading task. These findings were interpreted as supporting the distributed nature of semantic representations in which features are assumed to reflect access to conceptual knowledge, and this information quickly comes on line in isolated word recognition tasks.

In a related vein, there is recent evidence from the categorization literature that categories with richer dimensionalities (i.e., more features and more correlations among features) are easier to learn than categories with fewer dimensions (Hoffman and Murphy, 2006). Thus, rather than resulting in combinatorial explosions that make learning impossible, rich categories with many features lend themselves well to learning – a finding that is nicely mirrored in how people, even very young children, quickly and reliably learn to recognize and classify objects in the world. Indeed, it seems that learning to categorize complex objects, which might be quite similar in terms of features, is something most individuals can do reliably and easily. One concern that arises when one examines the richness of the stimuli in the environment, is the potentially infinite number of features that are available to identify a given concept. In fact, critics of feature-based models have argued that the number of possible feature combinations would result in combinatorial explosion, as knowing even a few features of a category could easily result in an enormous number of ways in which the features could be correlated and integrated (see Murphy, 2002, for a discussion). However, as McRae (2004) notes, two points are relevant in addressing this issue. The first is that the feature correlations tend to influence performance largely in implicit tasks – thus reducing the necessity of explaining how an individual can explicitly use the vast amount of information available. The second point is that the feature vectors that underlie semantic representations are generally sparse. In other words, the absence of a specific feature is uninformative, so, for example, knowing that a dog does not have feathers is relatively uninformative. Thus, although feature-based models might not fully capture the richness of the knowledge that individuals have about concepts, they have been useful in advancing research in the field of semantics.

## 2.28.4 Concept Learning and Categorization

Since semantic memory deals with the nature of representation of meaning, and categories are central to meaning, it is important to at least touch on the area of categorization and how concepts develop. In their classic book, Bruner et al. (1956) emphasized the importance of categorization in organizing what appears to be a limitless database that drives complex human learning and thought. Categorization has been viewed as a fundamental aspect of learning and indeed has been observed early in childhood (Gelman and Markman, 1986) and in other species such as pigeons (Herrnstein et al., 1976). Ross (*See* Chapter 2.29) provides a much more focused discussion of this topic.

One intriguing question that arises when one considers the content of semantic memory concerns the grain size and structure of the representations. In other words, is there a level at which objects in the real world are more or less easy to learn and categorize? One possibility is that the world is initially perceived as a continuum in which there are not separate 'things.' Through repeated interactions with verbal labels or other forms of learning, an individual learns how to discriminate separate objects (e.g., Leach, 1964). This approach places the burden on an extensive and demanding learning process. An alternative approach is that the human cognitive system is ideally suited to detect and recognize objects at a specific grain or level. The assumption that the system is biased toward recognizing specific patterns implies that the process of learning the appropriate verbal labels that refer to specific items in the environment is significantly easier. This problem – how very young children learn that when their mother points to a dog and says 'dog' the referent of the phonological pattern in question refers to an entire object, and not to furry things, things of a certain color, or loosely attached dog parts – has been extensively discussed by Quine (1960).

In an elegant series of experiments, Rosch and colleagues (e.g., Rosch et al., 1976) provided empirical evidence that there is indeed a specific level at which categories of objects are represented that contains the most useful amount of information. For example, identifying a given object as a DOG implies that one recognizes that the specific exemplar is a dog, although it may differ from other dogs one has encountered. Simply knowing something is a dog allows one to draw upon a pool of stored knowledge and experiences to infer appropriate behaviors and interactions with the categorized object. However, knowing the object is an animal is not as informative, given the wide variability among animals. For example, interactions with an elephant are likely to be quite different from those one might have with a spider. Conversely, classifying the exemplar as a Collie or as a German Shepherd does not add a significant amount of inferential power for most purposes.

Rosch et al. (1976) argued that at the basic level, categories are highly informative and can be reliably and easily discriminated from other categories. Exemplars of basic-level categories (e.g., DOGS, BIRDS, CARS, etc.) have many attributes in common, tend to be similar in shape and in how one interacts with them, and allow easy extraction of a prototype or summary representation. The prototype can be accessed and serves as a benchmark against which novel exemplars can be compared: Those that are highly similar to the prototype will be quickly and easily classified as members of the category. Exemplars that differ from the prototype will be recognized as less typical members of a category (e.g., penguins are quite different from many other birds). Hence, typicality effects fall quite nicely from this perspective.

Historically, there has again been some tension between abstract prototype representation and more feature-based approaches. Consider the classic work by Posner and Keele (1968). Although cautious in their interpretation, these researchers reported evidence suggesting that prototypes (in this case a central tendency of dot patterns) were naturally abstracted from stored distortions of that prototype, even though the prototype was never presented for study. They also found that variability across a sufficient number of distortions was critical for abstracting the prototype. These results would appear to support the notion that there is a natural tendency to abstract some representation that is a central tendency of exemplars that share some common elements. So, 'dogness' may be abstracted from the examples of dogs that one encounters. This could suggest that there is indeed a unified representation for dogness.

An alternative approach is that there is nothing unique about these central tendencies but, rather, such representations reflect the similarity of the episodically stored representations in memory. This is a particularly important observation because it suggests that there is a blending of different types of memories, that is, categorical information is simply decontextualized episodic memories. Consider, for example, the classic MINERVA model developed by Hintzman (1986, 1988). In this computational model, each episodic experience lays down a unique trace in memory, which is reflected by a vector of theoretical features. There is no special status of category representations or hierarchical structure. Rather, categorization occurs during retrieval when a probe (the test item) is presented to the system, and the feature vector in the probe stimulus is correlated with all the episodically stored traces. The familiarity of a test probe is a reflection of the strength of the correlations among elements in memory. Because the schema overlaps more with multiple stored representations, that is, it is the central tendency, it will produce a relatively high familiarity signal or strength in a cued recall situation. The importance of the Hintzman approach is that there is no need to directly store central tendencies, as they naturally arise out of the correlation among similar stored traces in the feature vectors. Moreover, as Hintzman argues, there is no need to propose a qualitative distinction between episodic and semantic memories, because both rely on the same memory system, that is, a vast storehouse of individual feature-based episodic traces.

The notion that categories are a reflection of similarity structure across memory traces and can be generated during retrieval clearly has some appeal. Indeed, Barsalou (1985) demonstrated the importance of ad hoc categories that seem to be easily generated from traces that do not inherently have natural category structure; for example, what do photographs, money, children, and pets have in common? On the surface, these items do not appear to be similar – they do not belong to the same taxonomic category, nor do they share many features. However, when given the category label "things to take out of the house in the case of a fire," these items seem to fit quite naturally together because our knowledge base can be easily searched for items that are in the house and are important to us. As Medin (1989) has argued, similarity depends on the theoretical frame that a participant uses to guide a search of memory structures. There appears to be an unlimited number of ways in which similarity can be defined, and hence similarity discovered. For example, lichen and squirrels are similar if one is interested in specifying things in a forest. This brings us to the remarkable context dependency of meaning, and the possibility that meaning is not defined by the stimulus *per se* but is a larger unit involving both the stimulus and the surrounding context. The word DOG in the context of thinking about house pets compared with the word DOG in the context of guard dogs or drug-sniffing dogs probably access quite different interpretations, one in which the focus is on companionship, furriness, and wagging tails, the other in which the more threatening aspects of dogness, such as sharp teeth, are accessed. One might argue that the context activates the relevant set of features, but even this is difficult until one has sufficient constraint on what those features actually are.

## 2.28.5 Grounding Semantics

In part because of the difficulties in defining the critical features used to represent meaning and potential problems with the tractability of prototypes of meaning, several researchers attempted to take novel approaches to the nature of the representations. There are two general approaches that we review in this section. First, because of the increase in computational power, there has been an increased reliance on analyses of large-scale databases to extract similarities across the contexts of words used in various situations. This perspective has some similarity to the exemplar-based approach proposed by Hintzman (1986, 1988) and others described earlier. In this sense, meaning is grounded in the context in which words and objects appear. The second approach is to consider the perceptual motor constraints afforded by humans to help ground semantics, that is, the embodied cognition approach. We review each of these in turn.

### 2.28.5.1 Grounding Semantics in Analyses of Large-Scale Databases

This approach attempts to directly tackle the poverty of the stimulus problem when considering the knowledge that humans have acquired. Indeed, since the days of Plato, philosophers (and more recently psychologists and linguists) have attempted to resolve the paradox of how humans can acquire so much information based on so little input. Specifically, how is it that children learn so much about the referents of words, when to use them, what their syntactic class is, what the relations among referents are, and so on, without explicit instruction? Some have argued (e.g., Pinker, 1994) that the poverty of the stimulus is indeed the reason one needs to build in genetically predisposed language acquisition devices. However, recent approaches to this issue (e.g., Latent Semantic Analysis, or LSA, Landauer and Dumais, 1997; Hyperspace Analogue to Language, or HAL, Burgess and Lund, 1997) have suggested that the stimulus input is not so impoverished as originally assumed. One simply needs more powerful statistical tools to uncover the underlying meaning and the appropriate database.

In an attempt to better understand how rich the stimulus is when embedded in context, Landauer and Dumais (1997) analyzed large corpora of text that included over 4.6 million words taken from an English encyclopedia, a work intended for young students. This encyclopedia included about 30 000 paragraphs reflecting distinct topics. From this, the authors constructed a data matrix that basically included the 60 000 words across the 30 000 paragraphs. Each cell within the matrix reflected the frequency that a given word appeared in a given paragraph. The data matrix was then submitted to a singular value decomposition, which has strong similarities to factor analysis to reduce the data matrix to a limited set of dimensions. Essentially, singular value decomposition extracts a parsimonious representation of the intercorrelations of variables, but, unlike factor analysis, it can be used with matrices of arbitrary shape in which rows and columns represent the words and the contexts in which the words appear. In this case, the authors reduced the matrix to 300 dimensions. These dimensions reflect the intercorrelations that arise across the words from the different texts. So, in some sense the 300 dimensions of a given word will provide information about the similarity to all other words along these 300 dimensions, that is, the degree to which words co-occur in different contexts. The exciting aspect from this data reduction technique is that by using similarity estimates, the model actually performs quite well in capturing the performance of children acquiring language and adults' performance on tests based on introductory textbooks. In this way, the meaning of a word is being captured by all the past experiences with the word, the contexts with which that word (neighbors) occurs, the contexts that the neighbors occur in, and so on.

The remarkable success of LSA, and other similar approaches such as HAL (Burgess and Lund, 1997), provides a possible answer to the poverty of the stimulus problem, that is, when considering the context, the stimulus is indeed very rich. In the past, we simply have not been able to analyze it appropriately. Moreover, the model nicely captures the apparent contextual specificity of meaning in that meaning is defined by all the contexts that words have appeared in and hence will also be constantly changing ever so slightly across subsequent encounters. Finally, the model is indeed quite important because it does not rely on a strong distinction between semantic and episodic memory since it simply reflects past accumulated exposure to language. In this sense, it has some similarity to the Hintzman (1986) model described above.

### 2.28.5.2 Grounding Semantics in Perceptual Motor Systems

An alternative approach that has been receiving considerable recent attention is that meaning can be grounded in perceptual-motor systems (e.g., Barsalou, 1999). Briefly, this perspective is part of the embodied cognition approach that posits that the cognitive system of any organism is constrained by the body in which it is embedded (Wilson, 2002). Thus, cognition (in this case meaning) is not viewed as being separable from perceptual, motor, and proprioceptive systems; rather, it is through the interactions of these systems with the environment that cognition emerges. Furthermore, the type of representations that an organism will develop depends on the structure of the organism itself and how it exists in the world. This approach has its roots in Gibson's (1979) ecological psychology, as it is assumed that structures in the environment afford different interactions to different organisms. It is through repeated interactions with the world that concepts and knowledge emerge. Importantly, the very nature of this knowledge retains its connections to the manner in which it was acquired: Rather than assuming that semantic memory consists of amodal, abstract representations, proponents of embodied approaches argue that representations are grounded in the same systems that permitted their acquisition in the first place (Barsalou et al., 2003).

According to the modality-specific approaches to knowledge, a given concept is stored in adjacent memory systems rather than being abstracted. For example, in Barsolou's (1999) account, knowledge is stored in perceptual symbol systems that emerge through repeated experience interacting with an object or an event. Briefly, Barsalou assumed that when a percept is encountered, selective attention focuses on context-relevant aspects of the percept and allows modal representations to be stored in memory. Repeated interactions with similar events or members of the same category result in the formation of a complex, multimodal representation, and a simulator emerges from these common representations. Simulators are the basic unit of the conceptual system and consist of a frame (which is somewhat similar to a schema), the purpose of which is to integrate the perceptual representations. Simulators provide continuity in the system. Importantly, the representations that are stored include not only modal, perceptual information (e.g., sounds, images, physical characteristics) but also emotional responses, introspective states, and proprioceptive information. Retrieving an exemplar or remembering an event is accomplished by engaging in top-down processing and activating the targeted simulator. Importantly, a given simulator can yield multiple simulations, depending on the organism's goal, the context, and the relevant task demands. For example, different simulations for DOG are possible, such that a different pattern of activity will occur if the warm and furry aspect of dog is relevant or whether the aspect of being a guard or police dog is relevant. Of course, this nicely captures the context sensitivity of meaning. Barsalou (1999) argues that perceptual symbol systems are as powerful and flexible as amodal models, as they are able to implement a complete conceptual system (see also Glenberg and Robertson, 2000).

Evidence in support of modal approaches to semantics can be found in both behavioral and cognitive neuroscience studies. We briefly review some of this evidence here, although a full review of the neuroscience literature is beyond the scope of this chapter (*See* Chapter 3.07 for further discussion of this area). For example, there is evidence from lesion studies that damage to the pathways supporting a specific modality results in impaired performance in categorization and conceptual tasks that rely on that same modality. Specifically, damage to visual pathways generally results in greater impairment in the domain of living things, which tend to rely heavily on visual processes for recognition. Conversely, damage to motor pathways tends to impair knowledge of artifacts and tools, as the primary mode of interaction with these items is through manipulation (see Martin, 2005). Consistent with the lesion data, neuroimaging studies indicate that different regions of the cortex become active when people process different categories. Regions adjacent to primary visual areas become active when categories such as animals are processed (even if the presentation of the stimulus itself is not in the visual modality), whereas regions close to motor areas become active when categories such as tools are processed. These findings have been interpreted as consistent with the hypothesis that people run perceptual-motor simulations when processing conceptual information (Barsalou, 2003).

Pecher et al. (2003) reported evidence from a property verification task indicating that participants were faster in verifying properties in a given modality (e.g., BLENDER-loud) after verifying a different property for a different concept in the same modality (e.g., LEAVES-rustling) than when a modality switch was required (e.g., CRANBERRIES-tart). Pecher et al. argued that the switch cost observed was consistent with the hypothesis that participants ran perceptual simulations to verify the properties (in this case sounds) rather than accessing an amodal semantic system. In a subsequent study, Pecher et al. (2004) observed that when the same concept in a property verification task was paired with two properties from different modalities, errors and latencies increased when verifying the second property. Pecher et al. interpreted this finding as indicating that recent experiences with a concept influence the simulation of the concept. Importantly, researchers have argued that such results are not simply a result of associative strength (i.e., priming) nor of participants engaging in intentional imagery instructions (Barsalou, 2003; Solomon and Barsalou, 2004).

Although the results summarized above are compelling and are supportive of the hypothesis that sensory-motor simulations underlie many semantic tasks, the majority of these studies have examined tasks such as property verification and property generation. The question thus arises of whether the results are somehow an artifact of the task demands, and specifically whether these results reflect the structure of the semantic memory system or whether subjects are explicitly retrieving information as they notice the relations embedded within the experimental context. Glenberg and Kaschak (2002) extended the evidence for embodiment effects to a novel series of tasks that do not appear as susceptible to task demand effects. In these experiments, participants read a brief sentence and judged whether the sentence made sense or not. The critical sentences contained statements that implied motion either toward the participant (e.g., "Nancy gave you the book") or away from the participant (e.g., "You gave the book to Nancy"). Participants responded by moving their hand toward themselves or away from themselves. Glenberg and Kaschak found what they called the action-sentence compatibility effect: When the required response was consistent with the movement implied in the sentence, participants were faster than when the implied motion and the actual physical response were inconsistent. These data appear most consistent with the view that when processing language, people relate the meaning of the linguistic stimulus to action patterns.

## 2.28.6 Measuring Semantic Representations and Processes: Insights from Semantic Priming Studies

As described above, there have been many empirical tools that have been used to provide insights into the nature of semantic memory. For example, as noted earlier, some of the early work by Osgood et al. (1957) attempted to provide leverage on fundamental aspects of meaning via untimed ratings of large sets of words and multidimensional scaling techniques. With the advent of interest in response latencies, researchers turned to sentence verification tasks that dominated much of the early work in the 1970s and 1980s. Although this work has clearly been influential, the explicit demands of such tasks (e.g., explicitly asking subjects to verify the meaningfulness of subject-predicate relations) led some researchers in search of alternative ways to measure both structure and retrieval processes from semantic memory. There was accumulating interest in automatic processes (LaBerge and Samuels, 1974; Posner and Snyder, 1975) that presumably captured the modular architecture of the human processing system (Fodor, 1983), and there was an emphasis on indirect measures of structure and process. Hence, researchers turned to semantic priming paradigms.

Meyer and Schvaneveldt (1971) are typically regarded as reporting the first semantic priming study. In this study, subjects were asked to make lexical decisions (word-nonword decisions) to pairs of stimuli. The subjects' task was to respond yes only if both strings were words. The interesting finding here was that subjects were faster to respond yes when the words were semantically related (DOCTOR NURSE), compared with when they were unrelated (BREAD NURSE). This pattern was quite intriguing because subjects did not need to access the semantic relation between the two words to make the word/nonword decisions. Hence, this may reflect a relatively pure measure of the underlying structure and retrieval processes, uncontaminated by explicit task demands. Moreover, the development of this paradigm was quite important because researchers thought it may tap the spreading activation processes that was so central to theoretical developments at the time.

The research on semantic priming took a significant leap forward with the dissertation work of Neely (1977), who used a framework developed by Posner and Snyder (1975) to decouple the attentional strategic use of the prime-target relations from a more automatic component. In this study, subjects only made lexical decisions to the target, and subjects were given explicit instructions of how to use the prime information. For example, in one condition, subjects were told that when they received the prime BODY, they should think of building parts (Shift condition), whereas in a different condition, subjects were told that when they received the category prime BIRD, they should think of birds (Nonshift condition). Neely varied the time available to process the prime before the target was presented by using SOAs ranging from 250 to 2000 ms. The important finding here is that the instructions of what to expect had no influence on the priming effects at the short SOA (i.e., priming occurred if the prime and target had a semantic relationship, independent of expectancies), but they did have a large effect at the long SOA, when subjects had time to engage an attentional mechanism (i.e., the priming effects were totally dependent on what subjects were told to expect, independent of the preexisting relationship). Hence, Neely argued that the short SOA data reflected pure automatic measures of the semantic structure and retrieval processes and could be used as a paradigm to exploit the nature of such semantic representations.

A full review of the rich semantic priming literature is clearly beyond the scope of the present chapter (see Neely, 1991; Lucas, 2000; Hutchison, 2003, for excellent discussions of the methodological and theoretical frameworks). However, it is useful to highlight a few issues that have been particularly relevant to the current discussion. First, there is some controversy regarding the types of prime-target relations that produce priming effects. For example, returning to the initial observation by Meyer and Schvaneveldt (1971), one might ask if DOCTOR and NURSE are related because they share some primitive semantic features or are simply related because they are likely to co-occur in the same contexts in the language. Of course, this distinction reflects back on core assumptions regarding the nature of semantic information, since models like LSA might capture priming between DOCTOR and NURSE, simply because the two words are likely to cooccur in common contexts. Researchers have attempted to address this by selecting items that vary on only one dimension (see, e.g., Fischler, 1977; Lupker, 1984; Thompson-Schill et al., 1998). Here, semantics is most typically defined by category membership (e.g., DOG and CAT are both semantically related and associatively related, whereas MOUSE and CHEESE are only associatively related). Hines et al. (1986), De Mornay Davies (1998), and Thompson-Schill et al. (1998) have all argued that priming is caused by semantic feature overlap because of results indicating priming only for words that shared semantic overlap versus those did not, when associative strength was controlled. However, Hutchison (2003) has recently argued that the studies that have provided evidence for pure semantic effects (i.e., while equating for associative strength), actually have not adequately controlled for associative strength based on the Nelson et al. (1998) free-association norms. Clearly, equating items on one dimension (associative strength or semantic overlap) while manipulating the other dimension is more difficult than initially assumed. In this light, it is interesting to note that two recent review papers have come to different conclusions regarding the role of semantics in semantic priming based on such item selection studies. Lucas (2000) argued that there was clear evidence of pure semantic effects, as opposed to associative effects, whereas Hutchison (2003) was relatively more skeptical about the conclusions from the available literature.

Balota and Paul (1996) took a different approach to the meaning versus associative influence in priming via a study of multiple primes, instantiating the conditions displayed in **Table 1**. As one can see, the primes were either both related, first related, second related, or both unrelated to the targets, and the targets could either be homographic words with distinct meanings (e.g., ORGAN) or a nonhomographic words (e.g., STRIPES). As one can see, the primes were related to the targets at both the semantic and associative level for the nonhomographs (e.g., LION and STRIPES are both related to TIGER at the associative and semantic level), but for the homographs the primes were related to the targets at only the associative level (e.g., PIANO and KIDNEY are only related to ORGAN at the associative level, since KIDNEY and PIANO are different meanings of ORGAN). Thus, one could compare priming effects in conditions in which primes converged on the same meaning of the target (nonhomographs) and priming effects where the primes diverged on different

**Table 1** Prime-target conditions from the Balota and Paul (1996) multiprime study

| *Nonhomographs* | | | |
|---|---|---|---|
| *Condition* | *Prime 1* | *Prime 2* | *Target* |
| Related–related | LION | TIGER | STRIPES |
| Unrelated–related | FUEL | TIGER | STRIPES |
| Related–unrelated | LION | SHUTTER | STRIPES |
| Unrelated–unrelated | FUEL | SHUTTER | STRIPES |
| *Homographs* | | | |
| *Condition* | *Prime 1* | *Prime 2* | *Target* |
| Related–related | KIDNEY | PIANO | ORGAN |
| Unrelated–related | WAGON | PIANO | ORGAN |
| Related–unrelated | KIDNEY | SODA | ORGAN |
| Unrelated–unrelated | WAGON | SODA | ORGAN |

Balota DA and Paul ST (1996) Summation of activation: Evidence from multiple primes that converge and diverge within semantic memory. *J. Exp. Psychol. Learn. Mem. Cogn.* 22: 827–845.

meanings (homographs). The results from four experiments indicated that the primes produced clear additive effects, that is, priming effects from the single related prime conditions nicely summated to predict the priming effects from the double related prime conditions for both homographs and nonhomographs, suggesting that the effects were most likely a result of associative level information. Only when subjects directed attention to the meaning of the word, via speeded semantic decisions, was there any evidence of the predicted difference between the two conditions. Hence, these results seem to be supportive of the notion that standard semantic priming effects are likely to be the result of associative-level connections instead of meaning-based semantic information. Of course, the interesting theoretical question is how much of our semantic knowledge typically used is caused by overlap in the contexts in which items are stored as opposed to abstracted rich semantic representations.

Hutchison (2003) notes two further findings that would appear to be supportive of associative influences underlying semantic priming effects. First, one can find evidence of episodic priming in lexical decision and speeded word naming tasks. In these studies, subjects study unrelated words such as (CITY-GRASS) and are later presented prime-target pairs in a standard lexical decision study. The interesting finding here is that one can obtain priming effects in such studies, compared to an unrelated/unstudied pair of words (see McKoon and Ratcliff, 1979). Thus, the semantic priming effects obtained in word recognition tasks can also be produced via purely associative information that develops within a single study exposure. However, it should be noted here that there is some question regarding the locus of such priming effects and that one needs to be especially cautious in making inferences from the episodic priming paradigm and the role of task-specific strategic operations (see, e.g., Neely and Durgunoglu, 1985; Durgunoglu and Neely, 1987; Spieler and Balota, 1996; Pecher and Raajmakers, 1999; Faust et al., 2001).

The second pattern of results that Hutchison (2003) notes as being critical to the associative account of semantic priming effects is mediated priming. In these situations, the prime (LION) is related to the target (STRIPES) only through a nonpresented mediator (TIGER). So, the question is whether one can obtain priming from LION to STRIPES, even though these two words appear to be semantically unrelated. Although de Groot (1983) failed to obtain mediated priming effects in the lexical decision task, Balota and Lorch (1986) argued that this may have resulted from the task-specific characteristics of this task. Hence, Balota and Lorch used a speeded pronunciation task and found clear evidence of mediated priming. Evidence for mediated priming has also now been found in versions of the lexical decision task designed to minimize task-specific operations (e.g., McNamara and Altarriba, 1988; McKoon and Ratcliff, 1992; Sayette et al., 1996; Livesay and Burgess, 1998). Of course, it is unclear what semantic features overlap between LION and STRIPES, and so these results would appear to be more consistent with an associative network model, in which there is a relationship between LION and TIGER and between TIGER and STRIPES, along with a spreading activation retrieval mechanism (see McKoon and Ratcliff, 1992; Chwilla and Kolk, 2002, for alternative accounts of the retrieval mechanism).

In sum, although the semantic priming paradigm has been critical in measuring retrieval mechanisms from memory, the argument that these effects reflect amodal semantic representations that are distinct from associative information has some difficulty accommodating the results from multiprime studies, episodic priming studies, and mediated priming studies. As noted earlier, there are available models of semantic memory (e.g., Burgess and Lund, 1997, HAL; Landauer and Dumais, 1997, LSA) and categorization (e.g., Hintzman, 1996, MINERVA) that would strongly support the associative contributions to performance in such tasks and, indeed, question the strong distinction between semantic and episodic memory systems. Hence, this perspective predicts a strong interplay between the systems. We now turn to a brief discussion of the evidence that directly addresses such an interplay.

## 2.28.7 The Interplay Between Semantics and Episodic Memory

Memory researchers have long understood the influence of preexisting meaning on learning and memory performance (see Crowder, 1976, for a review). Indeed, in his original memory manifesto, Ebbinghaus (1885) was quite worried about this influence and so purposefully stripped away meaning from the to-be-learned materials by presenting meaningless trigrams (KOL) for acquisition. Of course, semantics has penetrated episodic memory research in measures of category clustering (see Bousfield, 1953; Cofer et al., 1966; Bruce and Fagan, 1970), retrieval-induced inhibition (see Anderson et al., 1994), and release from proactive interference (see Wickens, 1973), among many other paradigms. Indeed, the interplay between preexisting knowledge and recall performance was the centerpiece of the classic work by Bartlett (1932). Researchers realized that even consonant–vowel–consonant trigrams were not meaningless (see Hoffman et al., 1987). At this level, one might even question what it would mean to episodically store in memory totally meaningless information.

One place where researchers have attempted to look at the interplay between semantic and episodic structures is within the episodic priming paradigm described earlier. In these studies, participants receive pairs of unrelated words for study and then are later given prime-target pairs that have either been paired together or not during the earlier acquisition phase. For example, Neely and Durgunoglu (1985) investigated the influence of studying previous pairs of words and word–nonword combinations on both lexical decision performance and episodic recognition performance (also see Durgunoglu and Neely, 1987). Although there were clear differences between the tasks in the pattern of priming effects (suggesting dissociable effects across the two systems), there were also some intriguing similarities. For example, there was evidence of inhibition at a short prime-target SOA (150 ms) in both the episodic recognition task and the lexical decision task from semantically related primes that were in the initial studied list but were not paired with the target. It appeared as if this additional semantic association had to be suppressed in order for subjects to make both the episodic recognition decision and the lexical decision. The finding that this effect occurred at the short SOA also suggests that it may have been outside the attentional control of the participant.

The power of preexisting semantic representations on episodic tasks has recently taken a substantial leap forward with the publication of an important paper by Roediger and McDermott (1995), which revisited an earlier paper published by Deese (1959). This has now become know as the DRM (after Deese, Roediger, and McDermott) paradigm. The procedure typically used in such studies involves presenting a list of 10–15 words for study (REST, AWAKE, DREAM, PILLOW, BED, etc.) that are highly related to a critical nonpresented item (SLEEP). The powerful memory illusion here is that subjects are just as likely to recall (or recognize) the critical nonpresented item (SLEEP) as items that were actually presented. Moreover, when given remember/know judgments (Tulving, 1985), participants often give the critical nonpresented item remember judgments that presumably tapped detailed episodic recollective experience. It is as if the strong preexisting semantic memory structure is so powerful that it overwhelms the episodic study experience.

It should not be surprising that many of the same issues that have played out in the semantic memory research have also played out in the false memory research. Indeed, one model in this area is the activation monitoring (AM) framework (e.g., Roediger et al., 2001a), which suggests that subjects sometimes confuse the activation that is produced by spreading activation that converges on the critical nonpresented item (much akin to the Collins and Loftus, 1975) with the activation resulting from the study event. This framework attempts to keep separate the episodic and semantic systems but also shows how such systems can interact. In contrast, Arndt and Hirshman (1998) have used the Hintzman (1986) MINERVA framework to accommodate the DRM effect by relying on the similarity of the vectors of the individually stored words and the critical nonpresented items. As noted above, the MINERVA framework does not make a strong distinction between episodic and semantic systems. Moreover, the MINERVA model is more a feature-based model, whereas the AM framework *a priori* would appear more akin to a prototype model, but no strong claims have been made along this dimension. A further distinction between the AM framework and the MINERVA approach concerns the relative contributions of backward associative strength (BAS, or the probability that a list item will elicit the target, or critical lure, on a free-association task) and forward associative strength (FAS, or the probability the critical lure will elicit a list item in such a task). According to AM accounts, the critical variable is expected to be BAS, as the activation flows from the list items to the critical lure. However, according to MINERVA, FAS should be more important, as the similarity between the probe (i.e., the critical lure) and the stored episodes (i.e., the list items) should be a more powerful determinant of memory performance. Results from a multiple regression analysis reported by Roediger et al. (2001b) indicated that, in the DRM paradigm, BAS was the better predictor, thus supporting the AM framework. (We thank Roddy Roediger for pointing this out.)

The question of the nature of the representation (i.e., associative vs semantic) underlying these powerful memory illusions has also been studied. For example, Hutchison and Balota (2005) recently utilized the summation paradigm developed by Balota and Paul (1996), described earlier, to examine whether the DRM effect reflects meaning-based semantic information or could also be accommodated by primarily assuming an associative level information. Hence, in this study, subjects studied lists of words that were related to one meaning or related to two different meanings of a critical nonpresented homograph (e.g., the season meaning of FALL or the accident meaning of FALL). In addition, there were standard DRM lists that only included words that were related to the same meaning of a critical nonpresented word (e.g., such as SLEEP). Consistent with the Balota and Paul results, the results from both recall and recognition tests indicated that there was no difference in the pattern of false memory for study lists that converged on the same meaning (standard DRM lists) of the critical nonpresented items and lists that diverged on different meanings (homograph lists) of the critical nonpresented items. However, when subjects were required to explicitly make gist-based responses and directly access the meaning of the list, that is, is this word related to the studied list, there was clear (and expected) difference between homograph and nonhomograph lists. Hutchison and Balota argued that although rich networks develop through strategic use of meaning during encoding and retrieval, the activation processes resulting from the studied information seem to primarily reflect implicit associative information and do not demand rich meaning-based analysis.

There is little doubt that what we store in memory is a reflection of the knowledge base that we already have in memory, which molds the engram. Hence, as noted earlier, semantic memories may be episodic memories that have lost the contextual information across time because of repeated exposures. It is unlikely that a 50-year-old remembers the details of hearing the Rolling Stones' "Satisfaction" for the first time, but it is likely that, soon after that original experience, one would indeed have vivid episodic details, such as where one was, who one was with, and so on. Although this unitary memory system approach clearly has some value (e.g., McKoon et al., 1986), it is also the case that there is some powerful evidence from cognitive neuroscience that supports a stronger distinction.

## 2.28.8 Representation and Distinctions: Evidence from Neuropsychology

Evidence for the distinction of multiple memory systems has come from studies of patients with localized lesions that produce strong dissociations in behavior. For example, the classic case of HM (see Scoville and Milner, 1957) indicated that damage to the hippocampus resulted in impairment of the storage of new episodic memories, whereas semantic knowledge appeared to be relatively intact (but see MacKay et al., 1998). Hence, one might be overly concerned about the controversy from the behavioral studies regarding the distinct nature of semantic and episodic memory systems. However, there are additional neuropsychological cases that are indeed quite informative about the actual nature of semantic representations.

### 2.28.8.1 Category-Specific Deficits

There have now been numerous cases of individuals who have a specific lesion to the brain and appear to have localized category-specific deficits. For example, there have been individuals who have difficulty identifying items from natural categories (e.g., animals, birds, fruits, etc.) but have a relatively preserved ability to identify items from artificial categories (e.g., clothing, tools, furniture). At first glance, such results would appear to suggest that certain categories are represented in distinct neural tissue that have or have not been disrupted by the lesion. Such a pattern may also be consistent with a localized representation of meaning instead of a distributed feature-based representation in which all concepts share vectors of the same set of primitive features.

Unfortunately, however, the interpretation of impaired performance on natural categories and intact performance on artificial categories has been controversial. For example, such deficits could occur at various stages in the information flow from discriminating visually similar items (e.g., Riddoch and Humphreys, 1987) to problems retrieving the appropriate name of an object (e.g., Hart et al., 1985). Such accounts do not rely on the meaning of the categories but suggest that such deficits may reflect correlated dimensions (e.g., difficulty of the visual discrimination) that differ between natural and artificial categories. In this light, it is particularly important that there have been cases that have shown the opposite pattern. For example, Sacchett and Humphreys (1992) reported an intriguing case that shows disruption of the performance on artificial categories and body parts but relatively preserved performance on natural categories. They argued that one possible reason for this pattern is that this individual had a deficit in representing functional features, which are more relevant to artifactual representations and body parts than natural categories such as fruits and vegetables. Whatever the ultimate explanation of these category-specific deficits, this work has been informative in providing a better understanding of how members within categories may differ on distinct dimensions.

In a similar vein, one hypothesis that has been suggested to explain domain differences in category-specific deficits is the sensory/functional hypothesis (Warrington and McCarthy, 1987; Farah and McClelland, 1991; Caramazza and Shelton, 1998). According to this proposal, natural categories such as animals depend heavily on perceptual information (especially on visual discriminations) for identification and discrimination. Conversely, functional information is more important for recognition of artifacts, such as tools. Thus, damage to regions of sensory cortex is expected to result in selective impairment of natural kinds, whereas damage to regions in or adjacent to motor cortex would result in impairment in artifacts. Although compelling, this view is not endorsed by all researchers. Caramazza and colleagues, in particular, have argued that the sensory/functional hypothesis fails to account for some of the patterns of deficits observed and some of the finer-grain distinctions. In particular, it is difficult for this model to account for the selective sparing or impairment of fruits and vegetables, body parts, and musical instruments that have been reported (see Capitani et al., 2003, for a recent review). Thus, the question of whether and how the type of knowledge that is most critical for supporting the representation of a particular domain is involved in category-specific deficits remains open.

To address this controversy, Cree and McRae (2003) extended the sensory/functional hypothesis to include a broader range of types of knowledge. They developed a brain region taxonomy that included nine different forms of knowledge, including sensory/perceptual in all modalities (vision, taste, audition, etc.), functional, and encyclopedic. Encyclopedic features included information about items such as LIVES IN AFRICA for ELEPHANT – in other words, information that likely was learned and not experienced directly. Cree and McRae then developed a nine-dimensional representation for the 541 concepts for which they had norming data and estimated the salience of each type of knowledge for each object and each category. In a series of cluster analyses, Cree and McRae found that the knowledge types nicely predicted the tripartite distinction between living things, artifacts, and fruits and vegetables reported in several neuropsychological case studies. In addition, Cree and McRae examined several distributional statistics, including the number of distinguishing and distinctive features and similarity to obtain a measure of confusability (i.e., the extent to which a given concept might be confused with another concept from the same category). The categories they examined did appear to be differentially sensitive to these measures, and the implemented model reflected patterns of impairment observed in patients. They concluded that knowledge type does underlie the organization of conceptual representations and that selective impairment in a particular brain region involved in maintaining such knowledge can result in the observed patterns of impairment in patients with category-specific deficits. Although many questions remain, it is clear that evidence from individuals with category-specific deficits has provided considerable insight into both the nature of category representation and the underlying neural representations.

### 2.28.8.2 Semantic Dementia

The most common form of dementing illness is dementia of the Alzheimer type (DAT). However, there is also a relatively rare and distinct dementia, referred to as semantic dementia (SD), which overlaps with DAT in features such as insidious onset and gradual deterioration of comprehension and word-finding ability. SD is a variant of frontal temporal dementia and typically involves one or both of the anterior portions of the temporal lobes. The consensus criteria for SD (Hodges et al., 1992) include impairment in semantic memory causing anomia, deficits in both spoken and written word comprehension, a reading pattern consistent with surface dyslexia (i.e., impairment in reading exception words such as PINT but preserved reading of regular words and nonwords that follow standard spelling to sound rules, such as NUST), impoverished knowledge about objects and/or people with relative sparing of phonological and syntactic components of speech output, and perceptual and nonverbal problem solving skills. These individuals are often quite fluent, but their speech is relatively limited in conveying meaning. They are particularly poor at picture naming and understanding the relations among objects. For example, the Pyramids and Palm Trees test developed by Howard and Patterson (1992) involves selecting which of two items (e.g., a palm tree or a fir tree) is most similar to a third item (e.g., a pyramid). Individuals with SD are particularly poor at this task and so would appear to have a breakdown in the representations of the knowledge structures.

An interesting dissociation has been made between SD individuals and DAT individuals. In particular, Simons et al. (2002) recently found a double dissociation, wherein individuals with SD produced poorer picture naming than individuals with DAT; however, individuals with SD produced better performance than individuals with DAT on a later episodic recognition test of these very same pictures (also see Gold et al., 2005). Clearly, the selective impairment across these two groups of participants is consistent with distinct types of information driving these tasks. Of course, one must be cautious about the implications even from this study, because it is unlikely that either task is a process-pure measure of episodic and semantic memory (see Jacoby, 1991), but clearly these results are very intriguing.

Recently, Rogers et al. (2004) proposed a model of semantic memory that maintains strong connections to modality-specific systems in terms of both inputs and outputs and has been particularly useful in accommodating the deficits observed in SD. This model has some interesting parallels to Barsalou's (1999) proposal, in that it assumes that semantic memory is grounded in perception and action networks. In addition, like the model proposed by McRae et al. (1997), Rogers et al. suggest that the system is sensitive to statistical regularities, and these regularities are what underlie the development of semantics. The particular contribution of Rogers et al.'s model, however, is that although semantic representations are grounded in perception–action modality-specific systems, the statistical learning mechanism allows the emergence of abstract semantic representations. Importantly, inputs to semantics are mediated by perceptual representations that are modality specific, and as a result, the content of semantic memory relies on the same neural tissue that supports encoding. However, different from Barsalou and colleagues' account, Rogers et al. do suggest that there is a domain-general, abstracted representation that emerges from cross-modal mappings. Thus, although the system relies on perceptual inputs, the abstract representations can capture cross-modality similarities and structures to give rise to semantic memory.

Rogers et al. (2004) implemented a simple version of their model using a parallel distributed-processing approach in which visual features provided the perceptual input and are allowed to interact in training with verbal descriptors through a mediating semantic level. Importantly, the semantic representations emerge through the course of training as the network learns the mappings between units at the visual and verbal levels. The units the model was trained on consisted of verbal and visual features generated in separate norming sessions. Once training was complete, several simulations were reported in which the model was progressively damaged in a way that was thought to mimic varying levels of impairment observed in individuals with SD. Overall, the model nicely captured the patterns of performance of the patients. Specifically, one pattern often observed in SD is a tendency to overregularize conceptual knowledge. For example, individuals might refer to all exemplars of a category using the superordinate label or a single label that is high in frequency (e.g., calling a DOG an ANIMAL or a ZEBRA a HORSE). This is possibly a result of the progressive failure in retrieving idiosyncratic information that serves to distinguish exemplars, such that only the central tendency (e.g., a prototype or most typical exemplar) remains accessible. Thus, less common items might take on the attributes of higher-frequency exemplars. The model displayed similar patterns of generalization as the SD individuals, a finding explained in terms of changes in attractor dynamics that resulted in the relative sparing of features and attributes shared by many exemplars but a loss of more distinctive features. This model provides an interesting account of semantic memory and the deficits observed in individuals with SD, one in which both perceptually based information and abstracted representations interact to give rise to knowledge of the world.

## 2.28.9 Neuroimaging

Investigations into the nature of semantic memory have benefited from recent advances in technology that allow investigators to examine online processing of information in the human brain. For example, positron emission technology (PET) and functional magnetic resonance imaging (fMRI) allow one to measure correlates of neural activity *in vivo* as individuals are engaged in semantic tasks (see Logothetis and Wandell, 2004). Although a full review of the substantial contributions of neuroimaging data to the questions pertaining to semantics is beyond the scope of this chapter (*See* Chapter 3.07 for a review), we briefly examine some of the major findings that have helped constrain recent theorizing about the nature and locus of semantic representations. Two major brain regions have been identified through neuroimaging studies: left prefrontal cortex (LPC) and areas within the temporal lobes, particularly in the left hemisphere.

The first study to report neuroimaging data relevant to semantic memory was conducted by Petersen et al. (1988), who used PET techniques to localize activation patterns specific to semantic tasks. Subjects were asked to generate action verbs upon presentation of a concrete object noun, and activity during this task was compared with the activity occurring during silent reading of the words. Petersen et al. reported significant patterns of activity in LPC, a finding that has since been replicated and extended to other types of attributes. Martin et al. (1995) extended this work to show that the specific attribute to be retrieved yielded different patterns of activation. Specifically, the locus of activation involved in attribute retrieval tends to be in close proximity to the neural regions that are involved in perception of the specific attributes. Thus, retrieval of visual information, such as color, tends to activate regions adjacent to the regions involved in color perception, whereas retrieval of functional information results in activation of areas adjacent to motor cortex. These findings mesh nicely with the perceptual/motor notions of representation in semantic memory reviewed above (e.g., Barsalou, 1999; Rogers et al., 2004). In addition, Roskies et al. (2001) reported that not only were regions in lateral inferior prefrontal cortex (LIPC) preferentially active during tasks that required semantic processing, but specific regions were also sensitive to task difficulty. Thus, it appears that frontal regions are involved both in the active retrieval from semantic memory and in processing specific semantic information.

Many researchers have suggested, however, that although frontal regions are involved in semantic retrieval, the storage of semantic information is primarily in the temporal regions (see Hodges et al., 1992). Indeed, another area that has been implicated in semantic processing is in the ventral region of the temporal lobes, centered on the fusiform gyrus, and especially in the left hemisphere. This area shows significant activation during word reading and object naming tasks, indicating it is not sensitive to the stimulus form but to the semantic content therein (see Martin, 2005, for a review). Furthermore, within this area, different subregions become more or less activated when subjects view faces, houses, and chairs (e.g., Chao et al., 1999), suggesting that different domains rely on different regions of neural tissue. This, of course, could be viewed as consistent with the category-specific deficits reviewed above. However, as noted by Martin and Chao (2001), although peak activation levels in response to objects from different domains reflect a certain degree of localization, the predominant finding is a pattern of broadly distributed activation throughout the ventral temporal and occipital regions, which is consistent with the idea that representations are distributed over large cortical regions.

Recently, Wheatley et al. (2005) reported data from a semantic priming study using fMRI that also converges on the notion of perceptual motor representations of meaning. Subjects silently read related, unrelated, or identical word pairs at a 250-ms SOA while being scanned. The related pairs consisted of category members that were not strongly associatively related (e.g., DOG-GOAT, but see the discussion above regarding the difficulty of selecting such items). Given the relatively fast SOA and that no overt response was required, Wheatley et al. argued that any evidence for priming should be a reflection of automatic processes. Consistent with other evidence that indicates there are reliable neural correlates of behavioral priming that were evidenced by reduced hemodynamic activity (Wiggs and Martin, 1998; Mummery et al., 1999; Rissman et al., 2003; Maccotta and Buckner, 2004), Wheatley et al. found decreased activity for identity pairs and a slightly smaller, but still significant, decrease for related pairs relative to the unrelated pairs condition. Importantly, Wheatley et al. were able to compare patterns of activation as a function of domain. Consistent with proposals by Barsalou (1999), they found that objects from animate objects yielded more activity in regions adjacent to sensory cortex, whereas manipulable artifacts resulted in greater activity in regions adjacent to motor cortex. These findings were taken as evidence that conceptual information about objects is stored, at least in part, in neural regions that are involved in perception and action.

Although the Wheatley et al. (2005) study used a task that was likely to minimize strategic processing, one question that remains to be addressed is whether the automatic and strategic processes involved in semantic priming tasks (see earlier discussion) can also be dissociated in neural tissue. In a recent study, Gold et al. (2006) reported that several of the brain regions previously implicated in processing during semantic tasks are differentially sensitive to the automatic and strategic processes involved in lexical decision tasks. In three experiments, Gold et al. manipulated prime target relatedness, SOA, and whether primes and targets were orthographically or semantically related. Long and short SOAs were intermixed in scanning runs to assess the relative contributions of strategic and automatic processes (see Neely, 1991). A comparison of orthographic and semantic priming conditions was included to determine whether any areas were particularly sensitive to the two sources of priming or whether priming effects are more general mechanisms. The results clearly indicated that different regions responded selectively to different conditions. Specifically, midfusiform gyrus was more sensitive to automatic than strategic priming, but only for semantically related primes, as this region did not show reduced activity for orthographic primes. Four regions were more sensitive to strategic than automatic priming, two in left anterior prefrontal cortex and bilateral anterior cingulate. Even more intriguing, the two regions in LIPC were further dissociated: The anterior region showed strategic semantic facilitation, as evidenced by decreased activity, relative to a neutral baseline, whereas the posterior region showed strategic semantic inhibition, or increased activity, relative to the neutral baseline. In addition, the medial temporal gyrus showed decreased activation concurrently with the anterior LIPC, supporting previous claims that these regions show greater activation in tasks that are more demanding of strategic processes but reduced activation when the strategic processes are less demanding (Wagner et al., 2000; Gold et al., 2005). In sum, it appears that the behavioral dissociations between automatic and strategic processes in priming tasks are also found in the neuroimaging data. The complexity of the patterns of activation involved in semantic tasks appears to indicate that the retrieval and storage of semantic information is indeed a distributed phenomenon that requires the coordination of a wide array of neural tissue.

## 2.28.10 Development and Bilingualism

Although we have attempted to provide a review of the major issues addressed in semantic memory research, there are clearly other important areas that we have not considered in detail because of length limitations. For example, there is a very rich area of developmental research addressing the acquisition of meaning in children (see Bloom, 2000, for a comprehensive review), along with work that attempts to capture the nature of semantic memory in older adulthood (see, e.g., Balota and Duchek, 1989). Of course, we touched upon these issues earlier when discussing how the small world networks of Steyvers and Tenenbaum (2005) develop over time, along with the work by Rosch (1975) on the development of categorization. Given that meaning is extracted from interactions with the environment, the developmental literature is particularly important to understand how additional years of experience mold the semantic system, especially in very early life. There are many interesting connections of this work to topics covered earlier in this chapter. For example, regarding the influence of preexisting structures on false memory, it is noteworthy that young children (5-year-olds) are more likely to produce phonological than semantic false memories, whereas older children (around 11 years and older) are more likely to produce the opposite pattern (see Dewhurst and Robinson, 2004). Possibly, this is a natural consequence of the development of a rich semantic network in early childhood that lags behind a more restricted phonological system.

Another very active area of research involves the nature of semantic representations in bilinguals (see Francis, 1999, 2005, for excellent reviews). For example, researchers have attempted to determine whether there is a common semantic substrate that is amodal, with each language having specific lexical level representations (e.g., phonology, orthography, syntax, etc.) that map onto this system. This contrasts with the view that each language engages distinct semantic level representations. Although there is still some controversy, the experimental results seem more consistent with the assumption that the semantic level is shared across languages, at least for skilled bilinguals. Evidence in support of this claim comes from a diverse range of tasks. For example, in a mixed language list, memory for the language of input is generally worse than memory for the concepts (e.g., Dalrymple-Alford and Aamiry, 1969). In addition, one finds robust semantic priming effects by translation equivalents (words in different languages with the same meaning, e.g., DOG in English and HUND in German), which is consistent with at least a partially shared semantic representation (e.g., de Groot and Nas, 1991; Gollan et al., 1997).

## 2.28.11 Closing Comments

The nature of how humans develop, represent, and efficiently retrieve information from their vast repository of knowledge has for centuries perplexed investigators of the mind. Although there is clearly considerable work to be done, recent advances in analyses of large-scale databases, new theoretical perspectives from embodied cognition and small world networks, and new technological developments allowing researchers to measure, *in vivo*, brain activity, are making considerable progress toward understanding this fundamental aspect of cognition.

# 2.29 Concept and Category Learning in Humans

**B. H. Ross, E. G. Taylor, and E. L. Middleton**, University of Illinois at Urbana-Champaign, Urbana-Champaign, IL, USA

**T. J. Nokes**, University of Pittsburgh, Pittsburgh, PA, USA

## 2.29.1 Introduction

Concepts and categories are crucial for intelligent thought and action. A child needs to learn to tell toys from tools and which types of dogs can be petted. A student needs to learn to distinguish the principle underlying a math problem, so that relevant principle knowledge can be applied. Researchers need to be able to decide what type of person has asked them to collaborate, to understand the concept of confounding, and to be able to communicate new ideas to others. The focus of this chapter is understanding the learning of categories and concepts. This learning is critical not only because little of this knowledge is innate but also because the learning of concepts and categories is a large part of acquiring knowledge.

We use concept to refer to a mental representation, an idea, that picks out a class of entities. A category is the class or set of entities that is referred to by the concept. One has a concept of dog, and then there is the category of dogs (both real and imagined). Different things in the category can all be treated similarly, with respect to some purpose. Cars are members of a category because they have much in common in terms of appearance and use. However, one might want to make finer distinctions, such as separating cars that can carry much stuff for moving from sports cars; at other times, such as in compiling assets, one might want to think of an expensive sports car as part of the same class as a boat and house. When possible, we use categories to refer to the learning or use of the members and concepts to refer to the knowledge of categories. Despite this distinction, they are often used interchangeably because it is often true that one is dealing with both together.

We also need to address briefly two important issues: Origins and types. First, although some researchers argue for the independent existence of concepts in the world (separate from the organisms that perceive them), we, as psychologists, believe it is more useful to think of them as arising jointly from the fit between the world and the organism. Although it is true that we do not just have any concepts, it is also true that different organisms have different concepts, and even among humans, the concepts we have often are a function of human activity. Second, although much of the work has focused on object categories, we clearly have many other categories besides objects, people, situations, problems, scenes, and so on. We try to include a variety of types in our discussion (also see Medin et al., 2000).

In this chapter, we provide an overview of the work on concept and category learning, with a focus on experimental work and modeling. We begin by considering the functions of concepts. We then address a large body of research that has examined conceptual structure for classification, with particular emphasis on prototype and exemplar approaches and models. We argue that this work has missed some important aspects of both how categories are learned and the importance of structure and prior knowledge. A goal of this chapter is to integrate the work on concepts and categories into the areas of cognition in which they are so crucial. All cognitive activity relies on concepts in some way, so an understanding of how they are learned is likely to have an impact on much other research. We provide an integration in three ways. One, we examine the learning of concepts and categories from a goal-oriented view, asking how the ways in which they might be learned influence the representation available for other cognitive activities. Two, we consider more complex concepts, as would be needed to account for results in most areas in which concepts are used. Three, we address this integration more directly by considering two very different areas of cognition, problem solving and language.

### 2.29.1.1 Functions of Concepts and Categories

Concepts and categories are fundamental building blocks of cognition. Murphy (2002) calls them the mental glue in that they link our past experiences (with toys, dogs, mathematical problems, collaborators) to our current ones. They are a part of all cognitive, and many noncognitive, theories. We mention here a few functions.

#### *2.29.1.1.1 Classification*

Classification is the determination that something is a member of a particular category: A carrot, an extrovert, a permutations problem, an instance of insurgency. This action allows one to access knowledge about the category that can be used for a variety of other functions.

#### *2.29.1.1.2 Prediction and inference*

When an object is classified as a carrot, you can predict how it will taste, how crunchy it will be. You can use knowledge of the category to infer how it was grown and how similar it is to a beet. Prediction is often considered a key function of categories (e.g., Anderson, 1991) in that it allows for selection of plans and actions.

#### *2.29.1.1.3 Understanding and explanation*

People need to know not just what, but why. We can explain aberrant behavior if we know that the person was grieving or drunk. This characterization might change our future actions with the person. If we start watching a TV program part-way through and cannot understand what is happening, being told it involves a love triangle may help us to make sense of the events.

#### 2.29.1.1.4 Communication

We are social animals, and much of our activity is geared toward interacting with others. Concepts provide a kind of social glue as well, as they facilitate communication and allow us to learn new concepts by indirect experience.

Concepts and categories underlie much of mental life, and their learning is complex. We must learn not just to classify items: Knowing something is a carrot, a permutations problem, or an extrovert does not help unless we know enough about carrots, permutations, or extroverts to accomplish our goals (e.g., how to prepare the carrot, solve the problem, quiet the extrovert). Thus, as we learn to tell what category an item is in, we also have to learn much else about the concept to allow prediction, explanation, and communication. The corresponding distinction between knowledge that allows one to classify and knowledge that allows one to perform other conceptual functions is a central one for this chapter, as well as for understanding concepts and categories in other areas of cognition.

## 2.29.2 Conceptual Structure

We turn now to the structure of concepts. How are categories mentally represented to allow these various functions to be accomplished? This question is essential for any examination of concept and category learning, because it provides a clear target for what must be learned. We can only provide a brief overview, but fuller descriptions can be read in Medin (1989) and Murphy (2002).

### 2.29.2.1 Views and Models

What determines which items go together in a category and which items are in different categories? A common intuition is that it depends upon similarity – more similar items are in the same category. One can think of items as consisting of a set of features. Similarity is defined as the overlap of features (such as Tversky, 1977) or, if one prefers spatial metaphors, as closeness in some multidimensional space (e.g., Shepard, 1962a,b). This idea of similarity underlies many views of conceptual structure, three of which are summarized in **Table 1**. We briefly present these views and associated formal models with a focus on classification learning.

#### 2.29.2.1.1 Classical view

The classical view of concepts takes a strict view of similarity: All items in a category must have a specific set of features. If an item has those features, it is in the category; if it does not, it is not. One can think of this as a definitional view of categories: The features are singly necessary and jointly sufficient for category membership. A triangle is any closed two-dimensional figure that has three straight sides. Any item that has all of those features is a triangle, and any item that does not have all of those features is not a triangle. In addition, the view includes the rule-based idea, in which items are classified as being in a category if they meet some rule, such as red, or red and large (e.g., Bruner et al., 1956). This view has a long history (see Murphy, 2002), and it matches many intuitions about category members sharing some common characteristics. However, because the classical view assumes all members possess the same set of common features, it does not explain why some category members are more typical than others (e.g., robins vs. penguins) or why it has proven so difficult for people to come up with a set of defining features for most categories (Wittgenstein, 1953, has a famous example of trying to define the category games). There are no current formal models that rely solely on a classical view.

#### 2.29.2.1.2 Prototype view

The prototype view (or probabilistic view) keeps the attractive assumption that there is some underlying common set of features for category members but relaxes the requirement that every member have all the features. Instead, it assumes there is a probabilistic matching process: Members of the category have more features, perhaps weighted by importance, in common with the prototype of this category than with

**Table 1** Similarity-based views of conceptual structure and their classification decisions

| | | |
|---|---|---|
| Classical | Unitary description: Definitional, rule-based | Classification: Category member if and only if all features are true of an item |
| Prototype | Unitary description (prototype): Probabilistic | Classification: Category member if more (weighted) features are true of the prototype than of other prototypes |
| Exemplar | No unitary description: Disjunctive representation | Classification: Category member if more similar to (weighted) category members than to members of other categories |

prototypes of other categories (and perhaps some minimum match level is required). An early presentation is available in Rosch and Mervis (1975), with a more recent presentation in Hampton (2006).

This type of representation has major implications for how to think about categories. First, some members may have more of the prototype features than others, such as a robin having more bird prototype features than a penguin. People tend to judge robins as better examples of birds than are penguins and are faster to classify robins as birds than they are to classify penguins as birds. Second, this view suggests that the category boundaries, which were strict in the classical view, may be fuzzy, with some cases that are far from the prototype and maybe even almost as close to another prototype. For example, whales have many fish-like properties, and bats have many bird-like properties. Both are viewed as poor examples of the mammal category and are slow to be verified as members of that category. Overall, this view leads to a set of category members that tend to have a family resemblance – no defining features, but some features will be possessed by many members and some features by a few members (similar to an extended family). Rosch and Mervis (1975) argue that this type of family resemblance characterizes many natural categories. See the top half of **Figure 1** for a simple example.

Smith and Minda (1998, 2000; Minda and Smith, 2001) proposed a model of prototype-based classification that matches an item to the various prototype representations and picks the most similar (see also Hampton, 1993). Using the spatial distance idea of similarity, the prototype models (a) determine the distance from the test item to each prototype, (b) compute the similarity from the distance, and (c) choose the category prototype as a function of the similarity. There are several specific choices to make as to how

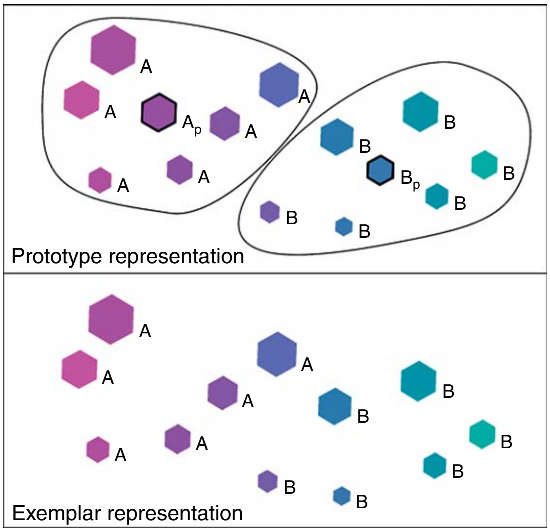

**Figure 1** Sample prototype and exemplar representations. Members of Category A tend to be large and pink, whereas members of Category B tend to be small and turquoise. The prototype representation in the top panel also includes a prototype item with the bold outline and P subscript, which was not presented but represents the center of the presented items. (Although the prototypes here can be characterized as instances, more generally prototypes are summary representations.) The exemplar representations in the bottom panel include all individual category members, but do not group them or include a center.

to formalize these ideas. For the reader interested in formal models, we provide a simple one with additive similarity and just two categories in **Table 2**.

The learning of the category is the building of this summary representation. Exactly how the prototype is learned is not usually specified. One possibility, for simple cases, is to assume a simple associationist-like mechanism, with frequently occurring values being more reinforced. The point is that the earlier experiences are used to build the summary representation,

**Table 2** Sample prototype model calculations (assuming *N* dimensions, city-block[a] metric, and two categories, A and B)

| *To calculate* | *Formula* | *Comment* |
|---|---|---|
| (a) Distance of test item, *t*, to prototype, *P* | $d_{tP} = \sum_{k=1}^{N} w_k \lvert t_k - P_k \rvert$ | $w_k$ Weights each dimension *k* by attention (or importance)[b] |
| (b) Similarity of test item, *t*, to prototype, *P* | $S_{tP} = 1 - d_{tP}$ | Additive similarity [c] |
| (c) Probability of choosing Category *A* | $P(A \mid t) = \dfrac{S_{tP,A}}{S_{tP,A} + S_{tP,B}}$ | Luce Choice rule over prototypes' similarities to the test item |

[a]City-block metric is common when the dimensions' distances seem to be evaluated separately and then added. It is as if one is walking in a city and can turn only at the corners, rather than as the crow flies (Euclidean). It is used here as an illustration of one distance metric.
[b]The difference between the values of the test item and prototype on each dimension is summed, weighted by the attention given to that dimension. The sum of the weights is constrained to be equal to 1 ($\Sigma$ $w_k = 1$) as a limited-capacity system (total amount of attention is limited).
[c]Similarity is assumed to be a linearly decreasing function of psychological distance.

which is then slightly revised with new experiences (in the same way one can keep various statistics of a sample as each new item is added).

#### 2.29.2.1.3 Exemplar view

The idea of a summary representation is attractive, and we clearly know a lot about categories such as birds. However, an alternative view is that the knowledge we use in making category judgments such as classification is not this summary representation but the set of category members: The conceptual structure is a collection of the mental representations of category members. When an item is presented, the person matches the representation of the item to the various previous items' representations and uses some subset (perhaps even just one item) selected by their similarity to the current item's representation. Thus, to classify a hawk as a bird, one would retrieve some earlier representations of hawks or similar birds and note their bird category; to decide what it ate, one would again use these more specific representations.

We know this lack of a summary representation seems strange at first thought, but often a new item will remind one of some old item from which one can make a classification or prediction ("is this person like my friend Bill in other ways?"). The exemplar view is an extension of this idea to allow the use of specific instances to classify the current item. Imagine you see a new ostrich-like animal with some unusual bird characteristics. If you relied on the bird prototype, you might not classify it as a bird. However, if you used similar birds, then you would likely classify it as a bird, as well as predict it probably does not fly or eat worms.

This exemplar view accounts for the prototype-like effects mentioned earlier. Some category members, such as robins, will be viewed as more typical than others, such as penguins, because a robin will be similar to many birds (not just the large number of robins, but also sparrows, thrushes, etc.), whereas a penguin will be similar mainly to the few penguins one has seen. The uncertain cases will be exemplars that are not very similar to any items in a category and may even be a little bit similar to atypical items in another category (see **Figure 1**, lower panel).

There are a number of formal exemplar models, with the best known being the Context Model (Medin and Schaffer, 1978), which was extended in a number of ways by the Generalized Context Model (GCM, Nosofsky, 1986). Like the prototype model, exemplar models also use the similarity of the test item to each category, but because there is no summary representation, the similarity of the test item to the category is just the sum of the similarity of the test item to each of the items in the category. The other main difference from prototype models is that multiplicative, rather than additive, similarity is assumed. Multiplicative similarity means that the similarity is not a linear function of the psychological distance, but instead, very close items (ones that are similar to the test item on many dimensions) matter much more. More specifically, exemplar models (a′) compare the similarity of the test item to all items, (b′) compute the similarity of the test item to each category by summing the test item's similarity to each of the category members, and then (c′) choose the category as a function of similarity. The equations for one such model are presented in **Table 3** for those readers with an interest in formal models. Most exemplar models capture only classification performance, but ALCOVE (Kruschke, 1992) extends the GCM to allow some

**Table 3** Sample exemplar model calculations (assuming *N* dimensions, city-block[a] metric, and two categories, A and B)

| *To calculate* | *Formula* | *Comment* |
|---|---|---|
| (a′) Distance of test item, *t*, to exemplar, $X_j$ | $d_{tj} = \sum_{k=1}^{N} w_k \lvert t_k - X_{jk} \rvert$ | $w_k$ Weights each dimension *k* by attention (or importance)[b] |
| (b′) Similarity of test item, *t*, to exemplar, $X_j$ | $S_{tj} = \exp(-c \cdot d_{tj})$ | Multiplicative similarity,[c] c indicates sharpness of generalizations |
| (c′) Probability of choosing Category *A* | $P(A \mid t) = \dfrac{\sum_{i \in A} S_{ti}}{\sum_{i \in A} S_{ti} + \sum_{i \in B} S_{ti}}$ | Luce Choice rule over exemplars' similarities to the test item |

[a]City-block metric is common when the dimensions' distances seem to be evaluated separately and then added. It is as if one is walking in a city and can turn only at the corners, rather than as the crow flies (Euclidean). It is used here just as an illustration of one distance metric.
[b]The difference between the values of the test item and prototype on each dimension is summed, weighted by the attention given to that dimension. The sum of the weights is constrained to be equal to 1 ($\Sigma\, w_k = 1$) as a limited-capacity system (total amount of attention is limited).
[c]Multiplicative similarity is not a linear function of psychological distance. Rather, close items (small distance) have much greater effect than in a linear function. The exponential function is commonly used and has a quick drop-off with distance. (Note that the exponential of the sum of distances across each dimension is equal to multiplying the exponential of each dimensional distance, since $\exp[a+b] = \exp[a] \cdot \exp[b]$.)

learning. In addition, there is no learning of summary representations, because only individual items need to be stored.

### 2.29.2.2 Evaluations of Prototype and Exemplar Models

There have been many (many) comparisons of prototype and exemplar models (for a review, see Murphy, 2002). The general result is that exemplar models do as well or better than prototype models in most cases (though see Smith and Minda, 1998, 2001). Our view, summarizing over many results, is that the advantage is largely a result of two factors: similarity calculation and selectivity (Ross and Makin, 1999). First, the exemplar models' multiplicative similarity (compared to the prototype models' usual assumption of additive similarity) means that the model does not combine features independently but, rather, is sensitive to the relational information among the features (e.g., Medin and Schaffer, 1978). The combination of features is being used beyond their separate contribution to determining classification. Thus, if one encountered small birds that sang and large birds that squawked, a prototype representation would not be sensitive to that particular relational (cooccurrence) information, whereas an exemplar model would. Although it is not a usual assumption, prototype models might also incorporate multiplicative similarity (e.g., Smith and Minda, 1998); this helps the fit, but it does not mimic the predictions of the exemplar model. (Multiplicative similarity is a nonlinear function, so calculating multiplicative similarity on the mean (prototype) is not the same as the mean of multiplicative similarities on the individual instances.) In fact, exemplar models implicitly keep all the statistical information (e.g., frequency, variability, cooccurrence) by keeping all the exemplars. One might argue that a prototype model could also keep various statistical information around to make it equivalent to such exemplar models (e.g., Barsalou, 1990), but no one has proposed such a formal model. Second, because exemplar models have no summary representation, the same knowledge is not used for all the different decisions. Thus, even unusual items can be classified by similarity to earlier unusual similar members. The ability to use different knowledge for different decisions means that the exemplar model can classify unusual items without compromising its ability to easily classify more typical items. This flexibility is important in allowing the exemplar model to fit a variety of classification data.

The exemplar model fits the data well for many classification experiments but has difficulties with other aspects of category-related judgments. One major issue is that it has no place for these summary representations that we all find attractive in thinking about concepts. In particular, to answer the question as to why these items are all members of the same category, the exemplar view is left with the unsatisfying answer that "they all have the same category label." That may be fine for arbitrary experimenter-defined categories in the laboratory but seems woefully inadequate for permutation problems, extroverts, and love triangles. (Note that the classical view can point to a definition and the prototype view to similarity to some common summary representation.)

### 2.29.2.3 Combined Models

It seems likely that people are not restricted to a single means of representation and that we might combine advantages of prototype and exemplar models, or at least general and more specific knowledge. We consider two types of proposals. First, one could take a prototype model and an exemplar model and simply combine them with some means of determining whether a decision would be based on the prototypes or exemplars. Smith and Minda (1998) show that a combined model can provide a better account of the data, with the prototype being more influential earlier, when each item to be classified has been presented only a few times, and the exemplar model controlling responses more as the same items are presented often. They do not specify a control mechanism, but perhaps the model that has greater confidence in its choice might determine the classification.

Second, there have been models that build upon simple models with a more integrated approach. Interestingly, rules, which can be viewed as simple classical models, are making a comeback: They appear to work better as part of the answer rather than the sole answer. ATRIUM (Erickson and Kruschke, 1998) combines simple rules with an exemplar model, ALCOVE (Kruschke, 1992). The authors provide experimental evidence showing that both types of knowledge can influence a task and then address how the two types of knowledge might be integrated to provide an account of the data. All inputs are examined by both the rule and exemplar modules, with the response a weighted function determined by how much attention is given to each. The model learns to shift attention between the modules as a function of which module is better at classifying particular inputs. (Also see the RULEX model by Nosofsky et al., 1994.)

A very different combined model, COVIS, has been proposed by Ashby and colleagues (Ashby and Ennis, 2006, present an overview). Human category learning is assumed to be mediated by a number of functionally distinct neurobiological systems, and the goal is to elucidate these systems and their behavioral consequences. An explicit system is important for rule-based tasks – those tasks with a focus on a single dimension for which people might generate and test hypotheses. Another, procedural-based, system deals with information-integration tasks that require combining information from multiple dimensions. This model combines rule- and procedural-based knowledge to account for a variety of behavioral results and data from neuropsychological patients.

### 2.29.2.4 Evaluation of Work on Conceptual Structure

#### *2.29.2.4.1 Successes*

The separation of different views of conceptual structure has generated much research. The prototype view has greatly extended our understanding of natural categories. The formal modeling on the exemplar approach has shown that exemplar representations coupled with multiplicative similarity are able to account for a wide variety of classification results. The more recent prototype modeling work shows that some findings that seemed problematic for prototype models may not be, though the exemplar model still seems to have an edge on overall accounts of the results. Although almost all of the exemplar work has focused on learning artificial categories, some recent work suggests the exemplar models may fit some real-world categories as well (reviewed in Storms, 2004).

#### *2.29.2.4.2 Limitations*

We label this part of the evaluation 'limitations' because the difficulties are not failures but restrictions. The simple point, to be elaborated in the next section, is that the field has examined only a small part of the picture for conceptual structure and learning. Thus, although the prototype and exemplar approaches and models have been explored extensively, especially in the laboratory, our understanding of concept and category learning may be quite limited.

First, almost all the work on adult category learning until a decade ago focused on classification learning, how people learn to assign items to specified categories. We learn concepts and categories in many ways – such as by interactions, inferences, problem solving, instruction – yet these have received little attention in research on category learning. Not only is much of the laboratory work limited to classification learning, it has rarely varied from a small range of particulars (here is an incomplete list): two categories, small number of features, small number of values per feature, small number of items per category, and divorced from any prior knowledge. Given all the possible ways that even the classification paradigm might be done, these seem very limiting. Of course, it is possible that all the ways of learning and all the possible ways of changing the classification paradigm will not matter in terms of our understanding of category learning, but the evidence suggests just the opposite. As elaborated in the next section, it appears that many of these changes lead to important differences in what is learned.

Second, the items being learned have been limited. In addition to the ways mentioned, almost all have been objects (or descriptions of objects), with little examination of problems, people, situations, scenes, and so on. In addition, the items in most experiments have generally consisted of features only, with no relational structure beyond cooccurrences. None of the main classification theories developed in the exemplar-prototype debates allow relations in their item representations. Given that real-world categories have much relational structure, as well as much prior knowledge, it is unclear how well these findings will relate to more complex cases.

## 2.29.3 Beyond Classification and Featural Representations

In this section, we consider some recent work that begins to address these limitations. First, research has extended concept and category learning from a focus on classification to consider other means of category learning. Second, we consider two formal models that were designed to examine category learning beyond classification, the Rational Model and SUSTAIN. Third, we review some work that has gone beyond representations of features to ask how more complex categories might be learned, including the influence of prior knowledge. Finally, we consider how far this new research has gone in providing a resolution, or at least a partial resolution, to these limitations.

### 2.29.3.1 Category Learning Beyond Classification

As we outlined at the beginning, concepts and categories have many functions, of which classification is just one. Classification is an important one: By determining what category an item is in, one has access to much relevant knowledge about that item. However, the near-exclusive focus on classification learning in laboratory experiments is problematic for two reasons. First, if we learn categories in multiple ways, it seems prudent to examine more than classification learning to get a full understanding of category learning. Second, classification learning has an important difference from most other conceptual functions. In classification learning, the goal is to determine what category the item is in. This requires figuring out what distinguishes the competing categories. However, most other functions, such as prediction, understanding, or communication, require using what you know about a particular category, with the other categories often not mattering at all. That is, classification requires distinguishing between categories, but most other functions require within-category knowledge. For example, Chin-Parker and Ross (2004) found that classification learning led to learning only about diagnostic features (those that are predictive of category membership). People learned nothing about the other features that were not predictive of a category, even though they occurred 80% of the time in both categories. This result is exactly as predicted by classification theories, such as the exemplar models mentioned earlier (e.g., Nosofsky, 1986). However, if one is predicting what a new animal eats, it requires knowing more than what type of animal it is; one also needs to know what food is eaten by animals of that type. If one is solving a math problem, knowing the type of problem is helpful only if it allows access to relevant information about how to solve problems of that type.

A number of laboratory tasks have been examined over the last 10 years that extend our understanding of category learning by examining types of learning other than classification. These tasks emphasize how categories allow us to accomplish the goals we have: Predict, solve problems, explain. We focus on three tasks here: Inference learning, in which the classification is provided; category use, in which the learner uses the category to learn some other task; and an unsupervised learning, in which no category information is provided. We give a rough outline of their procedural differences from classification learning in **Table 4** and a rough outline of the processing in **Figure 2**.

First, one can learn about categories by inferring features of category members. Inference learning is a

**Table 4** Simplified procedures for various category-learning laboratory tasks

| | |
|---|---|
| Classification | An item is presented<br>Subject responds with one experimenter-defined category label<br>Feedback given on classification<br>Next item is presented |
| Inference | An item (one feature missing) is presented, along with category label<br>Subject responds with value of missing feature<br>Feedback given on inference<br>Next item is presented |
| Category use | An item is presented<br>Subject responds with one experimenter-defined category label<br>Feedback given on classification<br>Subject uses category and item to do some task (inference, problem solve)<br>Feedback given on second task<br>Next item is presented |
| Unsupervised[a] (using Minda and Ross, 2004, to be specific on procedure) | An item is presented<br>Subject uses item to do some category-related task (prediction)<br>Feedback given on task<br>Next item is presented |

[a]Note: no mention made of category, but category is useful for prediction.

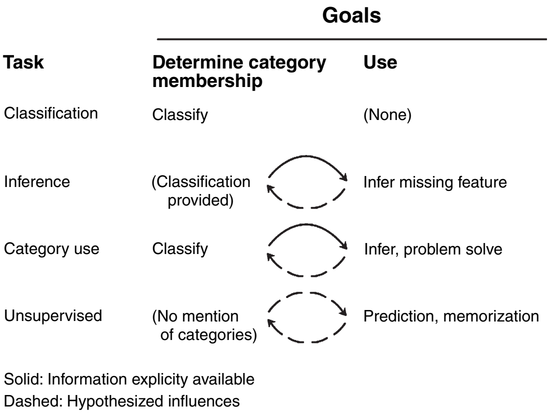

**Figure 2** Schematic to illustrate the relation among the different laboratory tasks used to study category learning.

paradigm that can be compared to classification directly: Rather than presenting *N* features and asking what category the item is in, the label is given along with *N*−1 features, and the person's task is to supply the missing feature (Yamauchi and Markman, 1998). Suppose there is an item in Category A that has three features; we can characterize this item as {A a1 a2 a3}. In a classification trial, the learner would be provided with {? a1 a2 a3} and have to provide the label A, whereas in an inference trial, the learner would get {A a1 a2 ?} and have to provide the missing feature, a3. The procedure is presented in **Table 4**. This task matches a common means of interacting with categories in which one knows the category and parts of the item but has to infer a missing feature: Given this dog, what will it eat? Or given this type of situation, what will happen next? This task appears to be very similar to classification learning but leads to rather different learning. In inference learning, people learn prototypical features that are not diagnostic (Chin-Parker and Ross, 2004) and features that vary in their exact presentation (Yamauchi and Markman, 2000). Focusing within a category leads people to learn what the category is like, not just what distinguishes it from another category (Yamauchi and Markman, 1998; see Markman and Ross, 2003, for a review; Johansen and Kruschke, 2005, for counterarguments). However, if one knows what a category is like (e.g., dogs, permutations), one can often tell if an item is a member of the category as well. In addition, inference learning, by focusing on what the category members are like, may also help people to understand the underlying coherence of relational categories (Erickson et al., 2005).

Second, other work has considered classification as part of a larger goal-related task and asked how category knowledge might be influenced. The rationale is that classification is not usually the goal; usually we want to do something with the classification. We classify an object as a pencil and use it to write, a person as a psychopath and stay away, a math question as a permutations problem and apply the appropriate formula. Ross (1997, 1999, 2000) has conducted research with a category use paradigm in which one not only classifies the item but also then uses the item to perform some goal-oriented task, such as make an inference about the item or solve the problem (see **Table 4** and **Figure 2**). In these studies, the uses of the category (e.g., inference or problem solving) influence the category representation, even for later classification. Performance on later classification tests is not a function just of the diagnosticity of the features but also of their importance for the use. Those features involved in the inference, for example, are viewed as more central to the category than equally predictive features that are not involved in the use. To be more concrete, Ross (1997) had people learn to classify patients (sets of symptoms) into two diseases and then choose the treatment to give that patient (which depended on both the disease and the symptoms). Two symptoms were equally and perfectly predictive of the disease, but only one was also predictive of the treatment. After learning, people were given a single symptom and asked which disease they would think a patient had if this was all they knew of the symptoms. Although both symptoms were perfectly predictive of the disease, learners were much more likely to correctly classify the one that was also predictive of the treatment. Even when we explicitly classify items, we continue to learn about the category from other nonclassification uses, and this knowledge influences a variety of later category-related judgments, including classification. Related results have been found with problem solving (Ross, 1997, 1999), and even with young children (Hayes and Younger, 2004; Ross, et al., 2005).

The goals for which categories are used during learning can have additional consequences that may influence the representation of real-world categories. Brooks et al. (2007) argue that tasks in which classifications are used for a different primary task may lead to a very different learning of the classification knowledge than classification alone. In a clever set of experiments, they show that the other task diverts attention away from analyzing the category structure for classification, such that learners believe the category has defining features when it does not. When we divert our resources to using the category, the knowledge learned from the classification may be a less central part of our category representation.

Third, we can look at cases in which people are not even told there are categories. If we have a helpful teacher/parent, we may get feedback on the category membership (classification) or labeled items (inference), but in many cases, such as much of our informal learning, we may not. In unsupervised learning tasks, the categories are not provided to the learner (e.g., Ahn and Medin, 1992; Heit, 1992; Wattenmaker, 1992; Clapper and Bower, 1994; Billman and Knutson, 1996; Kaplan and Murphy, 1999; Clapper and Bower, 2002; Love, 2003). Here, the particular interactions people have with the items may affect later formation of categories (e.g., Lassaline and Murphy, 1996). Many of these unsupervised tasks focus on the items and the categories, often through observation, memorization, or sorting. When there is a more goal-oriented learning task, such as predicting a critical feature or solving a problem, any learning about the categories or items is incidental to attaining the goal. Minda and Ross (2004) found in a prediction task (where category membership was crucial to the prediction) that the unsupervised learning led to paying more attention to a wider set of features than did classification learning.

In sum, although classification learning has been the dominant paradigm for studying category learning, including other tasks may provide a more complete picture of category learning. Classification is a critical function of categories, but it is critical because it provides access to knowledge about the item that can be used to infer, predict, understand, or explain. Classification learning promotes learning what distinguishes the categories, whereas these other functions of categories tend to promote learning what each category is like.

### 2.29.3.2 Formal Models That Do More Than Classify: Rational Model and SUSTAIN

Most category-learning models have focused on classification learning, but a few have considered other category functions. We consider two prominent models, J. R. Anderson's (1990, 1991) Rational Model of categorization and SUSTAIN (Love et al., 2004), with an emphasis on learning mechanisms and extensions to multiple functions of categories.

#### *2.29.3.2.1 The Rational Model of categorization*

The Rational Model is a component of Anderson's (1990, 1991) rational analysis of cognition. The central claim of the model is that categories serve as a basis for prediction. Classification is a specific type of prediction in which the task is to predict the category label. The model stores clusters of exemplars with similar properties. The primary goal of the model is to develop clusters that optimize the accuracy of a variety of category-based predictions.

Predictions in the model are based on conditional probabilities. The probability that a new exemplar with a set of properties $F$ has property $j$ (on dimension $i$) is:

$$P_i(j|F) = \sum_k P(k|F)P_i(j|k), \quad [1]$$

where $P(k|F)$ is the probability that an item belongs to cluster $k$ given that it has properties $F$, and $P_i(j|k)$ is the probability that an item in cluster $k$ has property $j$ on dimension $i$. The idea behind equation 1 is that predicting a missing property involves the summing of probabilities across multiple clusters, with the influence of each cluster weighted by its probability, given the new item. The sum of these values across all clusters is the probability that the new item has property $j$.

Clusters are learned that optimize the accuracy of predictions. The first exemplar forms its own cluster, and each added exemplar is either placed into an existing cluster or a new one that contains only itself, whichever maximizes within-cluster similarities. Thus, a new item that is dissimilar to the earlier items is more likely to begin a new cluster. The probability that a new item will be placed into cluster $k$ depends on (1) how similar the item and cluster features are and (2) the size, or base rate, of the cluster, with the item more likely to be placed into a cluster that represents more items.

Two aspects distinguish this model from the classification models described earlier. First, clusters differ from prototype and exemplar representations in that the goal of clustering is more abstract: to capture statistical structures in the environment suitable for making predictions. Interestingly, clusters sometimes mimic each of the other approaches (cf. Nosofsky, 1991), suggesting that aspects of both prototype and exemplar representations are useful.

Second, the model predicts features as well as category labels, so it can be used for nonclassification tasks, such as inference learning (see Yamauchi and Markman, 1998). In addition, it provides an explanation for how people might induce a missing feature of an exemplar when the category is unknown. Suppose that you hear an animal rustling behind a bush, and you think it is probably a dog but possibly a raccoon. What is the probability that the animal barks? In terms of equation 1, dog and raccoon are different values of *k*. Murphy and Ross (1994, 2005; Malt et al., 1995; Ross and Murphy, 1996) tested this hypothesis in a large number of studies and usually found evidence against it. Their work shows that people instead tend to base predictions on the most likely category only (dog in the previous example). Although the Rational Model was not supported, it provided a strong alternative view and has led to a consideration of when single categories and multiple categories might be used for predictions.

#### 2.29.3.2.2 SUSTAIN

SUSTAIN (Supervised and Unsupervised STratified Adaptive Incremental Network; Love et al., 2004) is a network model of category learning that shows great flexibility compared with prototype and exemplar models for two main reasons. First, like the Rational Model, it seeks to build clusters that capture regularities or structure in the environment. Second, unlike the Rational Model, this search for structure is guided by the goals of the learner. This goal-oriented learning allows the model to account for a wide variety of category learning results beyond classification.

Categories in SUSTAIN are represented by clusters. Unlike the Rational Model, these clusters are not collections of exemplars but, rather, summary representations of encountered exemplars. The clusters formed are influenced by the goals of the learner, such as increased attention to the feature (including category label) being predicted and the features most relevant for this prediction. The details of the model are complex, so we outline the main steps of performance and learning here, then turn to a simple example.

The performance, such as prediction of a feature, relies upon the clusters. The item is compared to each cluster, and the most similar cluster determines the prediction. The summary representation of each cluster includes a distribution of expectations for each dimension (e.g., how likely the different values are to occur). The item's features are compared to these various distributions, with selective attention occurring through the tuning of receptive fields on each dimension (akin to visual receptive fields that are, for example, sensitive to a small range of orientations at particular locations). The activation of the cluster increases with the similarity of the item's features to the summary representation (weighted by the selective attention weights). The different clusters can be thought of as trying to explain the input for the particular goal, with lateral inhibition among the clusters leading to a winning cluster that determines the output. Thus, unlike the Rational Model that sums over all the clusters (see equation 1), only the most likely cluster is used to determine the prediction (consistent with the Murphy and Ross, 1994, results).

SUSTAIN is biased toward simple category representations (i.e., few clusters) but does develop more elaborate clustering schemes for complex stimulus sets. Learning involves updating old clusters and developing new ones. In supervised learning, if the correct prediction is made, SUSTAIN will compare the output of the winning cluster to the target response and make small adjustments in receptive field tunings and summary representation values in the direction of the target values, if needed. These changes will lead to a repetition of the item producing a cluster output closer to the target values. If an incorrect prediction is made, a new cluster is created that is centered around the item. (In unsupervised learning, a new cluster is formed if the current item is not sufficiently similar to any existing cluster.)

This explanation is a bit abstract, so we illustrate with a simple example. Imagine there is an object that can be described by three binary features: shading (filled = 0, empty = 1), color (blue = 0, red = 1), and shape (circle = 0, triangle = 1). Thus, we can represent an (empty red circle) as (1, 1, 0). Suppose this was the first item presented, then Cluster 1 (CL1a) would simply be (1, 1, 0) as seen in **Figure 3**. Now suppose the second item was (empty red triangle), item (1, 1, 1), and it was similar enough to be put in the same cluster. The updated Cluster 1 (CL1b) would be adjusted to be (1, 1, 0.5). The last value does not represent a triangular circle but, rather, an increased probability that a new item represented by that cluster will be a triangle. If the third stimulus (empty blue circle), (1, 0, 0), is not sufficiently similar to CL1b (unsupervised learning) or does not predict the correct response (supervised learning), the model recruits a new cluster CL2a to represent that item, as shown in the figure.

Recall that SUSTAIN prefers simple cluster sets when possible. To demonstrate, if the stimuli in **Figure 3** were divided by shape into two categories, it is likely that SUSTAIN would develop two clusters, each at the center of the front and back face of the cube, (0.5, 0.5, 0) and (0.5, 0.5, 1). These would indicate a high probability of circle//triangle for the front/back cluster and intermediate probabilities for other dimensions. This is a simple clustering solution, because it strongly emphasizes just one feature.

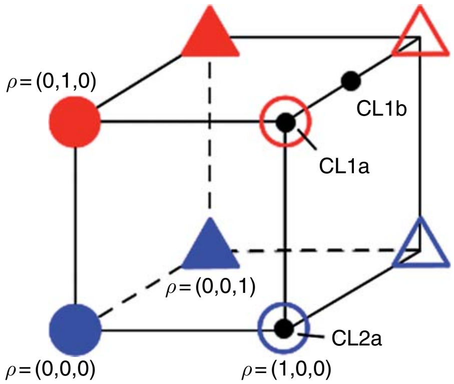

**Figure 3** Binary-valued stimuli to illustrate working of SUSTAIN. Coordinates are shading (0 = filled, 1 = empty), color (0 = blue, 1 = red), and shape (0 = circle, 1 = triangle). Black dots represent clusters CL1a, CL1b, and CL2a following the presentation of items (1, 1, 0), (1, 1, 1), and (1, 0, 0), respectively.

Like the Rational Model, the clusters in SUSTAIN adapt to their learning environment, but they are also sensitive to the goals of the learner (e.g., Barsalou, 1985; Solomon et al., 1999; Medin, et al., 2006). In supervised learning, new clusters are created in response to an incorrect decision, allowing the model to adjust to specific learning criteria. This differs from clustering in the Rational Model, where new clusters are created in response to exemplars that are generally dissimilar to existing clusters.

SUSTAIN's ability to adapt to different category functions is also seen in comparing classification and inference learning. Using a family resemblance structure (where all items are similar to a prototype for the category), Love et al. (2000) found that inference learning often led to a single cluster (i.e., close to the prototype), whereas classification tended to create several clusters per category, indicating the use of simple rules and memorization when classifying. (See also Love and Gureckis, 2005, for a related application to a real-world difference in goals.)

In summary, SUSTAIN focuses on the relationship between learning goals and category structure. In a sense, SUSTAIN generalizes the contributions of the Rational Model by proposing that, in addition to capturing the structure of the environment, categories also capture a learner's goal-specified relationship with the environment.

### 2.29.3.3 Beyond Featural Representations

Much of the current work on category learning is limited not just in how the categories are learned but also in what is learned. The categories learned in these studies are different from real-world categories in two important ways. First, the category structure is feature-based with only very simple relations among the features. Most, if not all, real-world categories have much more complex structures, and relations are essential. Second, the materials are usually devised to make as little contact with any world knowledge as possible, to allow an unconfounded examination of category learning. However, the learning of most (and perhaps all) real-world categories is influenced by our world knowledge: By minimizing the influence, we may be ignoring a major influence in the learning. We discuss each of these ideas with a brief examination of relevant models.

#### *2.29.3.3.1 Relational information*

Most of the categories studied in experimental settings with adults consist of a small number of features (usually 2–5), with some of the features predictive of each category. These simple structures, cleverly designed, are often sufficient to provide tests of particular aspects of current formal models. The underlying (implicit) assumption is either that real-world categories have such structures (which they do not) or that the learning principles derived from studying such simple structures will apply to learning more complex structures. This latter possibility remains feasible, though we present evidence throughout this section suggesting that there are many important differences. The main point we wish to make here is that the category structures that have typically been examined are a very small subset of the possible structures and do not have much to do with real-world category structures (see Murphy, 2005).

Let's take a simple example of relational structure, within-category correlations. We can classify an item as a bike using features such as handlebars, tires, and such. Bicycle handlebars include ones that are either dropped or straight, and bicycle tires include ones that are knobby or slick. However, these are not independent features: Dropped handlebars and slick tires usually go together (racing bikes), as do straight handlebars and knobby tires (mountain bikes). These within-category correlations are common in many real-world categories: They do not add to the category predictiveness of the features, but they are important as signals to additional category structure, such as subcategories. When within-category correlations have been examined in laboratory studies of classification learning, they do not appear to be learned easily, if at all (Chin-Parker and Ross, 2002). This difficulty is generally consistent with classification learning models, because the within-category correlations do not improve the classification predictiveness. Despite this unanimity of classification models and laboratory classification learning data, people do learn within-category correlations in the world. They even learn it in the laboratory when given inference learning (Chin-Parker and Ross, 2002) or when prior knowledge promotes the correlation (Murphy and Wisniewski, 1989).

The point is that as one moves to more complex relations among features, we know little about category learning. Of course, the structure of real-world categories is far more complex than a single within-category correlation: Imagine the structure for carrots or permutations. The dominant classification models are all feature based and do not allow for complex relational information (though see Pazzani, 1991). The problem is that adding relational information greatly complicates models and brings a host of additional issues that need to be addressed (e.g., Hummel and Holyoak, 2003).

#### *2.29.3.3.2 Knowledge*

What people know affects what they learn: Cricket fans gain much more from watching a cricket match than do those of us who know nothing about the game. Not surprisingly, the effect of knowledge is also true in category learning: Knowledge can have large effects on the ease of learning as well as what is learned (see Murphy, 2002: chapter 6, for a review). Continuing the example on within-category correlations, knowledge has a large effect. Murphy and Wisniewski (1989) had people learn categories containing within-category correlations. For example, their materials included correlated features that were conceptually related (for a clothing category: worn in winter, made of heavy material) or not (blue, machine washable). They found that in the absence of knowledge relating the features, classification learners did not learn these within-category correlations. However, in the condition in which knowledge related the features, classification learners did show sensitivity to the correlations. Ahn and her colleagues argue that there are so many possible correlations in the world that people cannot notice all of them, so people use their knowledge to notice correlations that are meaningful to them (e.g., Ahn et al., 2002; though see McRae, 2004).

We mention briefly three other effects of knowledge on learning. First, the learning of new categories that are consistent with prior knowledge is greatly accelerated compared with learning unrelated or inconsistent categories. For example, Wattenmaker et al. (1986) showed that categories consisting of items whose features related to a theme such as honesty (e.g., returned the wallet he had found in the park) were faster to learn than categories whose items had unrelated features. Second, even learning to classify items into categories consistent with knowledge but for which a prior concept is unlikely to be available (e.g., arctic vehicles) is faster than learning to classify into unrelated categories (e.g., Murphy and Allopenna, 1994). Third, the learning influence of prior knowledge does not restrict learning to only those features related to the prior knowledge, but generally, those are learned more quickly than the unrelated features of the items (e.g., Kaplan and Murphy, 2000).

How does knowledge influence category learning? Wisniewski and Medin (1994) suggest three important possibilities (also see Heit and Bott, 2000). First, knowledge might weight or select features of the item. Second, knowledge might allow one to infer additional, relevant features. Third, although these first two possibilities view knowledge as independent of the learning process, knowledge and learning may be more tightly coupled or interactive. Learning may influence the activated knowledge, which may then influence later learning. As one example, learners might begin to change how they interpret some features as they see how the features relate to their goal. The main point of this work is that knowledge and concept/category learning cannot be thought of separately: Our knowledge of particular concepts is intimately intertwined with other knowledge, and we use that other knowledge both to help learn new information about concepts and that this learning in turn may influence our other knowledge.

Despite this large influence of knowledge on category learning, most category learning research has examined cases in which knowledge influences are minimized (Murphy, 2005). If there are interactions between the influences of knowledge and the learning, some (unknown) part of what we learn from examining category learning in the absence of knowledge may not be applicable to the cases in which knowledge is used. In addition, there may be learning processes with knowledge that are not required in the knowledge-free classification learning experiments.

There has been some progress in considering how to account for the influence of prior knowledge on category learning in a more general way, including

Heit's Baywatch model (Bayesian and empirical learning model, e.g., Heit and Bott, 2000) and KRES (Knowledge-Resonance model; Rehder and Murphy, 2003). Space precludes much description of these complex connectionist models, but both models add nodes to represent prior knowledge in addition to the usual ones to represent the features of the items. The presented item activates its features but also activates prior knowledge that it is related to, providing an additional source of activation for the category decision. The models account for a wide variety of data. For example, KRES predicts that the learning of categories consistent with prior knowledge is accelerated compared with unrelated categories, and even features unrelated to the prior knowledge are learned. In addition, this model incorporates the interactive view between knowledge and learning by the learning influencing the connection weights between features and between features and prior knowledge.

These models of prior knowledge do not include relational representations. Relational models are beginning to be developed (e.g., Hummel and Ross, 2006; Kemp et al., 2006; Tomlinson and Love, 2006) but need also to address the pervasive influences of prior knowledge.

#### 2.29.3.4 Directions for Providing Integration

We have considered some limitations of the current category learning work both in terms of the learning tasks and in terms of the featural representations. Different means of learning about categories provide a variety of knowledge about the category not just for classification but also to support all the category-based cognitive activities. In addition, the knowledge about a category has to be intimately related to our other conceptual knowledge to be useful. What does this suggest about concept and category learning?

A main lesson that we have taken from a consideration of these various limitations is that the study of concepts and category learning needs to be integrated into other areas of cognition. Conceptual knowledge needs to support many cognitive activities, not just classification, and examining these category-based activities across a variety of domains will both point out places in which we need to further our understanding of category learning and help to make the work on category learning more relevant to other areas of cognition. Much of our learning depends on our goals, so considering more than category learning is an important part of ensuring this integration.

Murphy and Medin (1985), in a seminal paper, proposed that the study of conceptual structure could not rely on similarity to explain why objects might cohere, or go together, in a category. Although similarity might be a useful heuristic in some cases, it is too unconstrained to provide an explanation of category coherence. They proposed that the coherence of the category depended on its fit to people's prior knowledge – the naive theories people have. This proposal changes the idea that the category members are similar to that they have some similar underlying rationale. Their internal structure is defined not just by features but also by relations connecting features. In addition, their external relations are critical: They must relate somewhat consistently with other knowledge the person has. This view is often called the theory view to make clear that it views category coherence as depending upon people's theories, not simple similarity.

This proposal has had a major influence on how conceptual structure is thought about and investigated. It was instrumental in leading to much of the work on how knowledge influences category learning. We mention two interesting illustrations. First, Wisniewski and Medin (1994) gave subjects a set of children's drawings of people and asked them to provide a rule for each category; they were told either that one group of drawings was from creative children and the other from noncreative children or, for other subjects, that one group was from city children and the other from farm children. The rules generated were very different, picking up on aspects of the drawings that were consistent with some ideas of those types of people. For example, one feature was seen as a pocket, indicating detail, when it was from the drawings by creative children, but was seen as a purse when it was from drawings of city children. Second, Ahn and Kim (2005; Kim and Ahn, 2002) have examined clinical psychologists' understanding of various psychodiagnostic categories (such as depression or anorexia). Although the training they receive emphasizes a prototype representation (classification is often in terms of some criterial number of features being present), the clinical psychologists often apply their causal theories of the disorders to help diagnose and determine treatments. Thus, this theory view has led to a wealth of interesting research relating prior knowledge to concept learning. The main shortcoming of this view is the lack of specific details on how knowledge influences learning.

There are likely to be many cases in the learning of complex categories in which the constraints imposed by theories are not sufficient even for classification. For example, in learning to classify members of many real-world categories, there may be hundreds of potential features that could be important for determining category membership, so what determines which features people use? Knowledge may reduce the number of likely features and relations but still leave too large a number to consider. One possibility is that the importance of the features and relations for the overall goal of the task may provide a heuristic as to which ones are important for classification. For example, one might not be able to tell how to classify a particular math problem, but as one gets experience solving problems of that type, those aspects of the problem critical for solution may provide a good clue as to how to classify future problems. The comparison to other category members with respect to these useful features may also help to lead to a deeper understanding of why the problem is solved in this way.

It is important to clarify this suggestion and make clear how it relates to the general integration goal of this chapter. Concepts and categories support a variety of functions. The usefulness of this knowledge across the different functions provides constraints that one cannot get from a single function. In addition, the changes to the representations as one both uses and gets feedback on one function provides knowledge that can be used for other functions. For example, learning to classify complex items, with many features and relations, is a very difficult task if one relies only on feedback from the classification (which may be why classification learning experiments typically use few features and values). However, if these same categories are used for inferences or problem solving, that use provides suggestions as to what features and relations one might consider. Similarly, background knowledge can be used to help focus on relevant features and relations or even to learn new features that are important for later classifications (e.g., Wisniewski and Medin, 1994). The apparent difficulty of learning complex concepts is partly a result of thinking about it as some isolable process that relies only on classification and feedback on the classification. People have many sources of information from both the various interactions with the items and their prior knowledge to help in learning new concepts and categories.

## 2.29.4 Integrating Concepts and Categories into Cognition

We have been arguing throughout this chapter that it is important to think about concept and category, learning more broadly to integrate it into the many cognitive activities in which they play such a critical role. In this section, we illustrate this possibility by examining concepts and categories in two very different areas, problem solving and language.

### 2.29.4.1 Problem Solving

Categories play a critical role in human problem solving. Being able to correctly classify a problem as a permutations problem allows you to recall and apply the appropriate formula. In this section, we describe how category knowledge can influence various aspects of the problem-solving process, how problem categories change with experience, and how problem solving can affect the category representation.

Most models of problem solving consist of some version of the following five stages: (1) problem identification and creating a mental representation of the initial problem state and goal; (2) identifying and selecting a set of operators, procedures, or strategies to make progress toward that goal; (3) applying those operators and generating a solution; (4) assessing whether the solution satisfies the goal; and (5) storing the solution with other knowledge about the problem/category (Newell and Simon, 1972; Bransford and Stein, 1993; Pretz et al., 2003).

Categories impact all aspects of this process and are especially critical in the early stages (**Figure 4**). The process of problem identification is a classification that determines whether or not the current problem is like other problems encountered in the past. After the problem is classified, the problem solver can then recall and apply a set of procedures, strategies, or rules to solve the problem, such as recalling the appropriate formula for a permutations problem. Category knowledge may also be helpful in later stages of problem solving, such as evaluating whether or not a potential solution satisfies the known constraints of the problem type.

The problem goal is also important. Since category knowledge is used in the service of accomplishing some particular task, knowing how the goal relates to the problem features is a critical part of understanding the problem and identifying the appropriate solution procedures to solve it. As an illustration,

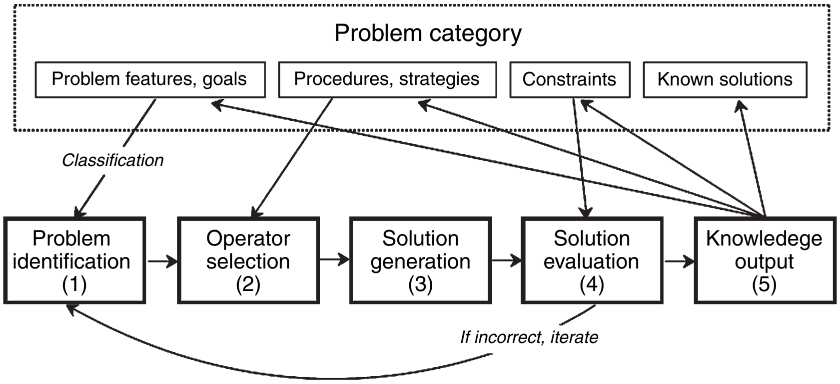

**Figure 4** Five stages of problem solving (lower boxes) and relation to knowledge of problem categories (upper box). Arrows connecting boxes in the lower portion of the figure represent the general order of processing. Arrows connecting boxes between the upper and lower portions represent interactions between problem solving and category knowledge.

imagine that, as you are ready to drive to work, you notice the lights were left on, and the car does not start. If you classify the situation as a dead car battery, you can search your relevant category knowledge, perhaps recalling that one solution is to use jumper cables and ask your next-door neighbor for a jump. However, if your primary goal was to get to work on time, you might access other relevant knowledge such as calling a friend for a ride. For categories to be helpful for problem solving, they must go beyond simple diagnostic features and include information about the problem or goal procedures or strategies to accomplish that goal, and knowledge to evaluate the solution.

#### *2.29.4.1.1 Differences between expert and novice category representations*

Much research has shown that experts categorize problems with the principle or structural features of the domain, whereas novices rely on using the surface features (Larkin et al., 1980; Bedard and Chi, 1992). Chi et al. (1981) found that when physics experts were asked to sort a set of problems into those that could be solved similarly, they sorted on the basis of the underlying physics principles, such as Newton's Second Law, whereas novices sorted on the basis of the surface characteristics, such as problems with inclined planes. The physics experts had learned to associate the deep principles with the problem features and could take advantage of this knowledge for problem categorization.

The finding that experts use the deep principles of the domain to classify and reason about novel problems has been shown in many other domains including chess (Chase and Simon, 1973; Gobet and Simon, 2000), computer programming (Adelson, 1981), electronics (Egan and Schwartz, 1979), and mathematics (Silver, 1979, 1981), among others. How does one go from a novice category representation to that of an expert? One suggestion from the problem-solving literature is that much of the learning comes as a by-product of the problem-solving activity itself (Ross and Kennedy, 1990; Cummins, 1992). There are multiple possibilities for how this can occur, including adding new knowledge to the category, modifying previous knowledge by weighting particular category features, adding constraints to the category to further specify the category boundary, deleting inappropriate knowledge, or acquiring new, more specific categories. These possibilities suggest not only that categories are a critical aspect of human problem solving but that category representations can be adapted and changed through problem solving.

#### *2.29.4.1.2 Problem solving and category learning*

Much experimental work shows that problem solving can affect category learning (Ross, 1996, 1997, 1999). For example, Ross (1996, Experiment 2a) conducted a category use experiment (similar to the ones mentioned in the section 'Beyond classification and featural representations') in which students learned to classify equations into two categories and then solve them. The solutions of the equations differed, and the question was whether this would affect the participants' category representations and influence their future classifications. **Table 5** shows a sample of the materials. Every problem had an $x$ and a $y$ variable, and half of the participants solved for variable $x$ and the other half for variable $y$. The equations were

**Table 5** Sample materials from Ross (1996)

| *Phase of experiment* | *Equation* | *Solution* | *Solve for* x | *Solve for* y |
|---|---|---|---|---|
| Study | | | | |
| Type 1 | $9 + \frac{sx}{t} = \frac{5qy + b}{f}$ | | SMD | MSD |
| Type 2 | $sp + \frac{ry}{2} = \frac{g + 9x}{b}$ | | MSD | SMD |
| Test | | | | |
| | $k + \frac{9z}{a} = \frac{s + r}{t}$ | SMD | Type 1 | Type 2 |
| | $s + \frac{2}{n} = \frac{9 + mz}{p}$ | MSD | Type 2 | Type 1 |

SMD, subtract, multiply, divide; MSD, multiply, subtract, divide. At test all subjects solved for *z*. The ''solve for *x*'' and ''solve for *y*'' labels refer to the study conditions.

From Ross BH (1996) Category representations and the effects of interacting with instances. *J. Exp. Psychol. Learn. Mem. Cogn*. 22: 1249–1265. Copyright 1996 by the American Psychological Association. Reprinted with permission of the author.

created so that those who solved for variable *x* would use a subtract-multiply-divide (SMD) solution procedure on type 1 problems and a multiply-subtract-divide (MSD) solution procedure on type 2 problems, whereas those who solved for variable *y* would use the opposite procedures on the two problem types. At test, they classified novel test problems and solved for a new variable *z*. Tests requiring a SMD solution procedure tended to be classified as type 1 problems for those participants who solved for *x* and as type 2 problems for those who solved for *y* (and vice-versa for test problems that required the MSD solution procedure). Although the two groups classified the same problems into the same categories during learning, they classified the test items into opposite categories because of how they interacted with the items. The way in which problems are solved can influence which categories people have.

Beyond traditional problem solving, Medin and colleagues show strong influences of extended interactions on how tree experts classify and reason (Medin et al., 1997; Lynch et al., 2000; Proffitt et al., 2000). Taxonomists and maintenance workers sorted a set of trees on the basis of morphological features, but each weighted the importance of those features differently, whereas the landscapers sorted more on the basis of utilitarian features, such as providing shade or ornamental quality (Medin et al., 1997). The experts' category representations were influenced by how they interacted with items in the category. Proffitt et al. (2000) found that all of the groups used ecological-causal domain knowledge in addition to general taxonomic knowledge to make inductions. These results are consistent with the laboratory results showing that experience interacting in a domain influences a person's category representation and subsequent reasoning from those categories.

The role of concepts and categories in problem solving is pervasive. For categories to be useful for problem solving, they require more than simple featural representations, including information about the goals, solution procedures, and constraints of the problem. Problem categories change with experience: There are general shifts from surface feature representations to structural (relational) representations, as well as influences of the particular uses.

### 2.29.4.2 Language

Categories are also critical in language use. We focus on one area within language performance (i.e., the encoding of syntactic number) to explore different kinds of categories, the processes that operate on them, and the functions such categories serve in language performance.

In general, the types of categorical structures necessary to support language processing seem to depart considerably from those focused on in category learning research. For example, during language production, transforming a message that is full of meaning into an utterance that is full of sound (Bock and Miller, 1991) may involve (at least) coordinating systems of categories corresponding to syntactic structure (e.g., the syntax of phrases or sentences), grammatical functions and thematic roles (e.g., subject, object, agent, patient), word types (e.g., noun, verb), word-specific grammatical information (e.g., grammatical gender and number), word meanings, morphophonology, and prosodic structure. Particular to syntactic number, the production of a lexical singular (e.g., cat/argument/dustbuster) or a lexical plural (e.g., cats/arguments/dustbusters) is thought to be rooted in a kind of categorization involving the apprehension of the referent of a noun as a single thing or more than one thing (Eberhard et al., 2005). Some categorizations are not simple: A bowl full of "fresh or dried food that is usually made from flour, eggs, and water formed into a variety of shapes" may be conceived of as a mass or as comprising individual units and so the speaker may elect to call it pasta or noodles, respectively. This categorization determines the appropriate lexical number characteristics of the noun.

Consistent with our emphasis on category use, assigning lexical number (singular or plural) is not an end in and of itself – lexical number characteristics serve the function of communicating to a listener the numerosity of referents, and they are critical in the computation of grammatical agreement (such as between a subject and a verb; Eberhard et al., 2005; but see Vigliocco et al., 1996). Grammatical agreement in turn serves important communicative functions such as linking pronouns to their referents and helping listeners syntactically bind subjects to their predicates when syntactic ambiguity arises. For example, subject–verb agreement helps disambiguate who has rabies in "The *dog* chasing the *men* that *has* rabies."

Beyond categorizing a referent as one thing or more than one thing, singular nouns in many languages divide into count nouns and mass nouns. The count/mass distinction is thought by some to reflect distinct modes of construal relevant to individuation and allows an interesting examination of concepts in language use.

Count nouns like animal(s), argument(s), and noodle(s) must have a determiner in the singular form (*Animal is fierce), are regularly pluralized, and take the quantifiers many and few. Mass nouns such as wildlife, evidence, and pasta do not need to take a determiner in the singular (Wildlife is flourishing), are not regularly pluralized, and take the quantifiers much or little. What are the psychological implications of this distinction? The cognitive individuation hypothesis proposes that count nouns denote individuated entities and mass nouns denote nonindividuated entities (Mufwene, 1984; Wierzbicka, 1988; Jackendoff, 1991; Bloom, 1994; Bloom and Kelemen, 1995; Bloom, 1996; Wisniewski et al., 1996; Wisniewski et al., 2003; Middleton et al., 2004). The class of individuated entities includes common objects such as cats, blenders, and airplanes but also includes things bounded spatially (even to an absence of matter, e.g., a hole, Giralt and Bloom, 2000) or temporally (events, such as a footrace or a party; Bloom, 1990). Individuation can apply to entities linked by common fate or goal (e.g., a gang, a flock) or common purpose (a bikini may be conceived as an individual because the two pieces perform one function; Bloom, 1996), as well as from a variety of other factors (see Goldmeier, 1972; Jackendoff, 1991; Soja et al., 1991; Bloom, 1994).

#### *2.29.4.2.1 Categorization and cognitive individuation*

The process of individuation is not just a categorization based on the physical features on an entity. Cognitive individuation involves active construal of an entity, which can be flexibly applied and has important consequences. Specifically, if a person individuates an entity, that person predicates that features of the entity must hold specific functional relationships to each other (Wisniewski et al., 2003; Middleton et al., 2004). For example, if one individuates a configuration of wood as a table, one is comprehending how the configuration of four upright pieces of wood and a horizontal wooden plane go together to support the important function of supporting stuff. This construal does not allow pieces to be randomly removed or rearranged. In contrast, if one categorizes the table as a nonindividuated entity, one might focus on the material rather than the configuration. If so, one might predicate the important property of 'is flammable,' which does not depend on the configuration.

Evidence that individuation is a flexible process in which different outcomes (e.g., individuation vs. nonindividuation) can arise given the same stimulus was reported by Middleton et al. (2004; Experiment 4). One group of participants viewed a bounded pile of coarse decorative sugar in a box (a novel stimulus) and chose to refer to it with count or mass syntax. A second group viewed the stimulus, followed by a mode of singular interaction where they repeatedly took an individual grain and placed it through one of several holes in a rectangular piece of cardboard. Participants in this second group were more likely to refer to the stimulus with count syntax than the control group. This demonstrates that individuation is not directly tied to the features of a stimulus. Rather in this case, how a person interacted with the entity was related to its individuation status, and this in turn was reflected in the syntax they used. This point introduces the functionality of the count/mass distinction: Using count or mass syntax provides a means to communicate distinct construals of an entity in terms of individuation. This may be particularly useful when the mode of construal as an individual or nonindividuated entity is atypical for a referent. Consider 'too much woman' as in "[S]he's [Jennifer Lopez] too much woman for that piece of snore [Ben Affleck]." Using mass syntax with what is typically a count noun (i.e., woman) allows the speaker to communicate construal of womanly attributes as lying on a continuum, with Jennnifer Lopez falling on the high end (at least, too high for Ben Affleck). Attributes of other common objects can be construed as lying on a continuum, as communicated in "[M]any border collies are destroyed because they proved to be too much dog for their owners," where 'dogness' may be some value along a continuum composed of activity level, obedience, ferocity, and so on. (These examples are extracted from American Web sites.)

Language may not just reflect concepts, it may influence the representation of concepts. The boundaries of basic categories may not be invulnerable to the effects of language (e.g., Boroditsky, 2001; Gordon, 2004). As one example, Imai and Gentner (1997; see also Imai, 1995) showed that Japanese- and English-speaking children differentially weighted the importance of a similar substance and similar configuration when choosing which item was the same as an example. This issue of how language may lead to differences in categorical structure is potentially very important inasmuch as we learn a large proportion of our concepts through communicating by direct instruction or implicitly through conversation (see Markman and Makin, 1998).

## 2.29.5 Conclusions

In this chapter, we have presented an overview of research on concept and category learning, but we have done so from a particular perspective. Although classification models and experiments have dominated the laboratory work in this area, some recent work has questioned both the focus on classification and its use of simple featural-based items. This work has promoted a broader examination of concept and category learning in three ways. First, a variety of category-learning paradigms are being investigated, along with models that can perform other category functions besides classification. Second, the complexity of the material being learned has increased to include relational categories, prior knowledge, and nonobject categories. New models are also being proposed to begin to account for these complexities. Third, this perspective encourages a consideration of how concept and category learning may be viewed in other areas of cognition. These advances should provide a richer, broader view in the future, so we can better understand the learning of concepts and categories and their crucial role for intelligent thought and action.

# 2.30 Language Learning

**G. O. Deák and A. Holt**, University of California at San Diego, La Jolla, CA, USA

## 2.30.1 Introduction

### 2.30.1.1 What Is Language, and What Makes It a Unique Learning Problem?

Language presents an unparalleled problem for any account of human learning. As adults we have little insight into, or memory of, the learning task we faced during infancy and early childhood. Adult language processing is normally so efficient that we cannot introspect the cognitive or neural processes that accompany such prosaic language-uses as making small talk or listening to a story – processes that include attention-modulation, classification, retrieval, inference, and cognitive control.

By examining language development in infants and children we may gain insight into the challenges, progress, and process of this singularly important and universal learning task. The overall topic is extremely complex, and a thorough treatment would include detailed consideration of phenomena including multilingualism, second-language learning, language loss, aging, developmental disabilities, genetics, and animal learning. Due to space limitations, however, and the intricacies of each of these topics, this overview will focus on the paradigmatic phenomenon of first-language learning by healthy infants and children.

To begin, we must address the thorny question of what makes language a unique modality for social information, and why language acquisition might be a singularly difficult problem for the cognitive and social sciences.

### 2.30.1.2 Why Is Language Hard to Learn?

Human languages (numbering between 3,000 and 8,000, depending on definitions and some unknowns) share some basic features. The world's languages differ in many regards: the set of sound-distinctions that change the meaning of an utterance (or movements that change the meaning of a sign); how meaning-elements can be altered and combined to express complex meanings; what specific meanings are encoded by words (and by derived words, phrases, or idioms); and how various speakers and listeners in a community may use language for different purposes in different situations. Given the stunning variability of the world's languages, effort has been made to identify linguistic universals. The broadest universals are: hierarchical structure (e.g., rules for combining, changing, and deleting/reducing phonemes (speech sounds), morphemes (smallest meaning units), words, and phrases); arbitrariness of form; modifiability of forms (by assimilation, simplification, or metaphor); and combinatorial complexity. Other universals are more specific. For example, despite phonological variability across languages, there is a common ordering by which, for example, vowels are accrued. As another example, all languages can somehow refer differently to *self* versus *other*. Other universals are more like parameters that take one of several 'values,' and these must be learned by children presumably from culture-specific input (as opposed, in the case of 'true' universals, to learning from some universal experiences).

Despite these universals, the profound differences between languages make it hard to specify children's ability to learn language. Children must be prepared to learn language with phonological tone variations (e.g., Mandarin dialects; Yoruba) or percussive 'click' or air-ingestive noises (Sindhi, Xhoso, Zulu), or languages like Hawaiian with very limited phonology. In terms of morphology (i.e., patterns of variation in word structure), children must be prepared to learn languages with limited verb morphology but extensive use of auxiliary verbs, like English, or languages with extensive verb inflections and vowel harmony (i.e., where the root vowel changes the verb's inflections), like Hungarian. Specific examples abound: children learning English must make some verbs reflexive by adding '[possessive pronoun]-self,' whereas children learning Hebrew must learn to affix /hit-/ to most verbs – unless the first sound is a fricative (e.g., /s-/), in which case there is a complex switching of phonemes in the root verb and inflected affix. Mohawk uses a morphological inflection /-atat-/ to indicate reflexive action, but also has a 'semireflexive' morpheme to indicate relatively high involvement or self-generation of an activity. Many more examples can be found in syntax: for example English-speaking children learn that roles (subject, object) are cued by word order; Italian-speaking children must learn to use other cues (e.g., animacy). In semantics, English-speaking toddlers must learn that 'diaper' and 'underwear' refer to things with similar shapes that cover the same body parts but different material and contexts of use, whereas 'hat' and 'gloves' differ in shape and body parts but share material and contexts of use; and 'clothes' refers to all of these but is a mass noun (which usually refer to uncountable things like liquids). Finally, in pragmatics Spanish-speaking children must learn different second-person pronouns for adults and peers; Japanese children must learn different honorifics for men and for women; English-speaking children may say 'you' in all cases.

Thousands of between-language differences like these highlight the complexity of the learning problem faced by children and the difficulty of specifying what children might be prepared to learn *a priori*. Yet even within a language the learning problems are daunting. For example, the regular English past tense inflection is an affix /-ed/ after the main verb. But in fact the phonological form can be /-d/ (e.g., 'bugged'), /-t/ ('marked'), /-ed/ ('blasted'), or /-id/ ('melted'). Moreover, different speakers or dialects use different variants of the same ending, *and* the phoneme before the ending changes the sound of the ending. Thus, in spoken language there is much more variability of form than in writing. Also, there are many irregular past-tense forms: 'run'/'ran' or 'swim'/'swum' (medial vowel change); 'is'/'was' (initial consonant-vowel change); 'go'/'went' (different word), etc. Ignoring the reasons for these differences, from the learner's position most of these are at best only loosely predictable. They must be memorized as exceptions, or inferred from subtle patterns (e.g., verbs ending in /-ing/ ['bring'; 'sing'] have a medial vowel change (/-i-/ to /-u-/).

Children sometimes learn these exceptions early: for example 3-year-olds are sensitive to a constraint on pluralizing the head of a compound noun, which sounds grammatical for irregulars ('mouse-eater' to 'mice-eater') but not regular nouns (e.g., 'rat-eater' to *'rats-eater') (Gordon, 1985). No one teaches children this explicitly, but by age 3 children have begun to learn not only the obvious rules but less-obvious conditional regularities like these. This illustrates children's preparedness to acquire a massive hierarchical system of probabilistic heuristics and exceptions for allowable forms of words, phrases, and sentences. There is much evidence that 2- and 3-year-olds are learning to treat language as an abstract, modifiable, combinatorial system of conventional forms, transformations, and uses (Gordon, 1985; Clark, 1997; Tomasello, 1999; Bates et al., 2003). Yet 3-year-olds still have much to learn. This is a critical point: it is often assumed that children are astoundingly good language-learners despite the intrinsic difficulty of the task. Certainly the task seems difficult, but compared with what? Vision? Motor skills? Such questions are difficult to answer because they require an information-theoretic comparison of different learning problems, and making any such comparison in an even-handed way would be difficult or impossible. Similarly, it is nearly meaningless to claim that children learn language 'quickly.' Compared with what? Learning calculus? Learning to drive? Any such comparison is so problematic that the absurd difficulty of the question becomes obvious. Children require a good five years of steady, ample language input (for hours every day), with massive social and physical support, to achieve fluency. The cost of failure is exclusion from social interaction and information. Stated like this, it becomes hard to defend any assumptions about the specialization of language-learning processes.

To move from fuzzy assumptions toward a clearer understanding of the language learning problem and how children solve it, the following sections summarize what infants learn in the first year, what toddlers learn in the second and third years, what preschoolers learn in the third and fourth years, and what older children continue to learn thereafter. A critical issue throughout is how these changes differ from language to language. It is critical because we want a valid characterization of the universal capacity for language learning. First, though, we address two factors that are part and parcel of that capacity: the ecological context of first-language learning and the relation of language learning to the human genome.

### 2.30.1.3 The Context of Language-Learning 'in the Wild'

Language is used differently in different communities, and this is part of the learning problem for infants. Infants and toddlers are not consciously reflecting on language as a learning 'problem' akin to some monumental homework assignment. Their motives are to affiliate with caregivers, maximize hedonic states and minimize unpleasant ones, predict what other people will do, and join in positive social exchanges whenever a felicitous opportunity arises. Language is an integral part of the events that fit these motives: it is present in all sorts of social events from birth and even before (DeCasper and Fifer, 1980). The point is often forgotten: infants are not *trying* to learn language. They are trying to satisfy dynamic endogenous needs and modulate their affective states. This requires action, reaction, and learning about dynamic social environments. Language is a diffuse category of information that variably (but not randomly) occurs concurrently with social events. Sometimes language information is correlated with ongoing social events and variables, as during one-on-one baby-talk. Other times it is independent of the infant's experience, as when a caregiver chats with another adult while feeding the infant. Thus, an infant's language input is *sometimes* tailored to her ongoing experience. Sometimes it is not.

Thus, to understand how infants and children can acquire any language we must consider in part the range of language-uses in infants' social environments. For example adults modify their speech when speaking to infants, and infants prefer to hear infant-directed speech (Cooper and Aslin, 1990; Pegg et al., 1992). It therefore seems infant-directed speech should facilitate infants' language learning, and in fact it can facilitate adults' learning (Golinkoff and Alioto, 1995). However, there are language communities where adults do not address babies. Still, infants in these communities seem to acquire language at about the same rate as infants who regularly hear infant-directed speech (Lieven, 1994), though they might experience some delays in productive competence (Brown, 1998). Thus infant-directed speech is not a 'hard' prerequisite of learning, although it might accelerate *some* aspects of language acquisition.

The points are that (1) all cultures do not communicate with their infants in similar ways; (2) it is not obvious how different cultural practices influence language learning: we must test these empirically (e.g., Bornstein et al., 1998). Other examples in the following sections show that our intuitions of 'what matters' in language learning often lack empirical support.

### 2.30.1.4 How to Think About Genetic Factors in Language Learning

There is no doubt that language is a species-specific capacity. Some universal language features are not acquired by any other species, however smart their members are in other regards. Specifically, hierarchical structure, modifiability/extensibility of forms, and combinatorial complexity are all absent or profoundly limited in our nearest evolutionary neighbors, the great apes (Terrace et al., 1979; Deacon, 1997). What, then, allows learning in nearly every child in every human community?

Explanations from genetic causes have limited power to explain language outcomes (Braine, 1992; Elman et al., 1996; Karmiloff-Smith, 1998). Certainly language learning requires genetic coregulation of brain development that leads, in a protracted and dynamic cascade of multifactorial changes, to particular information processing phenotypes. Yet that claim is very different from a stronger claim, that some specific evolutionary adaptation(s) were propagated in our ancestors *because they coded for* specialized, species-specific (and adaptive) language phenotypes. That is possible but entirely hypothetical. Nevertheless, strong claims for *specialized* genetic bases of language have been made, buttressed by reference to the well-publicized discovery of a family with many members who have severe language deficits (Gopnik, 1997). Affected family members shared a point mutation (i.e., single-amino-acid substitution) of a gene in chromosome 7 (Lai et al., 2001). The gene, dubbed FOXP2, induces RNA transcription to affect the expression of an indeterminate number of other genes, including some that code for proteins that affect neural structures (e.g., calcium channels). The downstream effects of FOXP2 mutations have been hotly debated. Vargha-Khadem et al. (1998) found differences in several brain regions including Broca's area (left inferior-frontal cortex), which is nonexclusively involved in language production, and caudate nucleus (in the basal ganglia), which is involved in motor coordination and which communicates with frontal cortex. Both changes might explain the profound speech deficits in affected family members. However, those deficits are hardly isolated: affected family members also show generalized motor coordination deficits. Given that language production is an incredibly elaborate feat of motor coordination, one would expect *general* motor problems to manifest as speech deficits. Another finding is that most affected members show mild verbal *and* nonverbal mental retardation. This is not surprising because a transcription factor could have widespread effects on neural development.

Comparative studies further complicate the FOXP2 story. Multiple species – mice, for example – have versions of FOXP2. Mice FOXP2 differs from human FOXP2 by three base changes (i.e., amino acid) (Enard et al., 2002). However, two of these are unique to humans and hypothesized to have evolved in the last 200 000 years. Thus, although FOXP2 interacts with brain development in complex ways to produce many cognitive and behavioral effects, it is possible that recent mutations lead to new hominid neural and cognitive phenotypes that 'tipped the scale' to permit, among other cognitive capacities, language. It is also possible that the correlation is spurious.

In sum, although genes must be related to language learning, researchers have only recently started asking more sophisticated questions about the relations: what role do FOXP2 and other genes play in emergent cascades of neural and neurochemical processes during brain development? How are the neural networks that develop for association learning, perceptual-motor learning, and social-information processing altered by the coactivation of mutated gene forms? Such questions are central to our eventual understanding of language abilities and their expression as developmental products. However, current answers to these questions are almost pure speculation.

### 2.30.1.5 Are There Critical Periods for Learning?

There is a popular idea that language fluency can be attained only during a limited window of age, after which brain plasticity becomes reduced and fluency is difficult or impossible to achieve (Lenneberg, 1967). This is consistent with evidence of partial reduction in plasticity with age (Stiles, 2000) and with computational models wherein early input patterns have a greater effect on learned network weights than later input patterns (i.e., 'starting small'; Elman, 1993; Smith et al., 2001).

Most evidence for a critical period in language learning comes from studies relating L2 (second-language) competency to age-of-acquisition, controlling for years of exposure. (Critical periods in phoneme discrimination are discussed in the section titled ‘Classification problem: speech sounds in the infant’s sound-scape.’) Johnson and Newport (1989), for example, tested adult Korean and Chinese immigrants on English syntactic distinctions. They found a linear decline in competence with increasing age of acquisition, from 8 to 39 years, but no difference in starting ages ranging from 3 to 7 years. This suggests a gradual, continuous decline from about 7 years to adulthood in the capacity to master syntactic details of a new language.

Subsequent studies have shown that it is difficult to predict what syntactic competencies will be compromised by missing early experience. Mayberry and Lock (2003) compared adult English-speakers to adults who learned English in late childhood after learning (1) a signed language, or (2) a non-English spoken language, or (3) no language (as profoundly deaf infants in speaking family). Non-language learners were impaired in processing all sentence types, including simple ones. Early signers or non-English speakers were compromised only in processing complex or noncanonical sentences, especially dative alternations (“The father gave a boy a dog”) and relative clauses (“The boy who is chasing the girl is happy”), both of which can be considered generally difficult English syntactic structures. However, performance on complex sentences did not differ between the latter groups, suggesting that modality of first language has little effect on what forms are easier or harder to learn in L2.

Despite such converging evidence for critical period effects in articulation and syntax, the exact nature and cause remain controversial. Many studies do not document or factor out the learning conditions of immigrants of different ages, but these conditions are quite important: child immigrants are often immersed in school, whereas adults might spend time with other L1-speaking adults and receive far less L2 input (Stevens, 1999). In fact, some researchers argue there is little or no compelling evidence of critical periods for language (Birdsong, 1992; Flege, 1999). For example, a study of U.S. census data from a large sample of Spanish- and Chinese-speaking adults found that educational attainment (in U.S. schools) accounted for more variance in self-reported English fluency (26% and 42%, respectively) than age of arrival (6% and 9%, respectively) (Hakuta et al., 2003). Notably, the modest (<10% of variance) schooling-independent effect of age showed no inflection during a particular age range: the function was nearly linear, indicating no discrete cutoff in learning capacity associated with, e.g., puberty. However, Stevens (1999) also used census data and found subtle nonlinearities when regressing the probability of immigrants responding that they speak English ‘very well’ or ‘well’ against age of immigration, with the greatest change between 1 and 7 years of age. However, because census methods have limited sensitivity and validity, and because behavioral evidence shows no age range during which L2 learning rapidly declines (Johnson and Newport, 1989), we tentatively conclude that there is no narrow period of development (i.e., 1–3 years) during which language learning becomes crystallized or limited. Future research could tackle intriguing questions, such as why some adults learn L2 and achieve complete fluency, but others learn L2 during adolescence and never approach fluency.

### 2.30.1.6 Summary

The past two decades have shed considerable light on some *general* questions about the human capacity to learn language. From comparative studies we have learned that, although some nonhuman animals can learn and use up to a few hundred abstract symbols and respond correctly to short, simple, concrete sentences (Savage-Rumbaugh et al., 1993), there is no evidence they can flexibly and productively use symbols for a wide range of meanings (e.g., abstract/nonphysical concepts) or truly flexible syntactic structures, not to mention morphology. Nor do nonhuman animals show prosaic language uses like word play, commenting on absent referents, metaphor, humor, or nonliteral speech.

It seems clear that there is no precipitous critical period for learning, although there is some evidence for a gradual decline in the probability of mastering subtle phonological and syntactic distinctions of a new language, over starting ages ranging from about age 7 years to adulthood.

Finally, recent studies of language change provide fascinating insight into children’s role in language evolution (i.e., creolization): specifically in systematizing language structures (Senghas and Coppola, 2001; Senghas et al., 2004). For example, creole-signing children spontaneously create syntactic distinctions that mirror distinctions in natural languages (e.g., manner vs. path of motion), whereas those children may conflate manner and path of motion in their nonlinguistic gestures (indicating that the distinction is not *obligatory* but specially formalized in the new language). Other studies indicate that the SVO (subject-verb-object) word order canonical in English, for example, is not a 'natural' order: new signers may create an SOV sign order (Sandler et al., 2005).

Keeping in mind these concerns and conclusions about the learning environment and the genome in first-language learning, we now describe critical findings about how children acquire fluency. The results are organized by age divisions that are roughly defined by changing age-related learning tasks and social contexts. Despite this organization, much of language learning will be ongoing and continuous rather than stage-like. In all that follows, it can be assumed that a developmentally constant demand is to understand what other people are trying to communicate, and master enough abstract language forms to interpret others' meanings and to produce one's own messages such that one's intentions and perspectives can be inferred by others. It should also be assumed, despite some organization into distinct sections, that children do not learn separate aspects of language (syntax vs. morphology vs. pragmatics), rather that these theory-laden and historical distinctions are typically interrelated in human language processing data (Bates et al., 2003).

## 2.30.2 What Is Learned in the First Year

### 2.30.2.1 Classification Problem: Speech Sounds in the Infant's Soundscape

Languages do not use all the same speech sounds. Adult speakers of language X cannot always pronounce, or even discriminate, some phonemes of language Y. For example English voiced bilabial consonants form two phonemes, [b] and [p], that differ only in voice onset time (VOT, or the time between onset of vocal cord vibrations and air release). By contrast, in Thai the same spectrum is divided into three phonemes. English-speaking adults perceive the VOT spectrum as two discrete categories, with a high-entropy region around the /b/–/p/ distinction, but do not perceive a third category in the region of the added Thai contrast. How, if adult speakers cannot even perceive all phonemes, do infants learn whatever complement of speech-sound distinctions is relevant in their language?

During the third trimester of gestation the fetal auditory system is sufficiently developed to begin learning some abstract properties of speech sounds produced by the mother. Although the amniotic sac filters the acoustic content of speech, enough invariants are retained in this filtered signal that, after birth, neonates prefer the sound of their mother's voice (DeCasper and Fifer, 1980). Neonates also perceive some phonetic distinctions such as the /b/–/p/ VOT contrast (Eimas et al., 1971). This suggests that the extensive and well-demonstrated plasticity of auditory cortex (Ohl and Scheich, 2005), which begins prenatally, responds in humans to acoustic invariants of speech.

During the first few months infants become sensitive to differences between phonemes (consonants and vowels), including differences in place of articulation and VOT (Trehub, 1973; Eimas, 1974). Phoneme perception develops such that by 9–12 months infants are sensitive to native contrasts but less sensitive to nonnative contrasts (Werker and Tees, 1999). Werker and Tees (1984) found a decline from 6 to 12 months in English-learning infants' discrimination of a Hindi /Ta/–/ta/ contrast and a Nthlakampx /k'i/–/q'i/ contrast (defined by place of articulation). These distinctions (unlike, e.g., /ba/–/da/) are also subtle for nonnative adults (Werker and Tees, 1999), but can be learned with practice (McClelland et al., 2002). This suggests a sensitive period in phonological development. Phonological processing difficulties for L2 distinctions might, in some cases, lead to larger difficulties with speech processing that resemble L1 language delays (Tallal, 2004).

Despite evidence for a sensitive period in phonological development during the first year, adaptation of the auditory system to language-specific input begins well before 9–12 months. Within their first few days infants discriminate native (French) from foreign (Russian) speech (Mehler and Cristophe, 1994), though discrimination depends partly on how phonologically different the languages are (Nazzi et al., 1998). Whatever neurological changes accompany 9- to 12-month-olds' loss of sensitivity to nonnative contrasts, it is not the case that younger infants are insensitive to native speech features.

#### 2.30.2.1.1 *What categories are infants prepared to learn? Insights from signed languages*

To gain insight into what is distinctive about learning to perceive speech, we can consider how infants learning signed languages acquire the basic linguistic units, that is, motor forms including hand shapes, manual motions, and other body motions (e.g., facial gestures). In what ways, if any, has brain development evolved to favor processing and learning of speech sounds over other modalities?

It is not clear that language learning is at all specialized for speech. Petitto and Marentette (1991) argued that deaf children learning signed languages begin manual 'babbling' by 10 months or earlier. The emergence of a production distinction between signing and gesturing suggests prior perceptual analysis of hand morphology of signs. How young can infants perceive differences in hand shape that carry meaning differences in a signed language? Schley (1991) found 3-month-olds could discriminate at least one hand-shape difference. Though this is not conclusive it suggests there is no great delay in perceptual learning of language-relevant forms in nonspeech modalities. Further, Baker et al. (2006) suggest a critical period in acquiring hand-shape phonology: hearing infants at 4 months classified same- from different-shape tokens (from ASL); 14-month-olds did not. The timing of this loss of sensitivity is roughly similar to loss of nonnative speech sound sensitivity (Werker and Tees, 1999) and is further supported by evidence that older infants learning spoken language lose the tendency to interpret novel gestures as symbolic (Namy and Waxman, 1998).

### 2.30.2.2 Beyond Phonology: Finding the Words

When do infants begin to perceive larger units – specifically, combinations of speech sounds that we hear as words and phrases? This has been a major topic of research in the past decade. For example Jusczyk et al. (1993) found that infants around 7 months discriminate (and prefer) the stress pattern of their native language (e.g., strong-weak in English, e.g., 'mother'; 'bottle'). This preference could help infants parse words in the speech stream; a critical ability because there are no clear acoustic markers of the boundaries of words. How else might infants learn to separate words and inflections in the ongoing speech stream?

Another source of word-boundary information is the likelihood that two phonemes will occur in sequence within some word in a given language. Consider the phrase 'pretty baby,' which has a word boundary between /-y/ and /b-/ but, for all the infant knows, might be three words (e.g., 'pritt ebay bee'). However, the probability of the phoneme sequence 'eeb' in English is much less than the probability of 'tee' or 'bay,' so the former parsing is more likely. Infants can learn such differences in transitional probabilities within minutes, simply by listening to an artificial language with controlled transitional probabilities (Saffran et al., 1996). Thus, before their first birthday infants encode cues to the structure of words. These learning abilities are not specific to word-learning nor to humans: infants can learn analogous transitional probabilities in musical motifs (Saffran et al., 1999) or sequences of visual shapes (Kirkham et al., 2002). Also, tamarin monkeys can learn transitional probabilities in speech phonemes (Hauser et al., 2001). Thus, however important the phoneme-sequence-learning capacity is, it is not sufficient for human speech processing. Also, infants might learn words spoken in isolation faster than embedded words (Brent and Siskind, 2001), suggesting that word segmentation is, despite sequence-learning abilities, resource demanding and/or error prone.

### 2.30.2.3 First Words: Content and Conditions of Learning

#### *2.30.2.3.1 What do infants know about words?*

Deciphering the speech stream involves more than segmenting individual words: children need to associate certain sequences of phonemes with contexts of use or kinds of referents. How do infants learn word meanings? Infants by 4 months attend more to the sound of their own name than another name with the same stress pattern (Mandel et al., 1995). By 7 months such preferences extend to high-frequency words (e.g., 'cup'; Jusczyk and Aslin, 1995). By 11 months infants represent the phonological details of familiar words (Swingley, 2005). How readily do infants learn such representations? Eight-month-olds, after hearing a word several times, discriminated it from other words as long as two weeks later (Jusczyk and Hohne, 1997).

It seems infants can learn and remember sounds of specific words several months before they start using them productively. However, increased attention to familiar patterns is not the same thing as symbolic understanding. When do infants learn to associate words with object types, people, events, or properties? At 8 months infants show a slight tendency to associate an object that was recently paired several times with a novel word, but only if the speaker moved the object in synchrony with saying the word (Gogate and Bahrick, 1998, 2001). The importance of intermodal synchrony underscores the fragility of infants' word-referent associative learning. By 11–14 months, infants are sometimes above chance at attending to an object previously paired with a novel word 6 to 9 times (Woodward et al., 1994). However, it is unclear how much (or little) input is needed for various referents or situations, and whether infants learn anything beyond a weak intermodal association (Shafer and Plunkett, 1998). In other words, we still do not know when and how infants learn words as abstract symbols.

In interpreting all this literature a caveat is in order: much older preschoolers are sometimes insensitive to gross word-form violations (Barton, 1980), suggesting that phonological/lexical knowledge may remain immature long after infancy. The confusing range of sensitivity and insensitivity shown in various studies of infants and preschoolers (e.g., Fisher et al., 2004) demands more sophisticated models than currently exist. One issue is that infants are very sensitive to contextual factors (Naigles, 2002), so the exact conditions of input *and* of testing must be meticulously detailed and compared in order to make sense of different studies of infants' word-form knowledge.

### 2.30.2.4 Beyond Words: Learning Phrase Structure and Lexical-Syntactic Categories

Infants show some awareness of other linguistic patterns in the first year. Fernald and Mazzie (1991) showed that infants are sensitive to prosodic (i.e., melodic) contours of infant-directed utterances that correspond with different messages or meanings (e.g., approval vs. prohibition). Interestingly, prosodic patterns show some consistency across languages (Fernald et al., 1989; Grieser and Kuhl, 1998), suggesting that many societies come to exploit prosodic distinctions that are salient to infants, as a way to draw attention to distinct messages before infants can comprehend specific words or phrases.

Prosodic information might also help infants learn syntactic distinctions. Adults detect phrase and clause boundaries based on speech cues (intonation, stress, pauses, word duration), even when listening to a foreign language (Pilon, 1981). Although these cues are sometimes unpredictable or misleading, they may be more predictable in infant-directed speech (Stern et al., 1983). Several studies (e.g., Hirsh-Pasek et al., 1987; Jusczyk, 1997) indicate that 8- to 10-month-olds expect pauses at syntax-relevant clause and phrase boundaries. This preference is not specific to spoken language; infants also prefer pauses at phrase boundaries in classical music (Krumhansl and Jusczyk, 1990). Also, although prosodic structure could highlight syntactic structure in languages with strong word-order cues (e.g., English) it might be less useful in languages where syntax is carried by inflections (e.g., Hungarian; Icelandic). Still, English-learning infants as young as 2 months can use prosodic clause cues to represent two-word sequences, at least briefly (Mandel et al., 1996).

Infants in the first year might distinguish between kinds of words that correspond to different syntactic categories. Shi and Werker (2003) found 6-month-olds discriminate so-called content ('open-class') words (e.g., 'chair,' 'hide') from grammatical ('closed-class') words ('the,' 'you'), and prefer the former, even in a foreign language. No common phonological cue differentiates these word classes across languages, but some combination of cues is probabilistically available in any language (Morgan et al., 1996). The implication is that languages evolve a lexical 'division of labor *and* form,' so content words have more distinctive phonology than syntactic units. This might contribute to a developmental shift in the kinds of words infants learn as they populate their lexicon and acquire syntax (see the section titled 'New math: populating the lexicon').

It is not just that infants associate more interesting-sounding words with open-class units; they also learn sequences of words. Gómez and Gerken (2000) found that 12-month-olds developed expectations for order and repetition dependencies in small sets of artificial CVC words (e.g., 'pel' can start a sentence *or* follow 'vot'). After training, infants heard novel 'sentences' that were 'grammatical' or 'agrammatical' and listened longer to agrammatical sentences. Thus infants are sensitive to the same types of transitional probabilities between words that Saffran et al. (1996) showed for phonemes. This might support syntax learning.

This finding (see also Marcus et al., 1999) does not show that 12-month-olds have learned syntax, but that they are minimally sensitive to more- versus less-likely orderings of syllables or lexemes, given well-controlled input. Yet syntax involves more than order, and more than just CVC syllables. It involves a number of abstract categories or form classes, systematically related in various ways to other categories, under a system of complex principles and probabilities for changing and combining units. Currently we only know that infants discriminate (1) familiar from less-familiar orderings of syllables; (2) acoustic and prosodic cues that correlate with phrase and clause boundaries; and (3) phonological cues that differentiate broad syntactic categories (e.g., content vs. grammatical words). It remains unknown how this learning contributes to later syntactic knowledge in the next several years.

#### 2.30.2.5 First Uses: Reasons to Learn Language

Recall that, although language researchers describe infants as trying to solve a taxonomy of massively complicated mapping problems, that description is imposed upon the infant whose goals are to stay regulated, reduce uncertainty, and maximize hedonic states. Caregivers who help infants meet these goals sometimes emit streams of vocal noises (or gestures). Why should infants learn these? One reason must be that infants are motivated to affiliate with people, and interested in what people say. Infants must pick and choose information in rich environments. Some human features, such as faces (Fantz, 1963), voices (DeCasper and Fifer, 1980), and hands (Deák et al., 2006) tend to attract infants' attention. If caregivers also talk about their actions while infants are watching them, it can give infants good input for learning words. Hart and Risley (1995) showed that language input – amount and variability of speech – predicts infants' language skills into preschool. Similarly, Tamis-LeMonda et al. (2001) found maternal responsiveness (i.e., reacting quickly and appropriately to the infant's signals) at 9 and 13 months predicted language outcomes including age at first words and acquisition of 50 words. Notably, mothers' responses to infants' vocalizations and play prompts (e.g., acting on a toy while commenting) were the best predictors of language outcomes.

#### 2.30.2.6 Using Social Inferences to Bootstrap Learning

A major shift in our understanding of child language was sparked by evidence that early language is interwoven with intentionality (i.e., awareness of other people's mental states and emotions). Although this awareness becomes more precise and explicit through childhood, its first measurable signs emerge around 9–18 months of age.

Much research has focused on attention-sharing, periods when two or more individuals shift attention to a common focus. Such episodes facilitate communication, because the topic of conversation can be highlighted by extra-linguistic behavior (i.e., if interlocutors comment on whatever has their attention, and both are focused on the same thing, they will tend to share topic). Research and theory of the development of attention-sharing skills in infants, and its relation to language development, is reviewed by Baldwin and Moses (2001), Deák and Triesch (2006), and Tomasello (1999). In short, infants sometimes follow an adult's gaze or pointing gesture by 12 months of age, though the ability improves from 9 to 18 months (Butterworth and Jarrett, 1991; Deák et al., 2000; Brooks and Meltzoff, 2002). Infants might be either more likely to do so, or do so for longer, if the parent verbally encourages them to follow (Flom and Pick, 2003). Thus, parents' speech acts initially have an attention-modulating function for infants.

Does sharing attention conversely facilitate language development? There is no evidence of this in the first year, but early attention-sharing skills seem to support rather sophisticated inferences in the second year (see the section titled 'Inferring the meaning behind the words').

### 2.30.3 What Is Learned in the Second Year

During the second year toddlers' language will advance in several critical ways. Some burgeoning sensitivities of infants become active. Research points to advances in three major areas: lexical knowledge, pragmatics, and syntax. These areas are tightly related, but because research often treats them separately, the following section treats them (artificially) as separate.

#### 2.30.3.1 New Math: Populating the Lexicon

There has been controversy about what kinds of words toddlers first understand. The first 50 words typically include many generic object labels ('bottle'), proper names ('Lara,' 'mommy'), words for actions or modifiers ('up,' 'more'), and social routine words ('bye bye') (Nelson, 1973). One debate is whether first words are highly context restricted or under extended and, therefore, limited in abstraction. Snyder et al. (1981) found about half of 13-month-olds' first 50 words were in fact contextually restricted; yet some should be by definition (e.g., 'bye-bye,' 'peek-a-boo'). Huttenlocher and Smiley (1987) found infants rarely use labels in contextually idiosyncratic ways. Toddlers know so much less than adults about the referent categories of words that their semantic representations must be limited or distorted. Yet one study hints at fairly rapid corrections. Woodward et al. (1994) found 18-month-olds better than 13-month-olds at extending a novel word to a new exemplar like the training object. Thus, toddlers quickly learn to generalize generic words from first (idiosyncratic) referents to abstract classes and thereby reduce contextually restricted uses.

Once toddlers extend words taxonomically, they must still adjust the boundaries of the referent category. Toddlers sometimes overextend words (e.g., use 'ball' for all spheres; Rescorla, 1980) or underextend them (e.g., excluding penguins from 'bird'). Yet such errors do not indicate an inability to map words onto sensible categories. Most overextensions, for example, are based on spurious perceptual or functional similarities (Clark, 1973; Nelson, 1979). Also, there is no evidence that toddlers *typically* over- or underextend words. Many overextensions have a pragmatic basis and do not reflect systemic conceptual confusion (Thompson and Chapman, 1977). That is, when a 1-year-old calls a stranger 'daddy' she is probably not questioning her own legitimacy, but noticing some similarities between a novel referent (strange man) and a familiar one (daddy). Given the child's many lexical gaps, such remote similarities might constitute the only basis for choosing a rarified 'known' word to indicate the referent.

As children receive input they will modify the boundaries of word-meanings using factors such as typicality (White, 1982; Wales et al., 1983). However, we do not know which input factors alter these boundaries, or how.

Despite these early challenges, toddlers make rapid progress in populating their lexicons. One story is that after children learn 50–75 words their rate of word learning accelerates: the 'naming explosion.' This suggests that, after learning some symbolic mappings, toddlers achieve insight about the abstract meanings of words. We do not, in fact, know what higher-order realizations or inferences, if any, facilitate 1-year-olds' word-learning ability. Here, however, are some relevant facts.

First, 1-year-olds tend to interpret others' actions as symbolic. These include gestures as well as words (Namy and Waxman, 1998; Childers and Tomasello, 2002, 2003), so the acceleration is not strictly based on some insight about word-like sound strings. Second, many infants accelerate in word learning around 50–75 words, but others do not (Fenson et al., 1994). Thus, individual infants differ in word-learning trajectory, for reasons that remain unclear despite decades of attempted explanations (e.g., Nelson, 1979).

One hypothesized explanation is that an acceleration in word learning is related to new classification skills (Gopnik and Meltzoff, 1992). Evidence is suggestive but inconclusive. Another idea is that as children learn more words they develop more robust connections among the word representations in neural networks. As the neural representation patterns (i.e., vectors) evoked by particular words become more stable and better defined, this stability can make it easier to learn new word-referent associations (Plunkett et al., 1992; Gasser and Smith, 1998). For example, as children learn words they learn how certain word types (e.g., object labels) are associated with certain referent features (e.g., shape and material), and this can guide inferences about new word meanings (Smith et al., 2003). Thus, increasing semantic knowledge supports new word learning. This is an important principle of word learning throughout childhood and adolescence (Anglin, 1993; Deák, 2000b).

The acceleration in 1-year-olds' word learning is not uniform across kinds of words. An important finding (Fenson et al., 1994; Bates and Goodman, 1999) is that nouns dominate infants' first 50–100 words; however, relational words (i.e., verbs and adjectives) are thereafter learned relatively faster, and become a relatively larger proportion of new vocabulary. Another shift occurs after toddlers know about 300–500 words; learning of grammatical words and morphemes then accelerates. An exciting finding is that this pattern holds (in broad strokes at least) across at least a few Indo-European languages including Italian (Caselli et al., 1999; Devescovi et al., 2005), which differs from English in syntax. There are language-specific differences in vocabulary growth trends, but the relation between vocabulary growth and acceleration of relational words (first) and grammatical words (second) appears robust.

#### 2.30.3.2 Inferring the Meaning Behind the Words

In the second and third years the attentiveness that even younger infants show toward other people, especially in propensity to share attention and monitor others' emotions, becomes more sophisticated and interwoven with language. For example toddlers can use nonlinguistic social cues to reduce uncertainty of a speaker's referential meaning. Baldwin (1995) found 18-month-olds map a novel word onto whatever the speaker was attending to, not what the infant was attending to, even if they were attending to different things. Toddlers do even more sophisticated tracking and encoding of social cues accompanying others' speech acts. Akhtar et al. (1996) had 2-year-olds and two adults looking at objects in boxes. All participants looked at three objects, and then one adult left the room. The remaining adult then examined the fourth object, and the absent adult then returned, looked in the box and said, "... I see a gazzer in there!" Toddlers tended to associate 'gazzer' with the fourth object, though the returning adult never had picked it up, and the adult who picked it up had never said the word. From this it seems toddlers can infer the most plausible referent of a particular speaker's comment or label. Although this finding has invited competing explanations, converging evidence (Diesendruck et al., 2004) shows that 2-year-olds do in fact use social information (e.g., who was present when some referent was the focus of attention, the speaker's emotion while examining an object or performing an action, etc.) to associate words with referents. Toddlers also modify their own communicative behaviors to take into account an interlocutor's social knowledge (O'Neill, 1996), suggesting that they use information related to other people's mental states or knowledge in order to use and learn language effectively.

We cannot tell how reliably and accurately toddlers use social information to guide inferences about speakers' meanings. All studies are done in simplified, controlled 'best-case' environments, whereas the complex, messy world of everyday social interactions might be too variable to help toddlers make inferences. There are, however, two reasons to believe they can. First, young children with autism typically have profound deficits in joint attention and social inference skills and typically very delayed language skills in childhood and adulthood (Loveland and Landry, 1986; Mundy et al., 1990). Thus, infants who do not make use of social information have impaired language development (this is just correlational, but consistent with the hypothesis above). Second, there is naturalistic evidence that parents constrain the social context of their spontaneous communications with toddlers in somewhat predictable ways (Ninio and Snow, 1996; Pan et al., 1996). Thus, the messiness and unpredictability of everyday interactions is partly limited by parents.

#### 2.30.3.3 Combinatorial Explosion: Putting Words Together

The robust relation between vocabulary growth and acquisition of relational and syntactic words (or morphemes) extends to toddlers' syntactic competence (Bates and Goodman, 1999; Devescovi et al., 2005). Apparently toddlers need a 'critical mass' of words for objects, relations, events and states before they can assemble these units productively. Besides this regularity, how does early syntactic expression and comprehension develop in the second year?

Much work has focused on toddlers' two-word utterances. Early combinations are produced with regularity about the same time as the 50–75 word threshold, or 18–24 months. In four children studied by Bloom et al. (1975) an MLU (mean length of utterances, in morphemes) of 1.5 or better (e.g., about half of utterances having two words) was achieved around 22–24 months. Toddlers' first 2-word productions are described as 'telegraphic' because they lack grammatical words and inflections. Nonetheless, they express a variety of relations including action ('Kathryn jumps'), locative action ('tape on there'), locative state ('I sitting'), static state ('Caroline sick'), recurrence ('more milk'), possession ('Mommy sock') and others (e.g., negation) (Bloom et al., 1975). Some types of relations (e.g., action) are systematically verbalized before others (e.g., locative state), even across languages (Braine, 1976). It is unclear whether this is due to conceptual, syntactic, or motivation factors. However, 1-year-olds show some sensitivity to input in the relational meanings they learn. Choi et al. (1999) found differences in Korean and English toddlers' acquisition of spatial predicates such that Korean toddlers are more attentive to spatial relations (e.g., tight- vs. loose-fitting containment) with distinct words in Korean.

A key issue concerns the early emergence of syntactic categories in two-word utterances (Bloom et al., 1975). Such utterances are usually syntactically (and semantically) ambiguous: does 'Mommy sock' denote possession, action (e.g., putting-on), spatial contiguity, or something else? Syntax might help us disambiguate these alternatives, but are there incipient syntactic categories in toddlers' first combinations? Bloom et al. examined subjects' ordering of morphemes and substitutions (e.g., saying 'her jumps' and 'Kathryn jumps'). Such pronominal constructions suggest an intermediate step toward abstract categories like 'subject'. Two of four children were extensive pronoun users, suggesting proto-syntactic classes, but the individual differences makes interpretation difficult (see also MacWhinney, 1978, for evidence on early diversity of morphosyntactic development). Valian (1986) later showed, however, young 2-year-olds' productions of several form classes (noun, determiner, adjective, preposition, noun phrase, and prepositional phrase) to be well differentiated. Also, two-word speakers understand fully formed sentences better than telegraphic ones (Shipley et al., 1969). Thus, 2-year-olds know more about the correct syntax of individual words than it seems from the combinations they produce, and even 1-year-olds might have some rudimentary expectations (e.g., associating the first noun in a sentence with an actor; Hirsh-Pasek and Golinkoff, 1996). A critical question is how infants and toddlers acquire this knowledge. This has been controversial (Braine, 1976; Maratsos and Chalkley, 1980; Bates and MacWhinney, 1982; Pinker, 1984; Tomasello, 1992), and an adequate treatment is impossible due to space limitations. Nevertheless we will provide a historical synopsis.

Maratsos and Chalkley (1980) proposed that toddlers register long-term patterns of co-occurrence in use (and non-use) of words in particular patterns or contexts, in order to eventually learn syntactic frames. This theory, a precursor of connectionist models and early alternative to a Chomskian learning acquisition device (a mythical organ by which language input is assimilated to an innate syntax), offered a plausible means of incremental input-dependent learning. This type of account and its limits are insightfully critiqued by Maratsos (1998).

For a flavor of the history of this sort of 'nativist versus empiricist' debate, consider the controversy over children's acquisition of transformations over rules-with-exceptions. The test case is English past-tense verb forms, with a regular /t/ or /d/ suffix, but various exceptions including vowel change ('come'/'came'), consonant change ('make'/'made'), word change ('go'/'went'), or no change ('cut'/'cut'). Such messiness is hardly unique to English past-tense: English plural nouns have the same property, as do, for example, German gender categories and many other syntactic forms in many languages. The question is how children can acquire diverse forms for the same type of transformation. A relevant finding is that toddlers sometimes overregularize, producing forms like 'goed,' 'runned,' or 'breaked' (not 'went,' 'ran,' or 'broke'). Notably, such forms are often not the earliest produced; toddlers sometimes produce 'went,' then 'goed' for a while, then ultimately the correct irregular (Cazden, 1968). This right-wrong-right progression intrigues linguists because it suggests a progression from individual word-forms to a syntactic rule to rule-with-exceptions. Marcus et al. (1992) found that past-tense overregularizations are infrequent but variable across time and child, and the right-wrong-right pattern is an idealization with high variability. Also, individual overregularization rates correlate with the frequency of irregulars in the child's lexicon and linguistic environment.

How can we explain the variability of these errors across time and child of these errors? Marcus et al. (1992) argued that exceptions must become strong enough as memory traces to be retrieved before the rule is applied. This idea is only partly explanatory, but it leaves open the possibility of fleshing out the account by testing simulations of learning in artificial neural networks (ANNs). Despite early (and often spurious) objections to this approach, it is clear that many complex patterns, including overregularizations, can be modeled by ANNs (Plunkett, 1992; Hadley et al., 1998; Morris et al., 2000; Lewis and Elman, 2001). For example, a syntactic distinction considered by Chomskian theorists to be unlearnable (under 'Poverty of the Stimulus' arguments; see Pullem and Scholz, 2002, for critique) was shown by Lewis and Elman (2001) to be learned by a fairly simple ANN taking training input from natural speech samples.

Toddlers' syntactic knowledge can also be tested in experimental paradigms. For example Akhtar and Tomasello (1997) show that 3-year-olds, but not 2-year-olds, readily induce, from just a few instances, whether a novel word is transitive or intransitive. Although 2-year-olds learned that novel words referred to actions, they did not appropriately generalize their transitive or intransitive status. (Naigles, 2002, offers another interpretation.) Moreover, toddlers will accept and interpret agrammatical uses of familiar verbs (*"The zebra goes the lion") in ways that suggest fluid phrase/frame structure representations (Naigles et al., 1992). In short, although toddlers are starting to learn the syntactic properties of different words and phrases, their specific knowledge is variable, ephemeral, and unorganized by abstract distinctions such as transitive/intransitive.

## 2.30.4 What Is Learned in the Third and Fourth Years

### 2.30.4.1 Acquiring Semantic Relations

As children's vocabulary grows beyond a certain size they must work out a variety of semantic relations, such as inclusion, overlap, and exclusion. For example, are all pets animals? Could any puppy be an herbivore? Deák and Maratsos (1998) showed that 3-year-olds readily produce different labels for an item, and these respect the same semantic relations that adults recognize: if asked about a dog puppet, "Is it a cat?" children reply, "No, it's a dog!". If asked "Is it a doll?" they reply "No, it's a puppet!". The near-errorless pattern of rejections and same-category substitutions suggests that 3-year-olds – and perhaps 2-year-olds (Clark and Svaib, 1997) – represent semantic relations. As early as children know enough words to begin filling in semantic frameworks, they can constrain inferences and naming decisions.

What about adding new words to semantic frameworks? Even 2-year-olds try to make reasonable interpretations of novel words with respect to other words they know, how the word was used, and properties of the referent (Waxman and Senghas, 1992). For example preschoolers can use contrast to interpret new words (Au and Glusman, 1990): if they hear something described "not the red one, but the chromium one," they infer that 'chromium' names an unfamiliar color. Contrary to some claims (Markman and Wachtel, 1992), 2- to 5-year-olds do not by default assume that each word refers to a mutually exclusive category (Waxman and Senghas, 1992; Mervis et al., 1994; Savage and Au, 1996; Deák and Maratsos, 1998; Deák et al., 2001). However, under circumstances like high working-memory load, preschoolers may adopt a temporary mutual exclusivity approach (Liittschwager and Markman, 1994), possibly to simplify the learning task (Deák, 2000a; Deák and Wagner, 2003).

How do preschoolers eventually learn appropriate semantic relations? First, speakers sometimes couch words in meaningful information, like statements of contrast (Au and Glusman, 1990; Callanan, 1990); however, such information is not always enough (Deák and Wagner, 2003) and is more useful to older children (Smith, 1979). Second, syntactic context is sometimes helpful (Naigles, 1990), though for many words in many languages it is a very weak cue. Third, children sometimes analogize from familiar morphological (Anglin, 1993) and semantic (Johnson et al., 1997) relations, but the limits on such analogizing are not known. In short, we usually do not know how preschoolers situate a new word in an existing semantic framework.

### 2.30.4.2 New Uses of Language

Preschool children's language skills develop in the service of social knowledge and interaction. Different language communities value different linguistic skills (Heath, 1983), and 3- and 4-year-olds are improving at using language for different purposes (i.e., genres such as narrative, conversation, or teasing), in different contexts (e.g., home vs. school; mealtime vs. circle time) and with different interlocutors (e.g., siblings, peers, parents) (Dunn and Shatz, 1989; Dunn, 1996; Slomkowski and Dunn, 1996; Pan and Snow, 1999). Navigating these different contexts requires very flexible linguistic skills, and although preschoolers are not yet fully fluent, the preschool years bring great advances in the ability to use language appropriately in different situations.

## 2.30.5 What is Learned in Later Childhood

### 2.30.5.1 Learning the Nuances

A cursory survey of the child language literature indicates that children show basic fluency by 4 years of age and mastery of basic morphological and syntactic structures by about 5 years.

What remains to develop is the ability to apply basic linguistic knowledge in contexts that are more challenging or complex, or that require integration of linguistic and paralinguistic (and nonlinguistic) information within and between utterances. For example, Campbell and Bowe (1983) told children stories with a low-frequency homonym (e.g., during a car trip a "hare ran across the road"). Children were shown to interpret 'hare' in its dominant meaning (i.e., 'hair'), though this interpretation was nonsensical. Although children have difficulty learning homonyms (Doherty, 2004), and answering ambiguous questions (Waterman et al., 2000), this particular error involves integrating information across utterances in order to interpret (i.e., represent meaning of) a statement. Similarly, 6-year-olds have trouble flexibly attending to paralanguage and semantic content to interpret mixed messages (e.g., "My mommy gave me a treat" said in a sad voice); they tend to rigidly attend only on the most salient kind of information (Morton et al., 2003). This might explain older children's difficulty understanding jokes, irony, and sarcasm. In general, as children get older they can make more precise and context-appropriate inferences about a speaker's meaning, while maintaining syntactic, semantic, and pragmatic coherence over longer passages of conversation or narrative. This expansion in the 'scope' of linguistic performance is seen in semantic, syntactic, and discourse processing.

#### 2.30.5.1.1 Learning the nuances of relational semantics

Children sometimes have difficulty inferring the extensions of semantic relations, especially when novel words are involved. Class inclusion relations (inclusion, overlap, and exclusion) are among the simplest between categories (though not the only ones; e.g., Lakoff, 1987). Thus, the assertion "some fish are eaten" requires representing some overlap between two classes (fish and food).

Recall that by 3 years children can use familiar words in semantically appropriate ways (Deák and Maratsos, 1998). By 4–5 years they can infer the relation of a novel word to familiar ones based on class inclusion statements. For example if told "A *pug* is a dog" (where *pug* is novel), kindergartners usually infer that a pug must be an animal, but do not infer that a pug is a dog if told "A pug is an animal" (Smith, 1979). Still, the use of semantic information improves with age. Deák and Wagner (2003) attempted to teach children several novel words and the relations between them using class-inclusion statements. Four- and 5-year-olds learned few relations, whereas 6- and 7-year-olds learned most. It is unknown why older children are better at using direct input to learn semantic relations. Perhaps they sometimes analogize from familiar semantic relations (Johnson et al., 1997).

#### 2.30.5.1.2 Learning complex online syntactic judgments

Another synthetic linguistic skill is interpreting syntactic relations in the 'real time' of conversation. Adults quickly and reliably determine when a sentence is irreparably ungrammatical, as from an agreement error. However, adults can also withhold judgments in the face of an ambiguous sentence until all 'legal' interpretations of syntactic structure have been checked. For example in an auxiliary omission error such as "Mrs. Brown working at the library called home to say she would be late," adults can withhold judgment until the end of the sentence (Blackwell et al., 1996). Children, by contrast, prematurely try to resolve syntactic ambiguities before parsing is complete.

For instance, Trueswell et al. (1999; Hurewitz et al., 2000) demonstrated that 5-year-olds prematurely resolve a noun-modifier clause (e.g., "Put the frog on the napkin in the bowl") as destination-marking prepositional phrase. That is, they interpret "on the napkin" as a destination marker, placing an isolated toy frog onto an empty napkin instead of putting a frog already on a napkin into a bowl. The error unfolds as children listen to the sentence, as shown by eye-movement analysis: whereas adults shift gaze to the frog on the napkin, 5-year-olds look at the incorrect (second) frog early and do not show awareness of the ambiguity of the modifier. Interestingly, 5-year-olds can in other contexts correctly produce the same syntactic structure. Thus even when children can produce complex syntactic structures, they may make on-line parsing errors.

Children's syntactic judgments also become faster from 6 to 10 years. Children in this age range are in general slower than adults at detecting violations of agreement or word order, and are relatively slower to notice violations early in a sentence rather than late in the sentence (Kail, 2004). Moreover, semantic incongruity within a sentence seems to distract 6-year-olds and keep them from noticing syntax errors (Windsor, 1999). Such findings suggest limitations of working memory or processing efficiency. Grammaticality judgments require holding several sentence constituents in memory, and increased processing speed and efficiency from 2 to 10 years (Kail, 1991), as well as increased verbal working memory capacity (Gathercole et al., 1992), should make syntactic processing faster and more reliable.

#### 2.30.5.1.3 Learning the nuances: reference, pragmatics, and implicature

Syntactic judgments and constructions fundamentally involve pragmatic factors (Bates and MacWhinney, 1982). As children gain fluency, and adults expect them to maintain good discourse cohesion, they must master a wide variety of devices for maintaining good discourse cohesion: topic–introducing-and-shifting (e.g., "There was this guy. He..."), topic-continuing (e.g., "yeah, and..."), perspective-shifting (e.g., "No, *he* didn't do it, *she* did!"), etc. As these examples show, pronouns and generic descriptions are important elements of discourse (Karmiloff-Smith, 1979). Adults, for example, find it jarring to continue to use unique individuation within a narrative:

> Chris and Heidi went to a new restaurant. The waitress asked Chris and Heidi if Chris and Heidi wanted drinks. "No," said Heidi. Heidi had already had some wine.

Preschoolers can use pronouns for coherent reference; for example they use simple cues (e.g., gender) to pick out a pronoun referent (Blakemore, 1990). Five-year-olds who lag behind in this ability show other narrative comprehension deficits (Cain and Oakhill, 1999; Yuill and Oakhill, 1991). By 7 years, however, children select and substitute pronouns in more pragmatically appropriate ways (Lloyd et al., 1995; Hickman and Hendricks, 1999). Specifically, the ability to use an interlocutor's knowledge to select unambiguous referential terms develops from 4 to 7 years (Ackerman, 1993), during the same period when they improve at drawing inferences about a speaker's meaning based on nonliteral semantic and discourse implications (e.g., Özçalıskan, 2004).

### 2.30.5.2 From Fluency to Flexibility and Meta-Language

#### *2.30.5.2.1 Cognitive flexibility in child language*

Each of the linguistic achievements of late childhood involves greater precision of interpretation or production. This precision requires representing different perspectives (Clark, 1997), which in turn requires representational flexibility (Deák, 2003). Flexibility involves processes including shifting attention, generating/selecting new representations, suppressing prior cues and associations, etc. Deák (2000b; 2003) found that children's flexibility in using cues to infer novel word meanings develops from 3 to 6 years, and individual differences in flexibility predict vocabulary, but are unrelated to children's ability to inhibit lexical associations. One interpretation is that word-learning flexibility is independent of some related cognitive control processes, but nevertheless predicts word-learning efficacy. A significant question is whether the same kind of cue-using flexibility is used by children to make complex syntactic and discourse interpretation. There is as yet no evidence addressing this question.

Cognitive flexibility encompasses children's growing ability to formulate and select appropriate but nonobvious representations of a referent or sentence in light of contextual information. For instance, interpreting /har/ as a synonym for rabbit, not hair (Campbell and Bowe, 1983), requires flexibility and selectivity in retrieving alternate word meanings. Such sorts of cognitive control are prominent in mature language abilities.

Some claims about the development of cognitive flexibility have focused on limitations on cognitive resources such as working memory and inhibitory processes (Diamond, 1998). Evidence for these claims is mixed at best (Deák and Narasimham, 2003; Zelazo et al., 2003), but there is so little research on effects of working memory and inhibition on flexible representations during language processing that the matter is unresolved.

Another idea is that cognitive flexibility, including flexible language processing, rests on children's developing ability to coordinate multiple response-contingencies in their response selection (Zelazo et al., 2003). For example, Zelazo et al. (2003) claim 3-year-olds cannot use a two-level hierarchy of verbal rules to guide classification responses. Three-year-olds readily sort cards by either of two rules (color or shape), for example, but when asked to switch from one to the other they continue to follow the first rule (Zelazo et al., 1996). Is the problem their inability to handle the complexity of a hierarchy of rules? It seems 3-year-olds use quite complex linguistic contingencies to formulate or interpret syntactic utterances, at least in ideal circumstances (e.g., Bates and MacWhinney, 1982; Slobin, 1982), so it is difficult to assimilate natural language performance into Zelazo et al.'s (2003) theory. However, there is some evidence that children who do not flexibly respond to changing rules can benefit from semantic and pragmatic support (Munakata and Yerys, 2001; Kirkham et al., 2003). Also, studies of feedback suggest that children's errors are based on misunderstanding the rules or failing to notice rule-switch cues (Bohlmann and Fenson, 2005), consistent with the argument that cue comprehension is a critical factor in children's linguistic flexibility (Deák, 2003). Although it remains unclear how late-developing language skills intersect with the development of cognitive control, the two are not strongly correlated in individual 4- and 7-year-olds (Brophy et al., 2002), suggesting some dissociation.

#### *2.30.5.2.2 Becoming an expert language user*

As children's language skills become consolidated, they become faster and more accurate, especially when processing or producing more complex and novel utterances. This is hardly surprising but it raises key issues. One is that there are no neurobiological accounts of later language development. This is surprising given recent findings that fairly brief language training interventions can measurably change children's neural activity during language processing. This indicates prolonged neural plasticity (Shaywitz et al., 2004).

Another issue is that the large literature on expertise acquisition (Feltovich et al., 2006) is disconnected from the literature on later language development – which might be considered a nearly universal type of human expertise. The result of this disconnect is an odd conceptual separation of similar phenomena. For example, children acquire expertise in phonology such that lexical representations are organized in phonological similarity neighborhoods (Luce and Pisoni, 1998), which have characteristic perceptual expertise effects (Vitevitch, 1997). Five- to 7-year-olds have fewer similarity neighborhoods than adults (Charles-Luce and Luce, 1990), but these become refined with phonological and vocabulary development. Another near-universal form of human expertise, face processing (Gauthier et al., 1999), is acquired in ways that reveal plasticity and input-driven effects. It is likely that in the next decade language expertise, like face processing and other examples of childhood expertise, will no longer be viewed in outmoded nativist terms, but as a complex, emergent product of input-expectant learning.

#### 2.30.5.2.3 Knowledge about language

Older children develop metalinguistics, or the ability to reflect on language (Gombert, 1992). Metalinguistic awareness focuses on dissociation of representations, as between a word as an action and as a symbol of whatever it represents. For example children might have trouble judging which is a longer *word:* 'mosquito' or 'cow,' because they conflate the words with their referents. Metalinguistic development might facilitate discourse facility (e.g., Morton et al., 2003): to the extent that specific lexical and syntactic acts underspecify a speaker's meaning, the ability to reflect on speech acts *per se* can help children understand nonliteral language (e.g., irony, sarcasm, or figurative language; Levorato and Cacciari, 2002).

Young children's metalinguistic knowledge has been tested in synonym and homonym usage. Doherty et al. (2004) found preschoolers' ability to identify homonym word pairs (baseball bat vs. flying bat) improved from 3 to 4 years of age and predicted understanding of false beliefs (i.e., inferring that another person can have an incorrect belief) even when vocabulary development was controlled. This suggests that metalinguistic knowledge develops in conjunction with other meta-representational skills.

How does metalinguistic knowledge develop? Older preschoolers show a tenuous association of printed word to referential meaning (Bialystok, 1997). However, this seems to improve with bilingual experience, possibly because bilingual children have more experience dealing with the abstract nature of linguistic representations as they switch codes to talk with different people (Bialystok et al., 2000). However, this argument is tentative, as there is so little research on the development of metalinguistic knowledge.

## 2.30.6 Conclusions

Three critical positions have been alluded to above, and these are central to the ongoing study of child language learning.

First, as advances in neuroscience fundamentally change our understanding of human cognition, they challenge persistent myths and assumptions about language. Basic findings about the developing bases of language in the brain, including the plasticity of language development (Bates et al., 2003), render ideas like Chomsky's 'language acquisition device' quaint. The growing sophistication of computational simulations of language learning support neurally plausible accounts of language development. However, because methods for measuring neural function and change in infants and children are so limited, much remains to be discovered.

Second, despite extensive use of terms like 'syntax,' 'semantic,' 'morphology,' and 'discourse,' these are conveniences based on historical convention in linguistics. Though there do seem to be some aspects of nearly pure syntactic knowledge, for example (Maratsos, 1998), more typical are complex interrelations among aspects of linguistic knowledge (e.g., Hay and Baayen, 2005). For example, there are no *a priori* neural dissociations between syntax and semantics (Bates et al., 2002). The interrelatedness of linguistic knowledge can be shown in children as well as adults. An intriguing question is how neural and psychological specialization of various aspects of language emerge during development.

Finally, research on different populations, including infants and children with various developmental disorders, and adults with neurological and sensory deficits, and a wide range of languages, will be necessary to understand typical language development. Studies of communicative learning in nonhuman species, and of nonlinguistic learning in humans (e.g., Childers and Tomasello, 2003) are also necessary. Despite the challenges of synthesizing such a vast range of research, the history of child language research clearly shows that a myopic focus on competent, healthy, educated English speakers leads to mistaken assumptions about the nature of language and language learning.

# 2.31 Transfer and Expertise: The Search for Identical Elements

**P. A. Frensch**, Humboldt-University, Berlin, Germany

**H. Haider**, University of Cologne, Cologne, Germany

## 2.31.1 Introduction

Imagine you are traveling to London from the United States for the first time in your life. Having arrived at London's Heathrow Airport, you rent a car and take to the road. What is going to happen? The answer to this question is central to the issues treated in this chapter. In contrast to the United States, cars in England are driven on the left, rather than on the right side of the road. In addition, the driver's seat is on the right side of the car, and the stick shift is to the left of the driver. Thus, although the skills of driving a car in the United States and England share many common features, they are also quite different. One might ask, then, how well a person will be able to drive in England, assuming that the person has driven a car before in the United States. These questions address the issue of 'transfer.'

Transfer is always considered relative to a baseline condition. For example, one might ask how an experienced American driver compares to an experienced native English driver when driving in London. In all likelihood, the American driver will perform less well than the English driver, thus demonstrating less than perfect transfer from the American situation to the English situation. Alternatively, however, one might also ask how an experienced American driver compares to a novice English driver. In that case, the American driver will probably outperform the English driver, thus demonstrating 'positive' transfer from the American to the English situation.

According to a well-known definition by Ferguson, 'transfer' refers to

> any effects resulting from repetition, in the ability to perform a specified task, either the same task under different conditions or a different task. (Ferguson, 1954: 99)

Transfer is thus concerned with any effects that performing one task (original task) has on the subsequent performance of the same task under different circumstances or of a different task (transfer task).

Ferguson's definition of transfer makes it obvious that transfer is a very broad concept that relates to a large number of meaningful research questions. For example, does knowledge of Latin facilitate or impair the learning of mathematics? Or does listening to music by Mozart improve or not improve spatial reasoning? To get a better handle on the large variety of different questions and situations that transfer relates to, Perkins and Salomon (1992) suggested six dimensions that can be used to structure the domain of transfer: (1) positive versus negative transfer, (2) general versus specific transfer, (3) near versus far transfer, (4) vertical versus horizontal transfer, (5) literal versus figural transfer, and (6) low-road versus high-road transfer.

For example, transfer might be positive (facilitating) or negative (detrimental), and it might be general or specific. Transfer is positive if performing one task improves subsequent performance on a second task; transfer is negative when performing an original task leads to subsequent worse performance on the transfer task.

Transfer is said to be specific if only particular aspects of, rather than general attitudes toward, the original task affect the acquisition of a new task. In contrast, transfer is said to be general (or nonspecific) if it results from warm-up and learning-to-learn effects. Warm-up effects refer to the attainment of various sensory, postural, and attitudinal adjustments that are needed to tackle a task (e.g., adjusting eyes and head for proper viewing of items displayed on a computer screen, adapting to pacing conditions, etc.). These adjustments are usually made relatively early during task practice and, once made, need not be made again. Learning-to-learn refers to the attainment of general task procedures which, once activated, may then be applied to a subsequently encountered task situation. Examples include skill in detecting stimuli on a computer screen and discovering procedures that ease a mental calculation task. As will become evident later, in current information-processing theories the distinction between general and specific transfer is increasingly difficult to maintain. Different types of transfer (i.e., positive and negative transfer, or general and specific transfer, or near and far transfer) may well occur together, as when certain aspects of the original task facilitate the acquisition of the new task while other aspects hinder it.

As a psychological topic, 'transfer' has both a long and a controversial history. Theoretical discussions of transfer can be traced back to at least the early writings of Greek philosophers, such as Aristotle and Plato. At the time, transfer was an important concept because it helped to explain why a mind that was born blank (i.e., blank slate) was nevertheless capable of acquiring knowledge from the beginnings of its existence (c.f., the later writings of British Empiricists, such as Locke and Reid).

More recently, transfer has become a highly controversial topic for at least two different reasons: empirical and theoretical. Empirically, so-called 'far' transfer, that is transfer across conceptually different domains, has been notoriously difficult to obtain. Consequently, some theorists (e.g., Detterman, 1993) have even argued that transfer, at least transfer that has any practical implications, does not exist (but see, e.g., Halpern, 1998; Barnett and Ceci, 2002).

Theoretically, different conceptualizations of how the human 'mind' works have tended to foster radically different and incompatible views on the mechanisms underlying transfer that have been heatedly debated over the course of the past 100 years. To understand this point, it is necessary to realize that transfer is a higher-order phenomenon. That is, to explain transfer one need not only describe the mechanisms by which transfer is achieved but also the mechanisms underlying performance and learning in the two tasks between which transfer occurs. In other words, the theoretical explanation of how original and transfer tasks are learned and are performed constrains the theoretically possible explanations of how transfer is achieved.

## 2.31.2 Goals and Structure of the Chapter

In many contemporary texts on transfer, the main focus is on summarizing empirical findings that elucidate the conditions that lead or do not lead to different types of transfer. Thus, for example, it may be argued that transfer is affected by two classes of variables that relate to (1) the encoding of the original task, and (2) the retrieval of the transfer task. Variables affecting transfer via the encoding of the original task are, among many others, (1) the degree of learning of the original task, (2) the differential use of learning strategies, (3) the number and variability of shown examples, and (4) abstract training. Variables that affect transfer by increasing or decreasing the likelihood that a transfer task is retrieved include (5) the similarity of surface and structural components of the original and transfer tasks, (6) the similarity of processing in the two tasks, as well as (6) the provision of hints (for an excellent recent summary of the variables that have empirically been shown to affect transfer, see, for instance, Kimball and Holyoak, 2000).

In contrast to this empirical focus, the focus of the present chapter is primarily theoretical. That is, our main focus is on discussing some of the most important theoretical conceptions of transfer that have been offered in the past 100 years. Empirical data are described only to the extent that they further understanding of the theoretical conceptions. There are two reasons for why we focus on theories rather than on empirical findings. First, there already exists a number of excellent recent summaries of empirical research on transfer (e.g., Kimball and Holyoak, 2000), and little is gained by providing yet another summary chapter. Second, we strongly believe that the results of empirical research on transfer can only be understood in the context of a firm and clear theory, and that a deep and thorough understanding of transfer is more likely to result from a discussion of theories than from a summary of empirical research findings.

The chapter has thus two goals. Our first and main goal is to present an overview of important theories of transfer that have been developed in the past 100 years. By comparing older with more recent theories, it will become very obvious in which way and why our understanding of transfer has changed, and where we are currently heading.

Our second goal is to discuss the relation between transfer and expertise, that is, the question of whether or not expertise in any given domain modulates transfer. Although perhaps surprising at first glance, this specific question is a natural consequence of our statement that transfer can only be understood in the context of performance and learning theories. If indeed an understanding of how tasks are performed and are learned in the first place necessarily precedes the formulation of a transfer theory, then it is at least not unreasonable to suspect that transfer might be qualitatively different at the beginning and advanced stages of learning.

We begin with a brief overview of the two most important theories on transfer that existed at the beginning of the twentieth century: the Doctrine of Formal Discipline and the Theory of Identical Elements. Second, we discuss, in some detail, transfer theories that are based on the notion of 'identical elements.' Not surprisingly, we show that what has been termed 'identical elements' varies widely across theories. Intertwined with the description of the transfer theories, we discuss the relation between transfer and expertise. Next, we return to the original idea of the Doctrine of Formal Discipline and argue that derivates of this idea are still heatedly debated in present-day psychology. Finally, we briefly summarize the current state of affairs and offer some conclusions.

## 2.31.3 Transfer Theories at the Beginning of the Twentieth Century

One of the first theories of transfer that not only was taken seriously by philosophers of mind but was widely applied to school settings as well has come to be known as the Doctrine of Formal Discipline (Locke, 1693). The Doctrine of Formal Discipline was based on a meta-theory of the human mind according to which the mind is divided into a number of general faculties, such as attention, reasoning, and memory (faculty psychology). Each faculty can be likened to a muscle that can be trained in a variety of ways. Improved muscle strength (e.g., improved reasoning ability) then benefits all mental tasks that require the specific muscle or faculty. Thus, studying mathematical problems, for example, not only improves mathematical ability but also philosophical thinking – at least to the extent that the two subject areas require the same reasoning faculty. Studying subjects such as Latin and geometry, therefore, is of pedagogical value because it serves to 'discipline' the mind.

The theory was literally uncontested for many years; Thorndike and Woodworth (1901a,b,c) were the first to provide strong empirical evidence against the Doctrine of Formal Discipline. In one of their experimental situations, for instance, they had participants estimate the areas of different-sized shapes and found little evidence of transfer of estimation from one shape to another. The mind, they concluded (Thorndike and Woodworth, 1901a: 248) is "a machine for making particular reactions to particular situations," and "spread of practice occurs only where identical elements are concerned in the influencing and influenced function" (Thorndike and Woodworth, 1901a: 249). With their Theory of Identical Elements, Thorndike and Woodworth proposed one of the most durable theories of transfer, which laid the groundwork for most of the empirical and theoretical work that was to follow later.

Although the Theory of Identical Elements rapidly emerged as the most widely accepted principle describing transfer in the early years of the century and was believed to account for most of the available transfer data (e.g., Hunter, 1929; McGeoch, 1942), it was by no means without its critics. Orata (1928), for instance, criticized the Theory of Identical Elements for its inability to explain findings reported by Judd (1908) and proposed a mental model theory of transfer instead (for more recent elaborations on this topic see, for instance, Kieras and Bovair, 1984). In his study, Judd had two groups of primary schoolchildren throw darts at an underwater target. Only one of the groups had the principle of refraction explained to them. The groups performed equally well at the start when the target was submerged 30.5 cm. However, when the target depth was changed to 10 cm, the group that knew the principle of refraction performed better. Furthermore, there was no transfer from 30.5 to 10 cm in the group that did not have the principle of refraction explained. Although the actual group differences obtained were rather small, the pattern of this finding was later replicated by Hendrickson and Schroeder (1941).

At least part of the reason why Thorndike and Woodworth's Theory of Identical Elements has been so tremendously successful was that the theory was, on the one hand, general enough to cover many different task situations while, on the other hand, not too general to still be meaningful. The theory was really more a general framework than a specific model. What it was lacking (very obviously) was a clear definition of what 'identical elements' were, or even more basic, what the elements were in the two tasks or two skills between which transfer was to occur.

In the next section, we summarize historical and recent ideas on what 'identical elements' are. Most of the ideas have come out of the verbal learning and the information-processing traditions, which will be addressed in turn.

### 2.31.3.1 Verbal Learning Tradition

The domain of verbal learning has been one of the most carefully and thoroughly studied areas in modern psychology and, consequently, has generated a vast amount of theoretical and empirical information. For illustrative purposes, we begin our discussion in the area of serial verbal learning.

The objective in serial verbal learning is to learn a list of serially arranged words such that the list can be reproduced (in correct order) at a later point in time. The method of serial verbal learning was introduced by Ebbinghaus (1885) who arranged artificial verbal materials (nonsense syllables) into serial lists and read them to the beat of a metronome until they seemed just on the verge of being learned; then, he would look away from the sheet on which the list was printed, and would try to recite the list. Ebbinghaus's measure of learning was the amount of time it took him to learn the entire list; his measure of transfer was the percentage of time saved in relearning the same or similar lists.

### 2.31.3.2 Serial Learning Analysis

Ebbinghaus was not only the first to introduce the empirical method of serial verbal learning, but also the first to construct a theory for what is actually learned in serial verbal learning (Ebbinghaus, 1885). His theory was based on the ideas of British Associationists such as David Hume (1739/2000) and John Locke (1693). According to British Associationists, learning is viewed as the acquisition of connections, or associations, between the stimulus (S) and response (R) units that are indigenous to a given task. The basic requirements for the acquisition of associations are that the to-be-related S unit and R unit occur contiguously, that their contiguous occurrence be repeated, and that the evocation of the R unit be followed by some reinforcing event.

The basic principle of serial learning, according to Ebbinghaus, is that every item in a list of serially presented verbal items becomes associated with every other item, subject to two qualifications: First, the strength of an association between two list items varies inversely with their degree of remoteness, that is, with how far apart they are in the series. Second, forward associations, for any particular degree of remoteness, are stronger than backward associations. From these qualifications it appears that the basic mechanism that permits learning of a serial ordering is the formation of associations linking adjacent items in the forward direction. This chaining hypothesis was hardly considered hypothetical at all; it was almost self-evidently true to researchers between the time of Ebbinghaus and the late 1950s.

Given that Ebbinghaus's ideas of serial verbal learning were almost uncritically accepted until at least the late 1950s, it is clear that most theories of transfer of verbal learning during this period had to be, and in fact were, based upon the concept of forward associations. If what was learned in serial learning were primarily the forward associations, then these associations had to be the identical elements, the basic components proposed by Thorndike and Woodworth that were to be transferred to a new task. Early evidence for this claim came from Ebbinghaus's own research with derived lists.

A derived list is one that contains the same items as a list learned earlier, but in an order that is altered in some prescribed, meaningful manner. These orders can be arranged such that associations of varying degrees of remoteness, forward or backward, are presumed to transfer from the original list to the learning of the second, derived list. A forward first-order derived list, for instance, is one formed by skipping one item in constructing the new list; thus the original list A-B-C-D-E-. . .-K yields the forward first-order list A-C-E-. . .-K. Similarly, second-order, third-order, etc., lists can be formed by skipping two items, three items, etc.

The derived list method offered Ebbinghaus a potent means for testing the validity of his theory. Specifically, he constructed a number of transfer lists having first-, second-, third-, and seventh-order degrees of forward remoteness. For each of these derived lists, he had learned the original list 24 h earlier. The results of the experiment were expressed as savings – how much more rapidly it was possible to learn the derived lists than the corresponding original lists – and confirmed the predictions of Ebbinghaus's theory: all conditions with regularly derived lists resulted in more savings than a random-order control condition. Furthermore, the closer the remote associations being transferred, the greater the savings.

Ebbinghaus's original derived list experiments were later harshly criticized on methodological grounds. The most serious concern was an objection raised by Slamecka (1964) to the procedure of skipping a regular number of items when deriving the second lists. Slamecka noted that with a regularity of this sort, participants might discover the rule for derivation and use the first list to mediate acquisition of the second, derived, list. In one of his own experiments, Slamecka (1964) compared the Ebbinghaus procedure with one in which the average degree of remoteness on a derived list was fixed, but the number of items skipped was variable. With this new procedure, Slamecka did not find positive transfer from the first to derived lists.

As a result of these and other criticisms, theorists became increasingly convinced that the serial methodology was not the method of choice for empirical work on transfer of learning and needed to be replaced with paired-associate learning. Although a stimulus-response analysis of learning was almost universally accepted at that time, with each item in the list serving both as a stimulus for the next item and as a response for the previous item, the stimuli and responses could not be manipulated independently of one another in an experiment. With paired-associate learning, however, stimulus and response similarity could easily be manipulated independently. Paired-associate learning, therefore, quickly became the method of choice for scientists working on theories of transfer.

### 2.31.3.3 Paired-Associate Analysis

#### *2.31.3.3.1 One-component models*

In paired-associate learning experiments, participants are asked to learn two paired-associate lists, one after the other. Of interest is the relation between the two lists in terms of which learning can be applied from the first to the second list. Using an alphabetic code, one may represent various transfer situations by a double pair where the first pair, A-B, denotes the first list, and the second pair denotes the second list. For example, in the A-B, A-D paradigm, the second list has the same stimulus units, A, as the first list, but different response units, D; that is, one must learn to make different responses on the second list in the presence of familiar stimuli. In the A-B, C-B paradigm, in contrast, one must make familiar responses in the presence of new stimulus units. The A-B, C-D paradigm is often considered to be a baseline, or control, paradigm because there is no deliberate similarity relation between the two lists, and duration of practice is typically identical for the two conditions.

Most of the original work on transfer of paired-associate learning, culminating in Osgood's (1949) transfer surface, described in the paragraphs that follow, was based upon the same theoretical framework that Ebbinghaus's model of serial verbal learning was based upon, namely, classical S-R theory. Consequently, transfer was explained in terms of the similarities of the S-to-R associations acquired in the context of Task 1 and Task 2. According to the logic of classical S-R theory, transfer between the tasks can be experimentally manipulated by varying

(1) the similarity between the S units of Task 1 and Task 2, (2) the similarity between the R units of Task 1 and Task 2, and (3) both the similarities between the S units and the R units in Task 1 and Task 2 simultaneously and independently.

To illustrate, let us consider the situation in which stimulus (S) similarity is varied (from A to A′ to A″; the prime indicates the decreasing similarity) and responses (R) are kept identical. In this case, associative strength from a given S-R pair of Task 1 is said to generalize to its Task 2 counterpart that maintains the same R unit. The extent of the generalization is dependent upon the degree of similarity between the S unit of Task 1 and the S unit of Task 2 and decreases monotonically with decreasing similarity. The underlying mechanism of transfer is said to be stimulus generalization.

Classical transfer theory predicts optimal positive transfer for the A-B, A-B paradigm, in which both stimulus and response are kept identical in Task 1 and Task 2; high positive transfer for the A-B, A′-B paradigm, in which the stimulus unit of Task 2 is closely related to the stimulus unit of Task 1; less positive transfer for the A-B, A″-B paradigm; and no transfer for the A-B, C-B paradigm. Transfer research has provided substantial support for most of these predictions. Positive transfer has been the usual outcome for the A-B, A′-B paradigm (for instance, Dallett, 1962), and the amount of positive transfer appears to decrease with decreasing intertask similarity between the S units (Dallett, 1962; Brown et al., 1966).

Most of the existing data on paired-associate transfer were summarized by Osgood (1949) in his transfer and retroaction surface (the term 'retroaction' refers to retroactive inhibition, the effect a second task can have in impairing retention of a first task). This three-dimensional graph, depicted in **Figure 1**, shows how much transfer there is to be expected between two tasks as a function of how similar they are in terms of their stimulus and response units. Assuming a constant first list, A-B, the various points on the graph show how much transfer is to be expected with different second lists. For example, if the second list is identical to the first, the A-B, A-B paradigm, there will be high positive transfer. If the stimulus units remain the same but require entirely new responses, as is true in the A-B, A-D paradigm, negative transfer results.

Several studies (e.g., Dallett, 1962; Wimer, 1963) have examined a fair sample of all the possible relations within the transfer surface. As one might expect,

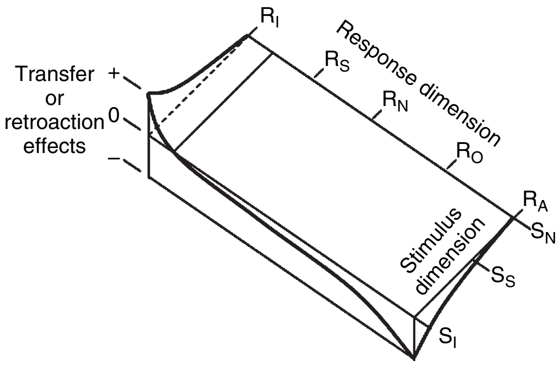

**Figure 1** Osgood's transfer and retroaction surface. Note that the medial plane represents transfer effects of zero magnitude. Response relations are distributed along the length of solid and stimulus relations along its width. Adapted from Osgood CE (1949) The similarity paradox in human learning: A resolution. *Psychol. Rev.* 56: 132–143, with permission from Elsevier.

these experiments were rather large and complicated. One of them (Wimer, 1963), for instance, combined five degrees of stimulus similarity between tasks with five conditions of response similarity. In general, the broad outcomes of these studies are in agreement with each other and with the predictions of the Osgood surface.

Although classical S-R theory has been quite successful in predicting transfer for situations in which the similarity of S units and/or R units was manipulated between tasks, it has been much less successful in predicting transfer in a situation in which the S units of Task 1 are unrelated to the S units of Task 2 while the R units are still identical (A-B, C-B paradigm). Classical S-R theory predicts no transfer in this case. However, Twedt and Underwood (1959) found a trend toward negative transfer, and other investigators have found significant amounts of negative transfer (e.g., Kausler and Kanotti, 1963).

Furthermore, reasonably good success in explaining the direction and magnitude of transfer has been shown only for the paradigms the theory is equipped to handle. Excluded from consideration, for instance, are paradigms that fall outside these boundaries, such as the A-B, B-C paradigm, for which slight negative transfer has been repeatedly found (e.g., Murdock, 1958; Goulet and Barclay, 1965). Thus, in order to explain all possible transfer conditions, rather than only a few, classical S-R theory had to be expanded into what have been labeled multi-component theories.

#### 2.31.3.3.2 *Multi-component models*

In multi-component models, it is assumed that the learning of paired-associate lists, and in general of any material, is a result not only of forward associative learning but also of backward associative learning, response learning, and stimulus learning (Martin, 1965; Kausler, 1966). Consequently, transfer may not only affect the acquisition of Task 2 forward associations but also any other of the proposed components. It should be clear that the addition of components, although not altering the basic logic of transfer, considerably complicates the analysis of transfer in paired-associate learning.

The direction and amount of overall transfer are now the combined result of the separate component effects. If negative transfer occurs for one component and zero transfer for all other components, then the overall transfer effect would necessarily be negative. However, if a second component contributes positive transfer, then the negative effect of the first component is diminished. Thus, predictions concerning overall transfer are based on the consideration of the specific effects of the separate components, with the amount of overall transfer simply being the algebraic sum of the amounts of transfer contributed by the separate components.

It should also become clear that the multi-component view of transfer is not compatible with Osgood's (1949) summary of transfer phenomena. Osgood's analysis is limited to situations in which learning consists only of acquiring the forward associative component. That is, Osgood's original transfer surface does not take into account familiarity with stimuli and/or responses. (Without going into details, we just briefly note that, in response to these problems, Martin (1965) called for a modification of Osgood's original transfer surface and proposed, instead, three different surfaces, one for each of three different components of transfer, namely, response learning, forward associations, and backward associations.)

### 2.31.3.4 Transfer and Expertise: Effects of First-Task Practice on Transfer of Paired-Associate Learning

In verbal learning theories of transfer, at least two different questions address the relation between transfer and expertise. First, one might wonder whether or not, in general, expertise facilitates or hinders transfer. That is, are experts 'better' or 'worse' at transfer both within and outside of their domain of expertise? To some extent, the answer to this question is trivial. Assuming that experts possess more knowledge in their domain than do nonexperts, they have, in terms of verbal learning theory, more stimulus representations, more response representations, and more associations at their disposal to transfer to a different task. Thus, they should be at an advantage in any situation that is similar to the situation they are expert at.

The question regarding potential benefits and costs of expertise, however, inevitably leads to a much more specific and theoretically much more compelling and important second possible question concerning the relation between transfer and expertise. In behaviorist single-component and multi-component views of transfer, this question boils down to how familiarity with or practice on the first task affects the content of transfer. That is, does expertise modulate what is transferred between two tasks? In multi-component views, this question can be much more complex and more difficult to disentangle than in the classical one-component approach. In classical S-R theory, to become more familiar with a task simply means that the forward associations grow stronger. Thus, familiarity with the first task enhances the effects of transfer, negative or positive, by increasing the strengths of S-to-R forward associations.

In multi-component approaches, however, the effects of familiarity can be selective; that is, the effects of familiarity can strengthen some components while not affecting others and vice versa. This added possibility makes research on first-task practice an elegant tool for testing the validity of multi-component views. Thus, prepracticing the stimuli but not the responses, for instance, will tend to make the stimuli more readily available for retrieval, but will not – or only minimally – affect the strength of the associations and the availability of responses. That is, by way of experimentally inducing familiarity with some components but not with others, the multi-component view of learning can be experimentally tested. Consequently, most of the studies in which practice on the first task was varied were primarily interested in proving their version of a multi-component learning theory, rather than in addressing the issue of whether the basic components of transfer change with practice on the first task. Nevertheless, these studies have provided some interesting insights and are briefly discussed.

Experimental studies on the effects of first-task practice on the acquisition of a second task can be classified in the following way: (1) studies in which only the response units of Task 2 received practice in Task 1 (basically an A-B, C-B paradigm), and (2) studies in which only the stimulus terms of the second task were practiced in Task 1 (basically an A-B, A-C paradigm).

For example, as Martin (1965) points out, multicomponent views explain transfer in the A-B, C-B paradigm as depending largely on two factors: negative transfer due to backward interference and positive transfer due to response availability. Thus, with a low degree of practice, the strength of B-to-A (backward) associations carried over as the source of interference for the B-to-C associations should be relatively slight. On the other hand, even with a low degree of practice, response learning of the B units should be fairly complete by the end of Task 1 practice. Assuming the B units are of low meaningfulness (to avoid further complications), the positive transfer from response learning is likely to outweigh the slight negative transfer from associative learning, thereby yielding slight overall positive transfer.

With a high degree of Task 1 practice, however, the strength accrued for B-to-A associations should be sufficient to assure strong interference with the B-to-C associations. The negative transfer from backward associative learning should now outweigh the positive transfer from response learning (which is unlikely to increase beyond the amount manifested with a low degree of Task 1 practice), leading to overall negative transfer.

This balance of forces was nicely illustrated in a study by Jung (1962), in which he showed that with a low degree of Task 1 practice there was a trend toward positive transfer, while with a high degree of Task 1 practice the trend shifted to negative transfer. Similar results were obtained in a study by Schulz and Martin (1964) in which familiarity with Task 1 response units was achieved not via amount of practice but via degree of response meaningfulness.

It appears then that within the framework of multi-component views of transfer, the effects of Task 1 practice on the performance of Task 2 can be readily explained by introducing a strengthening mechanism: With practice, stimuli and responses become more easily available and associations become stronger. Importantly, the components of transfer do not appear to change with practice at all. Instead, what changes with practice is simply the strength or availability of transfer components, but not the nature of transfer.

## 2.31.4 Information-Processing Theories

Most of the theoretical positions we review next (Johnson; Kieras, Polson, and Bovair; Singley and Anderson), although differing on the specifics, share a common assumption: The acquisition of a task consists of separate learning stages that result in a multilevel hierarchy of organization. The basic idea conveyed by this hierarchy, and the one that fundamentally sets these new theories apart from earlier stimulus-response views, is that higher-level units are not simply associations of lower-level units, but are functionally distinct from lower-level units and can be accessed and used independently.

Two groups of nested-hierarchy theories differ on how this hierarchical organization comes about and in how it is used. The 'nonassociative recoding' position (Crowder, 1976), first articulated by researchers like Jensen, Bower (e.g., Trabasso and Bower, 1968), and Johnson (1969), relies primarily on information-processing machinery; the 'multilevel-associative' positions of Hebb (1961) and Estes (1972) stay within the associations-through-temporal-contiguity framework, but escape the limitations of the approach.

In the following, we concentrate on the 'nonassociative recoding' positions simply because their development has led directly to the modern conceptions of transfer. Starting with Johnson's classic coding theory, we then turn to the more recent approaches taken by Kieras, Polson, and Bovair, and by Singley and Anderson.

### 2.31.4.1 Johnson's Coding Theory

Although originally developed to explain recall of sentences, Johnson's coding theory (Johnson, 1969, 1970, 1972, 1978) presents a rather elaborate model of how the process of grouping lower-level knowledge units into higher-level units is established during learning and how higher-order units are used in task performance. Coding theory is based upon the concept of recoding that was originally developed by Miller (1956). Miller proposed that when participants are presented with items that are to be remembered, they can increase their recall by recoding subsets of items into higher-order units.

Johnson calls the memorial representation of a collection of items that are grouped together a 'code.' The specifics of coding theory can be summarized in the following five points. First, the main theoretical property of codes is that they are unitary. They are single memory devices that can represent a number of individual items (i.e., memorial representation of a group of items). Because codes are unitary, they are recovered from memory in an all-or-none fashion; that is, once a code is recovered, all the information the code represents is recovered.

Second, codes are distinct from the information they represent. This distinction between code and content is analogous to the one often made between a category and the items from the category.

Third, an important implication of this distinction is that codes may be viewed as if they were opaque containers. That is, if the code and the represented information are distinct, then the recall of codes might be largely independent of the recall of the information represented by the code. For example, a participant might feel confident that she can remember a free-recall list because she remembers that it contained instances of birds, trees, and flowers. However, at the time of recall, she might discover that when she attempts to decode the category labels into their appropriate instances she is unable to remember the exact items that appeared in the list.

Fourth, codes can represent either individual items or other codes. Hierarchical coding occurs when the codes at one level of organization are recoded into higher-level codes. Note that any given set of items can be recoded into very different organizations. The sequence SBJFQLZ, for instance, could be organized by including SBJ in one chunk, FQLZ in another, and then recoding the codes for those two chunks into one higher-order code representing the entire sequence. Alternatively, the sequence could be organized into codes for three lower-order chunks like SB, JFQ, and LZ, and then the codes for these three chunks could be recoded into a code representing the entire sequence. For any given set of items, there exist many different organizations that can be imposed.

Finally, to allow for correct sequential retrieval of codes and items within codes, Johnson assumes that codes at any given level in the hierarchy and items within codes are distinguished by order tags.

The implications of Johnson's coding theory for an understanding of transfer should be fairly obvious. If learning a task is equivalent to learning a hierarchy of codes, rather than to learning a series of forward or backward associations, then codes, rather than associations, should be the identical elements, the components of transfer. Furthermore, what changes with practice and expertise is not simply the strength or availability of components, as in S-R, associative views, but the nature of the components themselves. With practice, lower-level codes will be recoded into functionally distinct higher-level codes.

Bower and Winzenz (1969) directly compared the S-R associative view of transfer with the code-based view in a study in which they repeatedly gave participants the same series of letter sequences. The Bower and Winzenz study was basically a replication of experiments by Hebb (1961) and Melton (1963) that had shown that the recall of a letter sequence was improved if it was repeated later in the session. Bower and Winzenz were able to show that this improvement from repetition occurred only if a sequence was grouped in the same way on both occasions. For example, if the series ABCDEFG was presented once with rhythmic grouping AB′CDE′FG and then later again with the grouping changed to ABC′DEF′G, then there was no improvement. However, if the same rhythmic breakdown was used on both occasions, then there was a gain from the first to the second trial.

Bower and Springston (1970) tested the same idea with prior experience from semantic, as opposed to episodic, memory. In their study, participants were asked to recall 12-letter strings that were broken into groups by pauses within the string. In some cases, the strings were broken by pauses so as to coincide with familiar acronyms, e.g., TV-IBM-TWA-USSR; but in other cases, the pauses did not coincide, e.g., TVI-BMTW-AU-SSR. Bower and Springston found that the facilitation occasioned by familiar acronyms was heavily dependent on whether the presented grouping corresponded with the acronym boundaries or not.

Note that in the Bower and Winzenz and Bower and Springston studies, the materials to be transferred from Task 1 to Task 2 were absolutely identical. That is, the effects reported could only be due to the differences in the organization of the materials. These studies, then, seem to demonstrate that codes, as defined by rhythmic grouping, rather than forward or backward associations, are transferred from one task to another. In a whole series of similar studies, Johnson and associates explored the role of codes in transfer of learning more systematically.

For instance, Johnson (1969, 1970) asked participants to learn a sequence of grouped letter triplets, such as SBJ′FQL′ZNG. Following the first-list learning, they were asked to learn another list that was identical to the first except that one letter in each of two groups was changed (e.g., SBJ′FQL′ZNG changed to ′SXJ′FQL′TNG). After learning the second list, participants were asked to recall the first list.

The results of these experiments showed that the loss for the unchanged letters from a group with a change was about 50% relative to a rest control condition (no second list), whereas the loss of the unchanged letters in groups without changes was about 10% or less. These findings are consistent with Johnson's coding theory and do not seem to be readily explainable by an S-R–based associative view of transfer.

Note that the coding view also predicts that the amount of transfer is not affected by which particular letter in a group is changed and also that the number of letters changed in a group should have no relation to the amount of transfer. That is, if a middle letter from a group is changed, transfer is no different than if the first or the last letter is changed. Furthermore, whether one, two, or three letters in a group are changed should not affect transfer, either. Both of these predictions have been confirmed experimentally (Johnson, 1970).

These and similar experiments provide rather strong evidence for the view that codes, rather than associations, are the basic elements of transfer. Unfortunately, the effects of practice on transfer have never been experimentally explored. With practice, the theory assumes, functionally distinct higher-order codes are formed from lower-order codes. Therefore, the components of transfer are predicted to change. One reasonable assumption to make would be, for instance, that what is transferred from one task to another are only the (reusable) codes at the highest possible level of hierarchy, an interesting and also experimentally testable prediction.

The appraisal of Johnson's coding theory depends on what criteria one decides to apply. Johnson's accomplishments seem very impressive if one looks at those aspects of the theory that relate to the explanation and prediction of transfer phenomena. The experimental effects associated with the theory are both clear-cut and nonintuitive. However, Estes (1972), for instance, has complained with complete justification that, despite Johnson's (1978) later elaborations, the theory is primarily a metatheory. That is, it leaves many of the most fundamental processes – sequential retrieval, coding mechanisms, decoding mechanisms – underspecified.

One could argue that at least one of the reasons why the mechanisms of coding theory are relatively unexplored may have been the fact that information-processing machinery only later, with the introduction of production-system architectures, has developed the tools for a full-fledged process analysis. Next, we describe two recent information-processing approaches to transfer that, although different in their theoretical conceptualizations, are both implemented in a production-system architecture. Therefore, it will be useful to briefly describe the general properties of a production system.

### 2.31.4.2 An Overview of Production-System Models

Production systems have become an almost generic theoretical formalism in cognitive psychology. Numerous production-system models of cognitive processes have been developed. Examples include problem-solving models (Newell and Simon, 1972; Karat, 1983), models of text comprehension (Kieras, 1982), and models of learning (Anderson, 1982).

In general, production systems represent knowledge as a collection of rules. Processing mechanisms interpret these rules, thereby generating a sequence of cognitive operations and actions. In its most fundamental form, a production system consists of two data structures, a long-term declarative memory of facts and a production memory, that are connected through a processing cycle. The production memory can be described as a collection of IF-THEN condition-action rules (productions) of the form

IF (condition) THEN (action)

The processing cycle works as a three-stage recognize-act cycle. It matches the IF parts of one or more production rules (from production memory) with the contents of some active part of the declarative memory (often referred to as short-term memory or working memory), decides which of the matched rules to fire (conflict resolution), and executes the THEN part of the selected rules, resulting in either the activation, modification, or execution of an existing memory structure.

Note that the condition part of a production rule can contain information at very different levels of abstraction. For example, it might contain current goals or subgoals or information about the external task environment.

Production systems are usually hierarchically organized and goal-driven. That is, a sequence of production rules is organized such that the system moves from satisfying one subgoal to satisfying another subgoal to satisfying a general goal and so on. This sequential, goal-driven behavior is modeled by having the production rule that just fired delete the subgoal accomplished and add a new subgoal to working memory. The sequential behavior of the model is, thus, controlled by manipulating the pattern of subgoals.

Next, we turn to two information-processing approaches that make direct use of the production-system formalism in their formulations of transfer theories. Both of these theories assume that production rules, rather than associations or codes, are the identical elements of transfer. Beyond this commonality, however, the two theories differ fundamentally.

### 2.31.4.3 Kieras, Polson, and Bovair's Theory of Transfer

Perhaps the simplest and most straightforward approach that any theory implemented in a production-system environment could take with regard to explaining transfer is the one taken by Kieras, Polson, and Bovair (e.g., Polson and Kieras, 1984, 1985; Kieras and Polson, 1985; Kieras and Bovair, 1986; Polson, 1987). Very much unlike the theories described so far, Kieras, Polson, and Bovair's approach to understanding transfer is not based upon a learning theory. Instead, these researchers, in essence, construct production systems for each of the two tasks involved in transfer, the original and the transfer task, and then examine them for the amount of production overlap by simply counting the number of productions that appear in both systems. The more productions the two tasks have in common, the greater the amount of transfer. Thus, according to this view, production rules are the identical elements of transfer that were postulated by Thorndike and Woodworth.

Production rules are transferred from one task to another if they are either identical or generalizable. They are identical if they have the same conditions and the same actions; they are generalizable when a condition can be derived from other conditions by replacing a constant with a variable. In fact, Kieras and Bovair (1986), for instance, note that in all their analyses of transfer, generalizations and identical rules were transferred equally quickly and were learned much faster than new production rules.

Note that transfer, in Kieras, Polson, and Bovair's view, is simply a matter of reusing old production rules in a new context. The model is simple and straightforward because it is based upon an essentially static representation of knowledge. All that is needed to predict amount and direction of transfer from one task to another is to construct two production systems that model task performances in the two tasks and to count the number of identical and generalizable production rules. Kieras, Polson, and Bovair take this approach even further by keeping the production systems they generate as simple as possible. As Kieras and Polson state, their production system is the

> . . . most elementary form of production system in that there are no conflict resolution rules, and very simple kinds of pattern matching are used in evaluating conditions. (Polson and Kieras, 1985: 207)

Likewise, they make no attempt to represent fundamental cognitive processes, such as memory retrieval or reading comprehension, and assume that each production takes the same amount of time to execute.

Note that, despite its simplicity, the identical-production-rules view of transfer has a clear advantage over classical associative theories of transfer: Productions are abstract entities that can be used to describe human behavior at different levels of abstractions. In associative models, stimuli and responses describe mostly overt behavior. Production rules, in contrast, can represent higher-order and lower-order goals as well as externally observable behavior or rule-based reasoning, etc. That is, they can be used to represent many different entities at various levels of generality. Thus, production rules are extremely flexible with regard to what they can represent.

Kieras, Polson, and Bovair have experimentally tested their model of transfer in various studies and in two different domains, namely, text editing (e.g., Polson and Kieras, 1985; Polson, 1987; Polson et al., 1987) and operating a simple device (e.g., Kieras and Bovair, 1986). The results of these studies demonstrate very clearly that production rules can, in fact, provide a very useful characterization of what is transferred from one task to another.

Kieras, Polson, and Bovair's approach to understanding transfer is best described as a cognitive engineering approach (Gray and Orasanu, 1987). As a general theory of transfer, however, the belief that the amount of transfer can be determined by simply counting productions can be criticized for at least two different reasons. First, production rules might differ with regard to how important they are in a particular system. Foss and DeRidder (1987) argue that productions that are higher up in the goal structure of a particular task might be more important for transfer than productions at a very 'late' level in the goal structure. Thus, a change in the syntax between old and new systems may result in a substantial number of differences in the production rules that describe the behavior of the user, but if all these changes are 'late' in the goal structure, then they might not have the same impact on transfer as an equal number of changes in production rules that affect subgoals 'higher' in the goal hierarchy.

The second criticism that can be leveled against counting identical production rules is the one mentioned already, namely, the fact that this theory – because it is not closely tied to a learning theory – completely ignores the level of skill at which the original task is performed.

Both of these criticisms have been addressed in a theory of transfer that was formulated by Singley and Anderson (1985, 1989). These authors propose essentially an extension to Kieras, Polson, and Bovair's view of transfer that is heavily dependent upon Anderson's theory of learning (Anderson, 1982, 1983, 1986, 1987).

#### 2.31.4.4 Singley and Anderson's Theory of Transfer

Like Kieras, Polson, and Bovair, Singley and Anderson (1985, 1989) propose that production rules are the common elements that are transferred from one task to another. Unlike Kieras, Polson, and Bovair, however, and very much in line with the theories discussed earlier, their view is based upon a powerful learning mechanism, implemented in Anderson's Adaptive Control of Thoughts (ACT*) theory of human cognition. In this learning mechanism,

> . . . knowledge comes in declarative form, is used by weak methods to generate problem solutions, and as a by-product, new productions are formed. The key step is the knowledge compilation process, which produces the domain-specific skill. (Singley and Anderson, 1989: 50)

This statement is central to ACT*'s account of learning. The theory breaks down the acquisition of skill into two major stages: a declarative stage, where a declarative representation of the skill is interpreted by general, nonspecific, problem-solving productions (such as analogy, means-ends analysis, pure forward search, etc.), and a procedural stage, where the skill is directly embodied in domain-specific productions. The transition from the declarative to the procedural stage is achieved by the process of knowledge compilation. Knowledge compilation consists of two separate mechanisms: the composition mechanism collapses sequences of general productions into a smaller number of highly specific productions (larger IF parts), and the proceduralization mechanism deposits domain knowledge from long-term memory directly into productions.

The initial use of weak methods and knowledge compilation are the main factors that influence the acquisition of domain-specific productions. However, two additional factors influence their execution, namely, strength accrual and working memory limitations.

The strength of a production determines how rapidly it applies. Production rules accumulate strength as they successfully apply; that is, as they are practiced and learned. Just as learning has an impact on production strength, it has an impact on working memory limitations; that is, working memory increases with practice. Because in ACT*, the only way errors can occur is through the loss of information in working memory (leading to the wrong production firing or the correct production firing but producing the wrong result), an increase in working memory will tend to decrease the likelihood of errors occurring.

Singley and Anderson's theory of transfer differs from Kieras, Polson, and Bovair's in two critical points. First, Singley and Anderson assign weights to the production rules shared by the two tasks, reflecting the frequency of their use. Production rules that are 'higher up' in the goal hierarchy will tend to be used more frequently than the more specialized productions at the lower end of the goal hierarchy and will therefore be assigned larger weights. Consequently, they will figure more prominently in transfer predictions than will productions at the lower end.

Second, Singley and Anderson assume that the components of transfer – production rules – change qualitatively with practice. According to the ACT* theory of learning, all productions arise initially from declarative encodings. With practice, the declarative component, however, will eventually become very small, and transfer will be predictable solely on the basis of procedural knowledge.

Singley and Anderson's theory of transfer makes four important predictions. First, during early stages of learning, transfer is a function of declarative and procedural knowledge. With practice, the impact of the declarative component will rapidly decrease, and transfer will be a function solely of procedural knowledge.

Second, transfer of procedural knowledge is captured by the identical-production-rules theory. That is, the amount of transfer between two tasks depends directly on the number of shared productions in the two tasks.

Third, if the basic components of transfer are productions, then transfer has to be specific to the use of knowledge. This prediction is derived from the condition-action asymmetry of production rules. In particular, the conditions of a rule imply the actions but not vice versa. This property implies the use specificity of knowledge (that is, no transfer) in certain situations where two sets of production rules are based upon the same abstract knowledge but have been dedicated to different uses.

And finally, the theory predicts that negative transfer is minimal. If indeed transfer is determined by the number of shared productions (and that number can never be smaller than zero), then it follows that transfer can be negative only in cases where earlier learned conditions still apply in a new task but now lead to either wrong or nonoptimal actions.

In general, it can be said that the experimental evidence for all four predictions is strong. For instance, Singley and Anderson (1985, 1989) studied transfer among two line editors (ED and EDT) and a screen editor (EMACS). Twenty-four expert typists with no prior text-editing experience were taught a minimum core set of commands for each editor. In the line editors, the core set included commands for printing, deleting, inserting, and replacing lines, and substituting strings within lines. In the screen editor, the core set included commands for moving the cursor forward, backward, and up and down, and deleting characters, words, and strings.

Participants performed the above editing operations for 3 h each day and a total of 6 days. The EMACS group spent all 6 days on EMACS. All other groups spent the last 2 days using EMACS. The ED-EDT and EDT-ED groups spent 2 days on one line editor and the next 2 days on the other. The control group spent 2 days typing at the terminal.

Singley and Anderson split their analyses into two different parts, macroanalyses and microanalyses. Transfer data from the macroanalyses showed near total transfer between the two line editors, moderate transfer from line editors to screen editor, and slight transfer from typing-only to screen editor. The magnitude of predicted transfer (on the basis of relatively simple sets of production systems for the three editors) correlated to .98 with the magnitude of the observed transfer, representing an almost perfect linear relationship between the production overlap predictions and empirical measures of transfer. From these results, Singley and Anderson (1989) concluded that the massive amount of transfer between the two line editors was due to almost identical production systems at both the higher level and the lower level of goal hierarchies, whereas the moderate transfer from line editors to screen editor was primarily mediated by identical higher-order goal structures.

Microanalyses revealed that these general results could vary quite considerably for different subtasks of editing. Singley and Anderson split each unit task into various components of text-editing performance. Their results revealed (1) that a complex task like text editing can be decomposed into different component parts, (2) that each of these components seems to be learned and transferred separately and in accordance with the identical-production-rules theory, and (3) that various components of the task decompose rather cleanly into planning and execution phases, with transfer of planning being much more pronounced than transfer of execution, which can essentially be neglected. In general, this study strongly supported Singley and Anderson's (1989) claim that production rules are the basic components of transfer.

To test the prediction that transfer is confined to the same use of knowledge and does not occur between different uses of the same knowledge, McKendree and Anderson (1987) compared participants' ability in List Processing Language (LISP) evaluation skills. They gave twenty participants four consecutive days of practice in evaluating combinations of four basic LISP functions. Two functions combined items into a list (INSERT and LIST), and the other two extracted items from a list (CAR and CDR – assigned the more mnemonic names of FIRST and REST). Participants practiced 150 trials on each of the 4 days.

After the first and the last session, participants were given a transfer task that required them to generate functions similar to those they had just practiced evaluating. All of the transfer problems involved basic functions or pairs of functions that the participants had seen immediately before in the evaluation task. Yet, while error rates on the evaluation task decreased dramatically from Day 1 to Day 4 (35% to 15%), the transfer task showed little improvement (29.3% to 26.6%). Despite becoming significantly better at evaluating functions, participants on Day 4 were not any better at generating functions than they were on Day 1.

Singley and Anderson's (1985, 1989) theory is easily the best articulated, clearly specified, and most complete theory of transfer to date. By making full use of Anderson's ACT* learning mechanism, the theory is capable of generating interesting and counterintuitive predictions that have already been, and continue to be, subjected to rather thorough and extensive experimental tests.

## 2.31.5 Comparison of Theories of Transfer

### 2.31.5.1 The Content of Transfer

Older S-R-based views of what is learned when a task is acquired and what is transferred from one task to another differ fundamentally from more recent information-processing views. Classical S-R theory and its various descendants all have in common that the most important components of learning are assumed to be associations, whether forward or backward, between externally observable stimuli and responses. In contrast, more recent information-processing theories view learning as the acquisition of general memory structures that are capable of representing observable as well as nonobservable behavior (goals, operators, methods, etc.).

The transition from classical associative theories of transfer to the identical-production-rules view has not been one of degree but has been quite dramatic: Production rules are abstract entities that can be used to describe human behavior at different levels of abstractions. They represent higher-order and lower-order goals as well as externally observable behavior or rule-based reasoning, etc. Using production rules as the basic units of transfer is an entirely different ballgame than relying on associations, stimuli, and responses.

### 2.31.5.2 Effects of First-Task Practice/ Expertise on Transfer

A second important difference between the classical S-R view of transfer and more recent information-processing approaches relates to the effects of expertise on transfer. Classical S-R theory and its various descendants have clearly and unequivocally defended the continuous nature of transfer, characterized by strengthening of associations and increased accessibility of stimuli and responses as a result of increasing expertise. In sharp contrast, the information-processing theories of transfer discussed earlier (with the exception of the static approach taken by Kieras, Polson, and Bovair) have assumed that, because learning is a discontinuous process, transfer is discontinuous also. Thus, the elements of transfer change qualitatively with increasing experience and familiarity on the first task.

However, the assumption that different knowledge representations are transferred to a novel task when the first task has been practiced extensively versus when it has not been practiced extensively has so far not been directly and experimentally demonstrated. In fact, when Singley and Anderson, for instance, modeled text-editing performance in three different text editors, one of their simplifying assumptions was that "the transfer task has the same organization before and after a subject's exposure to the training task" (Singley and Anderson, 1989: 251). This particular aspect shared by all modern theories of transfer, then, clearly is in need of experimental validation.

## 2.31.6 The Doctrine of Formal Discipline Revisited

Virtually all theories of transfer reviewed in this chapter are based upon Thorndike and Woodworth's Theory of Identical Elements (Thorndike and Woodworth, 1901a,b,c); that is, all assume that performance on a second task is (primarily) facilitated by reusing previously acquired specific memory representations. One might conclude then that transfer is primarily specific rather than general. Note, however, that the nature of what specific elements and general methods are has changed so substantially over the past century, as discussed, that it has become virtually impossible to differentiate between general and specific transfer. In fact, by including cognitive constructs as among the common elements that can be transferred, the more recent production system–based approaches have basically eliminated the old distinction between specific and general transfer. The entire task, including aspects of the stimulus and response as well as more general cognitive aspects, can now be described and analyzed under a unified system.

In the last section of the chapter, we briefly discuss some findings that have recently been offered in support of the notion of general transfer. The question we are mainly interested in answering is whether or not these recent findings do indeed lend new credibility to the old Doctrine of Formal Discipline or can alternatively be explained in terms of production system–based transfer theories, as our previous discussion suggests.

One particular recent line of research maintains that practice on a task not only leads to domain-specific task knowledge but to general reasoning skill as well. For example, Lehman et al. (1988; Lehman and Nisbett, 1990) compared the effects of graduate training in psychology, chemistry, medicine, and law on methodological and statistical reasoning. The authors' results revealed positive transfer of medicine and psychology graduate training to the ability to solve reasoning problems in everyday-life situations. In addition, graduate training in law positively affected the ability to solve conditional reasoning problems whereas graduate training in chemistry did not affect any of these abilities.

Thus, the Lehman et al. findings appear to support the assumption of general transfer. In accordance with the Doctrine of Formal Discipline, the authors concluded from their findings that

> . . . rules about assessing causality, rules for generalization, rules for determining argument validity, and rules for assessing the probativeness of evidence . . . (Lehman et al., 1988: 441)

can be taught to improve general thinking skill (see also, Fong et al., 1986; VanderStoep and Shaugnessy, 1997).

More recent experiments (Shraagen, 1993; Schunn and Anderson, 1999) lend further support to the findings of Lehman and colleagues. Schunn and Anderson compared domain experts (cognitive science researchers), task experts (social and developmental psychologists), and domain and task novices (undergraduates) regarding their ability to design memory experiments. Results showed that domain and task experts differed in terms of their domain-specific knowledge and procedures, whereas experts and novices differed in terms of general skills such as the quality of hypothesis generation, data evaluation, developing experimental designs, or drawing conclusions. In addition, the authors ruled out that these general skills were related to IQ. On the basis of the SAT, they divided the novices in their study into those with high abilities and those with low abilities. The performances of the two groups did not differ from each other, but, overall, the two groups were less able to apply general rules than were the two expert groups. The authors concluded that expertise leads to general skills that can be transferred to tasks in unfamiliar domains. The quality of reasoning within a specific domain, however, depends on domain-specific knowledge and processes.

In a subsequent study, Harrison and Schunn (2004) tested scientific reasoning abilities in the domains of psychology and biology of near-experts (graduate students; biologists and psychologists) and novices (undergraduates of both subjects). The authors used a bidirectional transfer paradigm; that is, all participants received problems from biology and psychology. Harrison and Schunn's results again showed that general skills that were applicable in both domains developed with increasing expertise; that is, near-experts were better able to transfer the general skills to unfamiliar domains than were novices.

Again, these findings appear to be consistent with the Doctrine of Formal Discipline. Training in scientific reasoning leads to skill that supports reasoning in other scientific domains or in everyday-life situations. Although the transfer effects were small and transfer was far from complete, the findings suggest that, beyond domain-specific knowledge, experience in one domain also leads to general skill that can facilitate problem solving in other domains. In accordance with findings by Ceci and colleagues (Ceci and Liker, 1986; Ceci and Ruiz, 1992, 1993), this effect of expertise is not related to IQ.

However, it can be shown that the findings described are consistent with and can be explained by production system–based transfer theories. Schunn and Anderson (1999), for instance, argue that participants acquire general search heuristics or production systems when they practice tasks in a domain as well as knowledge (declarative facts in ACT-R) that is used by the search heuristics. Some of the general heuristics that are implemented in production rules can be applied in other than the specific domains in which they have been acquired. This is the case if the new domain provides knowledge that the productions can use. That is, transfer is possible when previously acquired production rules are applicable to knowledge structures in the new domain – in other words, when the new and the old domain share identical features.

Furthermore, the production rule–based transfer theories assume that expertise leads to the strengthening of specific production rules and to the weakening of other rules (e.g., Anderson and Lebière, 1998). This, in turn, might lead to specific preferences in terms of how to approach a given problem. Domain-specific expertise thus shapes how one interprets a given situation and this influence might increase with increasing expertise (e.g., Bransford and Schwartz, 1999; Chen and Klahr, 1999; Harrison and Schunn, 2004; Lehman and Nisbett, 1990). Interestingly, this assumption would predict that expertise in one domain might change how one approaches problems in a new, unfamiliar domain. This effect is what Schwartz et al. (2005) might have had in mind when they proposed to expand the definition of transfer to include 'preparation for future learning.'

The domain-general effect of expertise resembles well-known findings in the field of insight problem solving (e.g., Luchins, 1942; Maier, 1931; Wertheimer, 1959) or of perceptual learning (e.g., Gibson and Gibson, 1955; Goldstone, 1998). For example, in insight problem solving, participants' previously acquired knowledge can prevent their generating the 'correct' mental representation needed to solve the problem at hand (e.g., Knoblich and Oellinger, 2006).

Overall, the recent findings suggest that some general transfer exists. However, rather than supporting the assumption that just about **any** mental activity at Time 1 improves just about **any** subsequent mental activity at Time 2, as was suggested by the Doctrine of Formal Discipline, these findings can be explained in terms of production rule–based transfer theories.

## 2.31.7 Summary and Concluding Remarks

Our main goal in this chapter has been to describe and compare important theories of transfer that have been offered in the psychological literature in the past 100 years. It should be fairly obvious that the nature of transfer theories has changed dramatically from the early days of the Doctrine of Formal Discipline and the Theory of Identical Elements to behaviorist conceptions of transfer and to present-day production system–based conceptions. Currently, the production rule as the unit of transfer provides a quasi-standard way of describing what the identical elements of Thorndike and Woodworth are. As has been argued, the transition from the earlier associationist to a production system–based theory of transfer has not been gradual but has been fairly dramatic. Along with this transition, the earlier distinction between specific and general transfer has lost much of its appeal and meaning. In today's theories, production rules can represent every conceivable piece of information, and whether it refers to observable or unobservable behavior makes little difference.

Being able to specify Woodworth and Thorndike's identical elements is one thing; however, being able to describe and understand the actual process of transfer is a completely different thing. Note that, as the currently dominating theories of transfer, such as Singley and Anderson's, are formulated, they do not capture the actual process of transfer. It is simply not very likely that when they are confronted with a transfer situation, participants create memorial representations of two tasks and then match them against each other. This scenario might help to predict the amount of transfer between two tasks; it does not capture the process of transfer. It seems much more realistic to assume, for instance, that a second task is not represented in isolation in memory when learned, but instead is represented in terms of its deviations from the original task.

In this regard, Polson et al. (1987) describe an interesting process model of transfer in terms of a repair theory. They propose that transfer between overlapping complex skills is largely a repair process where the representation of the first skill is 'edited' in order to reflect the new demands of the transfer task. This repair process is composed of three steps: determining which elements of the old skill need to be repaired, that is, which elements are no longer valid in the transfer task; determining what the new, replacement elements should be; and making the repair.

Polson et al. point out that, in transfer environments that offer both instruction and feedback, the first two steps in the repair process are greatly simplified. However, in situations where the transition between tasks is poorly defined and must be discerned by the participants themselves, interference may be introduced. Indeed, the classic Einstellung phenomenon (Luchins, 1942) can be described as a transfer situation in which the changing demands of the transfer task have not been pointed out explicitly to participants.

Another dramatic demonstration of this effect in a different setting is the classic part-whole negative transfer effect in verbal learning (Tulving, 1966; Sternberg and Bower, 1974). The basic phenomenon is that participants experience negative transfer when learning a second list of words after learning an initial list that is either a subset (part-whole transfer) or superset (whole-part transfer) of the transfer list if they are uninformed about the relation between the first and second word lists. However, if participants are explicitly informed that the transfer list either is a part of or contains the training-list words, the negative transfer turns to strong positive transfer, which is what one would have originally predicted on the basis of an identical elements approach.

Polson et al.'s repair theory has not been extensively tested and can only be regarded as a very rough first approximation of the actual process of transfer. However, it appears to be a rather safe bet to assume that research on the process of transfer will trade places with research on the basic elements of transfer in the very near future and will become one of the most important experimental battlegrounds for theories of transfer.

# 2.32 Implicit Learning

**P. Perruchet**, University of Bourgogne, Dijon, France

## 2.32.1 Introduction

All of us have learned much without parental supervision and outside of any form of planned academic instruction, and more generally without any intentional attempts to acquire information about the surrounding world. Countless examples could be found in domains as diverse as first-language acquisition, category elaboration, sensitivity to musical structure, acquisition of knowledge about the physical world, and various social skills. All of these domains have several features in common. In particular, they are commonly described as governed by complex abstract rules by scientists, whether they would be linguists, musicologists, physicists, or sociologists. Also, learning in those situations mainly proceeds through the learner's exposure to a structured environment, without negative evidence (i.e., without direct information about what would contradict the rules underlying the domain).

Despite the pervasiveness of these forms of learning in real-world settings, it is worth stressing that they have been virtually ignored by experimental psychology for decades. At the beginning of the cognitive era, the study of learning was essentially devoted to classical and operant conditioning on the one hand, and to the formation of concepts or problem solving processes on the other. The above phenomena seem hardly reducible to simple conditioning effects in regards to their complexity, and research on concept learning and problem solving does not provide *a priori* a better account, primarily due to the fact that the hypothesis testing strategies essential in these research domains do not seem applicable in situations where negative evidence is lacking. This empirical and conceptual vacuum opened the door to the upsurge of the nativist perspective, which characterized the cognitive approach from its outset.

This chapter presents a stream of research that is primarily aimed at exploring the forms of learning illustrated in the examples above through laboratory situations involving arbitrary materials (for overviews, see Berry and Dienes, 1993; Berry, 1997; Cleeremans et al., 1998; French and Cleeremans, 2002; Jimenez, 2003; Perruchet and Pacton, 2006; Reber, 1993; Seger, 1994; Shanks, 2005; Stadler and Frensch, 1998). This field of research evolved essentially from the end of the 1980s, although its roots are in the pioneering studies of Arthur Reber, who coined the term 'implicit learning' (IL) about 40 years ago (Reber, 1967). The implications of the results issued from IL research for the nativist/empiricist debate will be addressed in the final discussion, after having examined what is learned in this context, how 'implicit' is implicit learning, and the relations of laboratory research with real-world situations of learning.

## 2.32.2 Rules, Instance-Based Processing, or Sensitivity to Statistical Regularities?

### 2.32.2.1 Learning Rules

A large part of the literature on IL exploits the artificial grammar learning paradigm, initially proposed by Reber (1967). Participants first study a set of letter strings generated from a finite-state grammar that defines legal letters and permissible transitions between them (**Figure 1**). Typical instructions do not mention the existence of a grammar and are framed so as to discourage participants from engaging in explicit, intentional analysis of the material. Participants are then subsequently informed about the rule-governed nature of the strings and asked to categorize new grammatical and nongrammatical letter strings. Participants are typically able to perform this task with better-than-chance accuracy, while remaining unable to articulate the rules used to generate the material. This empirical outcome has been unambiguously confirmed by a vast number of subsequent experimental studies involving many variants of the situation.

Reber's (1967) original proposal was that participants have internalized the constraints embodied by

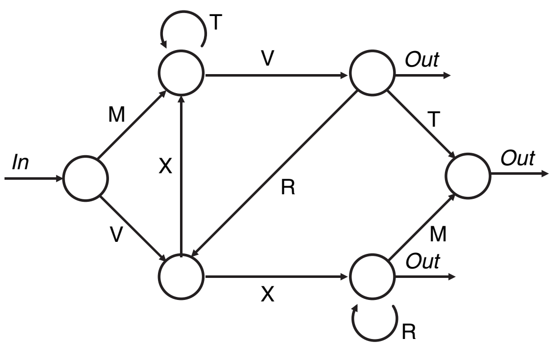

**Figure 1** The artificial grammar used by Reber and Allen (1978), Dulany et al. (1984), and Perruchet and Pacteau (1990) among others. For example, MTTV and VXVRXVT are grammatical, whereas MXVT is not grammatical.

the generation of rules during training. Rule abstraction is assumed to occur during the study phase, when participants are exposed to a sample of letter strings generated from the grammar. During the test phase, participants are assumed to use the acquired knowledge, stored in an abstract format, to judge the grammaticality of new items. Other illustrations of this reasoning can be found in many subsequent studies. Let us consider those by Lewicki et al. (1988) and McGeorge and Burton (1990).

In the Lewicki et al. (1988) paradigm, participants were asked to perform a four-choice reaction-time task, with the targets appearing in one of four quadrants on a computer screen. They were simply asked to track the targets on the numeric keypad of the computer as fast as possible. The sequence looked like a long and continuous series of randomly located targets. However, this sequence was organized on the basis of subtle, nonsalient rules. Indeed, unbeknown to participants, the sequence was divided into a succession of 'logical' blocks of five trials each. In each block, the first two target locations were random, while the last three were determined by rules. The participants were unable to verbalize the nature of the manipulation and, in particular, they had no explicit knowledge of the subdivision into logical blocks of five trials, which was a precondition that had to be satisfied if they were to grasp the other rules. However, performance on the final trials of each block, the locations of which were predictable from the rules, improved at a faster rate and was better overall than performance on the first, random, trials. Lewicki et al. (1988) accounted for these results by postulating that the structuring rules were discovered by a powerful, multipurpose unconscious algorithm abstractor.

In the McGeorge and Burton (1990) study, which initiated a stream of research on the so-called 'invariant learning,' participants were asked to perform an arithmetic task on a set of four-digit numbers. Unbeknown to them, each four-digit number contained one '3' digit (the 'invariant'). In a subsequent forced-choice recognition test, participants were shown 10 pairs of four-digit numbers. They were told that one of the numbers in each pair was seen during the study phase, and that they had to find it. In fact, all the numbers were new, but half of them contained one '3' as in the study strings, while no '3' occurred in the other half. Participants choose above chance the numbers containing a '3,' although they were unable to report anything pertinent to the invariant digit. The authors inferred that participants had learned the critical rule unconsciously.

These results, and most of the others in the early IL literature, have been shown to be empirically robust in subsequent studies. However, two other interpretations have been proposed. Their common intuition is that people do not abstract the rules of the domain, but instead learn about the product of the rules.

### 2.32.2.2 The Instance-Based or Episodic Account

The first historical alternative to the abstractionist position in the field of artificial grammar learning is the so-called instance-based or memory-based model proposed by Brooks (Brooks, 1978; Vokey and Brooks, 1992). In Brooks' model, subjects who are shown grammatical strings during the study phase store the strings in memory, without any form of condensation or summary representation. During the test phase, they judge for grammaticality of test strings as a function of their similarity to specific stored strings. The instance-based model works because, if no special care is taken to generate the material, grammatical test items tend to look globally more similar to study items than ungrammatical test items.

Vokey and Brooks (1992) made independent the usually confounded factors of specific similarity and grammaticality, in order to assess the size of the effect of each factor on grammaticality judgments. Test items were classified as similar when they differed by only one letter from one study item, and dissimilar when they differed by two or more letters from any study items. The authors obtained a reliable effect of specific similarity on grammaticality judgments (see also McAndrews and Moscovitch, 1985). As expected, similar items were more often classified as grammatical than dissimilar items when their grammatical status (i.e., their consistency with the grammar) was kept constant. However, the grammaticality factor also had a significant, and usually additive, effect. Similar evidence was collected by Cock et al. (1994) in invariant learning. The authors demonstrated that similarity to instances in the study phase was even a more important factor than apparent knowledge of the invariant feature in the McGeorge and Burton (1990) paradigm.

To account for the fact that the similarity to a specific training item fails to account for all the variance in performance, Vokey and Brooks (1992; Brooks and Vokey, 1991) suggested that the similarity may also be computed with the whole set of study items instead of a single one (see also Pothos and Bailey, 2000, for another measure of similarity). The currently prevalent interpretation keeps the idea of some kind of pooling or summation over multiple episodes, but privileges a formulation in terms of statistical regularities.

### 2.32.2.3 The Sensitivity to Statistical Regularities

While the instance-based model considers whole episodes (e.g., VXVRXVT in artificial grammar learning), this alternative account considers elementary components (e.g., the individual letters). The consequences are considerable. Indeed, large episodes are idiosyncratic, and hence they generate distinctive and independent memory traces. By contrast, elementary components occur iteratively under the same or other combinations, and hence it makes sense to describe the to-be-learned stimuli using statistical concepts, such as frequency, probability, or contingency. For this reason, this approach is designated here as the statistical account, even though it is most commonly referred to as the 'fragmentary' approach in the conventional IL literature. It is worth noting that the term 'statistics' does not necessary entail that learners perform statistical computations, an issue that will be addressed later (see the section titled 'Statistical computations and chunk formation').

The general principle of this account is straightforward: Organizing rules generates statistical regularities in the world, and people adjust their behavior to those regularities. Understanding how this account works in artificial grammar learning is easy. Looking at the grammar shown in **Figure 1**, it appears that that some associations between letters are possible (e.g., MV), and other impossible (e.g., MX), and that among the legal associations, some are more frequent than others (e.g., RX presumably occurs more often than RM). If participants learn something about the frequency distribution of the pairs of letters (bigrams) that compose the study strings, they should perform subsequent grammaticality judgments better than chance. Perruchet and Pacteau (1990) tested this hypothesis. They reasoned that, if subjects learn only bigram information when faced with the whole strings, the direct presentation of the bigrams, which precludes the use of any high-level rules, should not change the final performance. The prediction was confirmed; the performance of participants who had learned using the complete grammatical strings (as usual) and those who were trained using the bigrams from which these strings were composed were statistically indistinguishable. Other experiments from the same study and other studies (Dienes et al., 1991; Gomez and Schvaneveldt, 1994) confirmed the importance of bigrams knowledge, although they showed that participants also learn other piecemeal information, such as the location of permissible bigrams and the first and last letters of the strings.

The question is now: Does this interpretation work in general? It could be argued indeed that artificial grammar learning is especially well-fitted to a statistical interpretation, because the rules can be easily translated in terms of statistical regularities. To address this question, let us consider how the Lewicki et al. (1988) study presented above can be reinterpreted. Recall that a precondition to grasp the complex second-order dependency rules structuring the sequence was a parsing of the whole sequence into logical blocks of five trials, and that participants were fully unconscious of doing so. However, Perruchet et al. (1990) demonstrated that participants could learn the task without ever performing the segmentation of the sequence into logical blocks. Instead, they could become sensitive to the relative frequency of small units, comprising two or three successive locations. Some of the possible sequences of two or three locations were more frequent than others, because the rules determining the last three trials within each five-trial block prohibited certain transitions from occurring. In particular, an examination of the rules shows that they never generated back-and-forth movements. As a consequence, the back-and-forth transitions were less frequent *on the whole sequence* than the other possible movements. The crucial point is that these less frequent events, which presumably elicit longer reaction times, were exclusively located on the random trials. This stems not from an unfortunate bias in randomization, but from a logical principle: The rules determined both the relative frequency of certain events within the entire sequence and the selective occurrence of these events in specific trials (for an alternative interpretation based on connectionist modeling, see Cleeremans and Jimenez, 1998).

A similar reanalysis was performed by Wright and Burton (1995) on the McGeorge and Burton (1990) invariant task. Wright and Burton observed that a by-product of the invariant rule was to modify the probability of occurrence of observing a digit repetition in the strings. More precisely, the strings that contain one ‘3’ include, on the mean, a smaller proportion of repeated digits than the strings in which no ‘3’ occurs, all simply because the chances of generating repeated digits are lesser over three than over four successive drawings. The authors showed that at least a part of the participants’ above-chance performance during the test was due to the fact that they tended to reject the items containing repetitions, rather than the items violating the invariant rule.

What is new in these examples (for a similar illustration, see the reinterpretation of Kushner et al. (1991) by Perruchet (1994b)) with regard to the artificial grammar-learning situation is the fact that the link between the generating rules and the distributional statistics of simple and salient events is far from obvious. The fact that rules may have remote consequences, the learning of which having effects similar to the learning of the rules themselves, may obviously be thought of as a drawback in the experimental designs, without any implication out of the laboratory studies. However, it may also be thought of as a quite fundamental outcome, essential to understand the power of the statistical approach in the natural situation of learning, as the section titled ‘Discussion: about nativism and empiricism’ will emphasize.

### 2.32.2.4 Rules versus Statistics: A Crucial Test

How can rule-based and statistical interpretations be discriminated? When the rules of a domain generate a set of events so restricted that all the possible events can be exhaustively experienced by a subject, it may be impossible to discriminate between the two types of interpretations. However, this case is largely deprived of interest. Indeed, the power of the rules is that they make people able to adapt to new situations from previous exposure to a subset of the events the rules can generate. Here is the hint for a crucial test.

For a first example, let us consider an argument for rules put forth by Reber and Lewis (1977) in the context of artificial grammar learning. In a given experiment, participants are exposed to a subset of the virtual full set of strings generated by the grammar, and this subset cannot be perfectly representative of the full set for all aspects. For instance, the frequency distribution of the observed bigrams has a high probability of departing to some extent from the frequency of the bigrams composing the full set of strings. Reber and Lewis argued that if participants abstract the rules of the grammar, they should be sensitive to the bigram frequency of the virtual full set of strings, and not the frequency of occurrence of the bigrams composing the strings actually displayed in the study phase. They provided empirical data supporting this hypothesis, and Reber (1989) construed these data as one of the main supports for his contention that studying grammatical letter strings gives access to the abstract structure of the grammar. The logic of the argument is indeed sound, but unfortunately, the supporting data turned out to be due to various methodological drawbacks inherent to the Reber and Lewis procedure (Perruchet et al., 1992). In fact, participants are sensitive to the frequency distribution of the bigrams they actually perceived.

In the preceding example, the possibility of discriminating interpretations based on rules and statistics stems from the fact that the subset of items to which participants are exposed are not representative of the whole set of items due to sampling biases. The same logic may be implemented in a more systematic way, by training participants with a given material and testing them with different material. The following section examines the findings obtained in these so-called ‘transfer’ situations, which have been heavily used in IL research.

### 2.32.2.5 The Phenomenon of Transfer: The Data

In the standard paradigm of transfer in artificial grammar learning, the letters forming the study items are changed in a consistent way for the test of grammaticality (e.g., M is always replaced by C, X by P, etc.). Reber (1969) and several subsequent studies (e.g., Mathews et al., 1989; Dienes and Altmann, 1997; Manza and Reber, 1997; Shanks et al., 1997; Whittlesea and Wright, 1997) have shown that participants still outperform chance level under these conditions. The principle underlying the ‘changed letter procedure’ has been extended to other surface changes. For instance, the training items and the test items may be, respectively, auditory items and visual items (Manza and Reber, 1997), color and color names, sounds and letters (Dienes and Altmann, 1997), or vice versa. Successful transfer was observed in each case.

The phenomenon of transfer has also been observed in invariant learning. McGeorge and Burton (1990) found that the selection of number strings containing the invariant digit persisted when study strings were presented as digits (e.g., 1234) and test strings as their word equivalents (e.g., one two three four; see Bright and Burton (1998) for similar examples of transfer in another invariant learning task).

Transfer has even been observed in infants. In Marcus et al. (1999), 7-month-old infants were exposed to a simplified, artificial language during a training phase. Then they were presented with a few test items, which were all composed of new syllables. For instance, in one experiment, infants heard 16 three-word sentences such as *gatiti, linana,* or *tanana,* during the study phase. All of these sentences were constructed on the basis of an ABB grammar. The infants were then presented with 12 other three-word sentences, such as *wofefe* and *wofewo.* The crucial point is that, although all of the test items were composed of new syllables, only half of the items were constructed from the grammar with which the infants had been familiarized. In the selected example, the grammatical item was *wofefe. Wofewo* introduces a structural novelty in that it is generated from a concurrent ABA grammar. The infants tended to listen more to the sentences generated by the ABA grammar, thus indicating their sensitivity to the structural novelty. In another experiment, infants were shown to be able to discriminate sentences generated by an AAB grammar. Similar studies using more complex material have been performed with 11-month-old infants (Gomez and Gerken, 1999).

## 2.32.2.6 The Phenomenon of Transfer: The Interpretations

### *2.32.2.6.1 Rules?*

Marcus et al. concluded that infants have the capacity to represent algebraic-like rules and, in addition, "have the ability to extract those rules rapidly from small amounts of input and to generalize those rules to novel instances" (Marcus et al., 1999, p. 79). Demonstrations of transfer in more complex situations in adults have elicited similar comments. For instance, Reber, talking about performance in the changed letter procedure in artificial grammar learning studies, claimed that

> . . . the abstractive perspective is the only model of mental representation that can deal with the existence of transfer of knowledge across stimulus domains. (Reber, 1993: 121)

A rule-based interpretation may have difficulty accounting for the entire pattern of data, however. First, the traditional emphasis on positive results must not overshadow the fact that transfer failure has frequently been reported in the literature on IL. In the conclusion of their review on transfer in the most current IL paradigms, Berry and Dienes pointed out that

> . . . the knowledge underlying performance on numerous tasks . . . often fails to transfer to different tasks involving conceptually irrelevant perceptual changes. (Berry and Dienes, 1993: 180)

This empirical finding leads the authors to propose that limited transfer to related tasks is one of the important key features of performance in IL tasks. Moreover, in experiments where positive evidence of transfer is reported, performance levels on transfer situations are generally lower than performance levels on the original training situation. This so-called transfer decrement phenomenon raises a problem for a rule-based standpoint. In an authoritative discussion on the use of abstract rules, Smith et al. (1992) posit as the first of their eight criteria for rule use that "Performance on rule-governed items is as accurate with unfamiliar as with familiar material" (Smith et al., 1992, p. 7; see also Anderson, 1994, p. 35; Shanks, 1995, Ch. 5; Whittlesea and Dorken, 1997, p.66). Manza and Reber (1997) acknowledge this implication of their own abstractionist view. Clearly, this prediction of rule-based accounts has scarce experimental support at best.

However, observing that rule-based interpretation of transfer is, after all, not so well-fitted as might expected has limited interest until better interpretations are put forward. Are there alternatives?

### *2.32.2.6.2 Explicit inferences during the test?*

In the standard situations of artificial grammar learning, most people are able to learn the abstract rules of the grammar when they are instructed to search for rules (Turner and Fischler, 1993) or when they are given incidental instructions which guide them toward the deep structure of the material (Wittlesea and Dorken, 1993). A first alternative possibility to account for transfer in IL studies is that transfer is due to the involvement of explicit reasoning, despite the instructions given to participants.

This account finds support in the examination of the tasks in which transfer routinely succeeds and tasks in which transfer fails. As noted by Newell and Bright (2002), the tasks that trigger transfer are those in which participants are instructed to use knowledge that they have acquired during training, such as artificial grammar learning tasks and invariant learning tasks. These instructions inevitably shift subjects to a rule-discovery mental set. The tasks in which subjects are not explicitly engaged to rely on what they saw in study phase, such as serial reaction-time (SRT) tasks and control interactive tasks, are far less prone to transfer. In SRT tasks, for instance, a target stimulus appears on successive trials at one of a few possible positions on the computer screen. Participants are simply asked to react to the appearance of the target by pressing a key that spatially matches the location of the target on a keyboard. Typically, the same sequence of trials is repeated throughout the session. Participants exhibit a decrease in reaction times with regard to a control condition, without ever being informed about the presence of a repeated structure. In this case, transfer to dissimilar surface feature typically fails (Stadler, 1989; Willingham et al., 1989).

The role of explicit reasoning in changed-letter transfer in artificial grammar learning is further suggested by the fact that transfer is performed better when the training session involves intentional (i.e., rule searching) rather than incidental instructions (Mathews et al., 1989). Whittlesea and Dorken (1993) failed to obtain changed-letter transfer in subjects whose attention was not focused on the structure of the situation. In the same vein, Gomez (1997) showed that changed-letter transfer occurred only in subjects who had sufficient explicit knowledge of the rules.

Although these studies suggest that transfer performance partly depends on the involvement of conscious and deliberate processes, it is difficult to account for all the positive results in those terms. To evoke only one counterargument, the observation of transfer in infants (Gomez and Gerken, 1999; Markus et al., 1999) can hardly be explained by the recourse to intentional rule-breaking strategies. Is it possible to account for transfer in IL without any recourse to rules?

#### *2.32.2.6.3 Disentangling rules and abstraction*

There is no doubt that the evidence of transfer is indicative of abstraction. However, the view that abstraction is indicative of rule formation and rule use has been heavily challenged. As cogently argued by Redington and Chater (2002), "surface-independence and rule-based knowledge are orthogonal concepts."

To begin with a simple case, let us consider Manza and Reber's (1997) results, showing a transfer between auditory and visual modalities in the artificial grammar learning area. These authors interpret their findings as providing support for their abstractionist, rule-based view. However, the phenomenon can be easily explained otherwise. Any sequence – such as VXMTR – presented orally will be immediately recognized when displayed visually, irrespective of whether this sequence is generated by a grammar or not. This is because the perceptual primitives, namely the letters V, X, and so on, are processed to an abstract level that makes them partially independent of their sensory format. The differences between the two explanations is worth stressing. In the former case, a rule-governed pattern is assumed to be extracted from the auditory stimuli before being applied to the visual stimuli. In the latter case, matching is directly performed at the levels of the perceptual primitives. The same comment can be applied to many other studies. For example, the transfer between colors and the name of colors (Dienes and Altmann, 1997) and the transfer between digits and their word equivalents (McGeorge and Burton, 1990) can also be accounted for by the natural mapping between the primitives involved in the experiment.

At first glance, the above explanation does not apply to all transfer results. As a case in point, it does not seem to work for the studies by Marcus et al. (1999) in which transfer is observed between, say, *gatiti* and *wofefe*, because there is no natural mapping between *ga* and *wo*, or *ti* and *fe*. Reinterpretation of the Marcus et al. data is possible along the same line, however, if one assumes that the perceptual primitives can be relational in nature. The relation that needs to be coded is the relation 'same-different,' or, in other words, the only ability that infants need to possess is that of coding the repetition of an event. Indeed, as pointed out by McClelland and Plaut (1999), *gatiti, wofefe*, and more generally all the ABB items, can be coded as different-same, whereas none of the other items can be coded using the same schema.

As surprising as this conclusion may be, the demonstrations of transfer stemming from the more complex situations of artificial grammar learning in adults imply the coding of no more complex relations than event repetitions (e.g., Tunney and Altmann, 1999; Gomez et al., 2000; for an overview, see Perruchet and Vinter, 2002, Section 6). Lotz and Kinder (2006) confirmed and extended this conclusion. They showed that the sources of information used in transfer tasks in artificial grammar learning studies concern the local repetition between adjacent elements, as well as the repetition of nonadjacent elements in the whole items.

Overall, this analysis demonstrates that transfer, such as observed in IL settings, is in no way indicative of rule knowledge. It is fairly compatible with a statistical approach, provided one acknowledges the possibility that statistical processes operate not only on surface features (such as forms or colors), but also on more abstract properties and on simple relational features, such as the repetition of events. The idea that transfer does not imply rule abstraction has also gained support from the possibility of accounting for transfer performance within a connectionist framework (Altman and Dienes, 1999; McClelland and Plaut, 1999; Seidenberg and Elman, 1999; Christiansen and Curtin, 1999). Note also that transfer has been claimed to be compatible with an interpretation focusing on instance-based processing, thanks to the notion of abstract analogy (Brooks and Vokey, 1991), although Lotz and Kinder (2006) failed to find an empirical support for this account.

### 2.32.2.7 A Provisional Conclusion

There is evidence that the analogy with specific items may account for a specific part of variance in performance. The Vokey and Brooks (1992) demonstration, presented in the section titled 'The instance-based or episodic account,' has been challenged (Knowlton and Squire, 1994; Perruchet, 1994a), but additional evidence has been provided since then (Higham, 1997). The interest of the instance-based model resides in its highlighting the fact that behavior may be implicitly affected by individual episodes rather than simply by large amounts of training. However, there is a consensus on the idea that this account cannot be thought of as exclusive. It seems inevitable to jointly consider the pooled influence of a series of events to account for the whole pattern of data.

The two main views accounting for the influence of multiple past events are based on rules and statistics, respectively, but there is no symmetry between the two accounts. Indeed, no one disputes the existence of statistical learning. This consensus comes from the human ability to learn in the countless situations in which regularities cannot be described by a set of rules, as the concept has been defined above. As a consequence, the only possible question is: Do we need rules, in addition to statistical learning, to account for implicit learning in rule-governed situations?

Here is the end of the consensus. On the one hand, many authors respond "no." Their position is based on the fact that the sensitivity to statistical regularities is able to account for performance in most of the experimental situations that were initially devised to provide an existence proof for rule learning, including transfer settings. In addition, when a direct test has been performed to contrast the predictions of the two models, predictions of the statistical account have been unambiguously confirmed (see also Perruchet (1994b) on the situation devised by Kushner et al. (1991) and Channon et al. (2002) on the biconditional grammar). On the other hand, other authors (e.g., Knowlton and Squire, 1996) argue that empirical evidence requires a dual process account, mixing statistical learning and rule knowledge. Their position stems from experimental studies in which learning persists in test conditions where the simplest regularities – those that are presumably captured by statistical learning – have been made uninformative (e.g., Knowlton and Squire, 1996; Meulemans and Van Der Linden, 1997; but see Kinder and Assmann, 2000). This kind of evidence is not fully compelling, however, because it is not possible to ascertain that all the possible sources of statistical knowledge have been taken into account (see for instance the reanalysis of Meulemans and Van der Linden (1997) by Johnstone and Shanks (1999)). A more principled demonstration, in which some specified content of knowledge would fail to be approximated by statistical learning, would provide a far stronger argument.

The remaining of this chapter focuses on statistical learning. This does not mean that the possibility of implicit rule learning can be considered as definitely ruled out. This presumably will never be the case, because proof of nonexistence is beyond the scope of any empirical investigation. Needless to say, this approach does not mean either that rule learning does not exit at all; there is clear evidence that humans are able to infer and use abstract rules when conscious thought is involved. The very existence of science should provide a sufficient proof for the skeptic.

The implications of focusing on statistical learning are that the questions and their experimental approach will be considered irrespectively of whether the to-be-learned materials can be described in terms of rules or not. Note that this focus is in keeping with the recent literature on IL, which typically includes a number of situations that are not governed by rules such as SRT tasks with repeated sequences and word segmentation (e.g., Saffran et al., 1997), as well as other situations, such as contextual cuing (Chun and Jiang, 2003), that are not described in this chapter due to space limitations.

## 2.32.3 Learning about Statistical Regularities

Before examining the question of what processes underlie behavioral tuning to statistical regularities, one needs to identify the kinds of regularities to which humans are sensitive.

### 2.32.3.1 What Is Learnable?

#### *2.32.3.1.1 Frequency, transitional probability, contingency*

For many people, claiming that behavior is sensitive to statistical regularities amounts to saying that behavior is sensitive to the absolute or the relative frequency of events. For instance, participants in an artificial grammar experiment may have learned that MT occurred $n$ times, or that a proportion $p$ of the displayed bigrams were MT. Considering only frequency provides limited information, however. It may be interesting to know the probability for 'M' to be followed by 'T,' a measure called conditional or transitional probability. To assess whether 'M' is actually predictive of 'T,' this probability must be compared to the probability that another letter precedes 'T'. The difference between these two conditional probabilities is called DeltaP (Shanks, 1995). In addition, it may be worth considering the reverse relations, namely the probability for 'T' to be preceded by 'M.' This 'backward' transitional probability may be quite different from the standard, forward transitional probability. The normative definition of contingency in statistics (such as measured, for instance, by a $\chi^2$ or a Pearson correlation) requires a consideration of the bidirectional relations. When data are dichotomized, for instance, Pearson correlation is the geometrical mean of the forward and backward DeltaP (for a more detailed presentation, see Perruchet and Peereman, 2004).

The focus on frequency in early studies on IL does not mean that human behavior is only sensitive to this variable. Indeed, all the measures of association are generally correlated, so evidence collected to support one specific measure is equivocal if no special care is taken for controlling the other measures. Aslin et al. (1998) demonstrated that participants were sensitive to the transitional probability in word-segmentation studies. These results have been replicated in visual tasks (e.g., Fiser and Aslin, 2001), so that most recent studies on statistical learning take for granted that the statistics to which people are sensitive are transitional probabilities. This conclusion could be premature, given the correlations between the different measures, and the paucity of studies including different measures. In fact, the literature on conditioning has long suggested that even animals such as rats or pigeons are sensitive to DeltaP (Rescorla, 1967). Perruchet and Peereman (2004) compared several measures of associations, and they found that participants were more sensitive to the bidirectional contingency than to simpler measures of associations (although in a specific context). A conservative conclusion could be that people are sensitive to more sophisticated measures of associations than co-occurrence frequency, and further study is needed for assessing more precisely which statistic is the more relevant in each context.

#### *2.32.3.1.2 Adjacent and nonadjacent dependencies*

A dimension orthogonal to the previous one concerns the distance between the to-be-related events. The early studies endorsing a statistical approach in the IL domain focused on adjacent elements (typically the bigrams of letters). The importance of adjacent relations, however, does not mean that it is impossible to learn more complex information. A number of studies in SRT tasks have investigated how reactions times to the event $n$ improved due to the information brought out by the events $n$-1, $n$-2, $n$-3 (known as first-order, second-order, and third-order dependency rules, respectively), and so on. Second-order dependencies can be learned quite easily and are now used as a default in most SRT studies. Third-order dependency rules can also be learned, although less clearly (Remillard and Clark, 2001). However, higher-order dependency rules are seemingly much harder, or impossible to learn. For instance, even after 60 000 practice trials, Cleeremans and McClelland (1991) obtained no evidence for an effect of the event four steps away from the current trial.

In the situations discussed so far, the relations between distant events are not considered independently from the intervening events. By contrast, in the AXC structures investigated in several recent studies, a relation exists between A and C irrespective of the intervening event X, which is statistically independent from both A and C. Examining whether learning those nonadjacent relationships is possible was prompted by the fact that these relations are frequent in high-level domains such as language and music. The studies investigating the possibility of learning nonadjacent dependencies between syllables or words (Gomez, 2002; Newport and Aslin, 2004; Perruchet et al., 2004; Onnis et al., 2005), musical sounds (Creel et al., 2004; Kuhn and Dienes, 2005), digits (Pacton and Perruchet, in press), and visual shapes (Turk-Browne et al., 2005) report positive results. However, most of them conclude that learning nonadjacent dependencies presupposes more restrictive conditions than those required for learning the relations between contiguous events. Gomez (2002) showed that the degree to which the A_C relationships were learned depended on the variability of the middle element (X). For Newport, Aslin, and collaborators (e.g. Newport and Aslin, 2004), the crucial factor is the similarity between A and C. Learning seems also much easier in a situation where the successive AXC units are perceptually distinct (e.g., Gomez, 2002), than in situations where they are embedded in a continuous sequence (e.g., Perruchet et al., 2004). By contrast, Pacton and Perruchet (in press) provided support for a view in which nonadjacent dependencies can be learned as well as adjacent dependencies insofar as the relevant events are actively processed by participants to meet the task demands.

#### 2.32.3.1.3 Processing multiple cues concurrently

Up to now, we have examined how the learner exploits one source of information, for instance, event repetition. However, taken in isolation, a source of information often has a limited value in real-world settings. The system efficiency would be considerably extended if various sources could be exploited in parallel. The number of studies exploring this issue is still tiny, but they provide converging evidence for a positive assessment, as well in artificial grammar learning (e.g., Kinder and Assmann, 2000; Conway and Christiansen, 2006) as in SRT tasks (e.g., Hunt and Aslin, 2001). Studies on word segmentation have also demonstrated the possibility of combining statistical and prosodic cues (e.g., Thiessen and Saffran, 2003). The concurrent exploitation of various information sources can be simulated by connectionist networks (e.g., Christiansen et al., 1998), a feature that strengthens the plausibility of such a possibility in humans.

#### 2.32.3.1.4 Does learning depend on materials?

An impressive amount of data suggests that statistical learning mechanisms are domain general. For instance, although most studies in artificial grammar learning involve consonant letters, a large variety of other stimuli have been used occasionally, such as geometric forms, colors, and sounds differing by their timbre or their pitch, without noticeable difference. Conway and Christiansen (2005) directly compared touch, vision, and audition, and found many commonalities, although sequential learning in the auditory modality seemed easier than with the other two senses. Likewise, data on word segmentation have been successfully replicated with tones instead of syllables (e.g., Saffran et al., 1999; Saffran, 2002).

However, the fact that IL processes have a high level of generality across and within sensory modalities does not mean that they apply equally well to any stimuli, as if statistical learning mechanisms were blind to the nature of processed material. The well-known difficulty of publishing null results certainly accounts for a part of the apparent universality of IL mechanisms. A closer look shows, for instance, that learning may depend on aspects of the material that could seem *a priori* irrelevant. For instance, there is overwhelming evidence of rapid learning in standard SRT tasks, in which a target appears in successive trials at one of a few discrete locations. Chambaron et al. (2006) explored a similar situation, except that participants had to track a target that moved along a continuous dimension. They fail to obtain evidence of learning in several experiments, hence showing that, in spite of a close parallel between continuous tracking tasks and SRT tasks, taking benefit from the repetition of a segment in continuous tracking task appears to be considerably more difficult than taking benefit from the repetition of a sequence in SRT tasks. Moreover, recent research on statistical learning has shown that learning was highly dependent on low-level perceptual constraints. For instance, for a given statistical structure, the acoustic properties of the artificial speechflow have been shown to be determinant for learning to segment the speechflow into words (e.g., Onnis et al., 2005). Shukla et al. (2007) provides evidence that possible world-like sequences, namely chunks of three syllables with high transition probabilities, are not recognized as words if they straddle two prosodic constituents.

The efficiency of learning may also depend on high-level expectancies about the structure of the material. For instance, Pothos (2005) used an artificial grammar learning task in which the consonant letters were replaced by the name of cities. The sequences of cities were presented as the routes a salesman has to travel. In one group of participants, the training sequences matched the intuitive expectation that the salesman follows routes that link nearby cities, while in a second group, they conflicted with this intuition. Learning, as assessed by the comparison with an adequate control group, occurred only in the first group, as if a conflict between the knowledge acquired by processing the statistical structure of the stimuli and the intuitive expectations about stimulus structure prevented learning from occurring in the second group.

#### *2.32.3.1.5 About the learners*

Any discussion about learnability is meaningless without considering the characteristics of the learners. Most of the studies reported above have been performed on healthy adult participants.

Regarding first the effect of age, recent research on statistical learning has shown the surprising learning abilities of infants. These abilities have been initially revealed with auditory artificial languages (e.g., Saffran et al., 1996), but they are in no way limited to language-like stimuli. They concern sounds or combinations of visual features as well (e.g., Fiser and Aslin, 2001, 2002). Several studies have also investigated IL in children. They suggest that there is no noticeable evolution from 4- or 5-year-old children to young adults (e.g., Meulemans et al., 1998; Vinter and Detable, 2003; Karatekin et al., 2006). Other studies suggest that IL does not decline with healthy aging (e.g., Cherry and Stadler, 1995; Negash et al., 2003). Furthermore, a number of studies have reported impressive IL abilities in children (e.g., Detable and Vinter, 2004) and young adults (Atwell et al., 2003) with mental retardation, and in patients with psychiatric (e.g., Schwartz et al., 2003) and neurological disorders, including amnesia (e.g., Meulemans and Van der Linden, 2003; Shanks et al., 2006), Alzheimer's disease (Eldridge et al., 2002), Parkinson's disease (e.g., Smith and McDowall, 2006), closed-head injury (e.g., Vakil et al., 2002), and Williams Syndrome (Don et al., 2003). Statistical learning abilities have been shown in animals such as nonhuman primates (e.g., Hauser et al., 2001) or even rats (Toro and Trobalon, 2005).

These data have crucial implications for a number of fundamental and applied issues. They do not mean, however, that everyone shares equivalent abilities whenever statistical learning is concerned. In fact, comparative studies often select situations the difficulty of which is *a priori* well-suited for the full span of the investigated population. When the level of difficulty is increased, a difference often emerges. For instance, a deficit of performance has been observed in complex IL tasks in elderly people (e.g., Howard et al., 2004) and in amnesic patients (Curran, 1997; Channon et al., 2002). This dependency of IL with regard to learner's general competencies whenever the learning settings become complex enough is confirmed by studies on adult healthy people. For instance, Dienes and Longuet-Higgins (2004) observed that only participants experienced with atonal music were able to learn artificial regularities following the structures of serialist music.

### 2.32.3.2 Statistical Computations and Chunk Formation

#### *2.32.3.2.1 Computing statistics?*

Observing that performances in IL tasks conforms to statistical regularities may lead us to infer that learners compute statistics. Certainly, the idea that learners unconsciously compute statistics using the same algorithms as a statistician would use is somewhat implausible. However, the possibility of approximating the outcome of analytical computations through connectionist networks (e.g., Redington and Chater, 1998) offers a much more appealing alternative. Learning is performed by the progressive tuning of the connection weights between units within multilayer networks. Although different types of networks have been used (see Dienes, 1992), the Simple Recurrent Networks (SRN), initially proposed by Elman (1990), have been the most widely applied to IL. SRNs are typically trained to predict the next element of sequences presented one element at a time. Cleeremans and McClelland (1991) have shown that an SRN was able to simulate the performance of human learners in an SRT task in which the successive locations of the target were generated by a finite-state grammar, and the ability of SRNs to successfully account for performance in various IL paradigms has been confirmed since then in a number of studies (e.g., Kinder and Assmann, 2000). Certainly, due to the impressive ability of connectionist networks to simulate learner's performance, the idea that learners actually perform statistical computations is taken for granted by a number of authors. This idea is not compelling however. Inferring statistical computation from statistical sensitivity may amount to repeating the same error as the early researchers in IL, who inferred rule abstraction from the behavioral sensitivity to rules. An alternative interpretation emerges from the observation that IL generally leads to the formation of chunks.

#### *2.32.3.2.2 The formation of chunks*

The fact that learning leads to the formation of chunks is largely consensual. This is obviously the case in recent studies on word segmentation and object formation, in which performance is directly assessed through chunk formation. But this is also true in most of the other situations of IL, in which chunks are not the explicit end-product of learning. A number of studies have shown that participants learn small chunks of two or three elements in artificial grammar learning settings. Chunking the material, far from being a degraded procedure, is a highly efficient mode of coding. Indeed, dealing with small units facilitates transfer and generalization. This happens because, given the structure of finite-state grammars, new items are formed by recombining old components. However, this is true only if the chunks respect the statistical structure of the material. To put the matter simply, assuming five events (A, B, C, D, and E), forming the chunks 'AB' and 'CDE' is beneficial only if A and B on the one hand, and C, D, and E on the other hand, form cohesive structures. If 'AB' is frequently followed by C, and 'DE' frequently occurs in other contexts, then this mode of chunking would be ill suited (Perruchet et al., 2002).

The formation of chunks forming cohesive structures can be easily accounted for by the idea that learners compute statistics. For instance, for Saffran and Wilson (2003), verbal chunks are inferred from statistical computations and then serve as the stuff for further statistical computations. Fiser and Aslin (2005) also consider that the visual input is chunked into components according to the statistical coherence of their components. To use the five-event example, AB and CDE would emerge as from some kind of cluster or factorial analyses once the correlational structure of the events has been computed.

#### *2.32.3.2.3 Are statistical computations a necessary prerequisite?*

Chunks consistent with the statistical structure of the material can also emerge without prior statistical computations. Simple memory mechanisms could be sufficient. To begin with, let us consider the ubiquitous phenomenon of forgetting. Because frequently repeated events tends to be forgotten to a lesser extent than less frequent events, forgetting leads us to be sensitive to event frequency, without any statistical 'computation.' Several models of IL (Servan-Schreiber and Anderson, 1990; Knowlton and Squire, 1996; Perruchet and Vinter, 1998a) rest on this intuition. Again, in the example, the chunks 'AB' and 'CDE' would emerge from the fact that A and B on the one hand, and C, D, and E on the other hand, occur more often together than any other combinations of events. In Perruchet and Vinter's Parser model, those chunks emerge simply because other associations of events (such as ABC), if they occur, are forgotten due to their relative rarity. The difference with the statistical account is that, instead of being inferred from the results of statistical computation, chunk formation is the primary mechanism, and the cohesive chunks are those that are selected among a number of other ones due to well-known laws of associative memory, primarily forgetting.

Chunking is often thought of as exclusively sensitive to the raw frequency. This would indeed be the case if the strength of memory traces only depended on the repetitions of events. However, it has long been known that forgetting is due in large part to the interference generated by the prior or subsequent events that are related in some way to the target event. Now, and this is the crucial point, taking into account the effect of interference in chunk formation amounts to considering other measures of association than the raw frequency of co-occurrences. For instance, implementing forward interference is sufficient to make chunk strength sensitive to transitional probabilities (Perruchet and Pacton, 2006, Box 3). Moreover, Perruchet and Peereman (2004) have shown that the Perruchet and Vinter's (1998a) Parser model, thanks to the role ascribed to interference in chunk formation, was even sensitive to contingency, that is, to a measure of association more comprehensive than conditional probabilities.

To recap, the current debate is between those who argue that statistical computations are performed first, with the chunks inferred on the basis of their results, and those who argue that the chunks are formed from the outset, with the sensitivity to statistical regularities being a by-product of the selection of those chunks as a consequence of ubiquitous memory laws. Note that the two interpretations are equally consistent with associative learning principles. One advantage of the second option is its parsimony. Indeed, no additional computational devices have to be imagined to extract chunks from distributional information. In addition, the chunk model can be easily unified with the instance-based model, because both are grounded on standard memory laws. A unified view could find an integrative framework in the so-called processing account of IL. This account borrows, from research in memory, the idea that memory traces are no more than the by-product of the processing operations engaged during study, and that retrieval depends on the overlap between the processing undertaken during the study and the test phase (e.g., Roediger et al., 1989). Support for this view in IL studies stems from the demonstration of the encoding specificity effects in research into artificial grammar. For instance, Whittlesea and Dorken (1993) show that performances in the test phase are better if the processing involved during the test (pronouncing or spelling the letter strings) matches the processing involved during the study phase. Although the processing account is historically associated with the instance-based models of IL (e.g., Neal and Hesketh, 1997), its grounding principles could be applied to chunk-based models as well.

These considerations, however, cannot be considered as compelling. At this time, the available experimental studies intended to tease apart the predictions from statistical and chunk-based models have produced equivocal results (e.g., Boucher and Dienes, 2003). Clearly, the outcome of the debate is pending further empirical investigations.

## 2.32.4 How Implicit Is 'Implicit Learning'?

What defines implicitness in IL is far from being agreed upon. A distinction is made, in the following sections, between what occurs during the training phase and the test phase of an IL session. The study-test distinction has limited interest, insofar as in most real-world situations, and in several laboratory situations (such as SRT tasks) as well, any event both influences subsequent events and is itself influenced by the prior ones, hence serving the two functions simultaneously. However, this distinction provides a convenient means to tease apart different issues.

### 2.32.4.1 Implicitness during the Training Phase

#### *2.32.4.1.1 Incidental and intentional learning*

A feature which is a part of virtually all definitions of IL is the incidental nature of the acquisition process. IL proceeds without people's intention to learn. This characteristic is sometimes the only one to be retained, thus conflating the notion of IL and incidental learning (e.g., Stadler and French, 1994). The SRT tasks are often considered as those that offer the best guarantee of the incidental nature of learning, because this task is endowed with its own internal purpose, and it leaves quite limited time for thinking about the task structure. In most of the other IL tasks, instructions distract participants from thinking about the overall material structure, by focusing participants' attention on individual items. For instance, in artificial grammar learning, participants are generally asked for the rote learning of individual letter strings. In invariant learning, participants are asked to perform some arithmetic computation on each digit string. In other tasks, such as the word-segmentation task, participants are simply asked to listen to the artificial language, without specific demands.

#### *2.32.4.1.2 Is attention necessary?*

A question of major interest is whether performance improvement depends on the amount of attention paid to the study material during the familiarization phase. The main strategy consists in adding a concurrent secondary task during the training session, then observing whether performance improvement is equivalent to that observed in a standard procedure.

A few early studies claimed that the addition of a secondary task had no effect, or even could *facilitate* learning in very complex experimental settings. This leads to contrast the concepts of 'selective learning' and 'unselective learning' (e.g., Berry and Broadbent, 1988), with the latter being assumed to occur when the situation was too complex to be solved by attention-based mechanisms. The original results were not replicated, however (e.g., Green and Shanks, 1993), and to the best of our knowledge, the notion of unselective learning, as initially discussed in the studies conducted by Broadbent and colleagues, is no longer advocated.

The idea of two forms of learning, differing according to whether attention is required or not, has also been proposed in another context, but with the opposite stance. The hypothesis was that attention is required for learning complex sequences in SRT tasks, while nonattentional learning is efficient for the simplest forms of sequential dependencies (Cohen et al., 1990). However, observing learning under dual-tasks conditions does not imply the existence of a nonattentional form of learning, because the secondary task might not deplete the attentional resources completely (Stadler, 1995). Closing their survey on the role of attention in implicit sequence learning, Hsiao and Reber concluded:

> We view sequence learning as occurring in background of the residual attention after the cost of the tone-counting task [commonly used as a secondary task in this context] and the key-pressing task. If there is still sufficient attention available to the encoding of the sequence, learning will be successful; otherwise, failure will result. (Hsiao and Reber, 1998: 487)

Regarding artificial grammars, Reber (e.g., 1993) has also acknowledged that attention to the study material is necessary for learning to occur. In support of this claim, Dienes et al. (1991) have shown that the accuracy of grammaticality judgments was lowered when subjects had to perform a concurrent random number generation task during the familiarization phase.

Note also that other studies have shown that, without at least minimal attentional involvement, even simple covariations or regularities turn out to be impossible to learn (Jimenez and Mendez, 1999; Hoffmann and Sebald, 2005; Pacton and Perruchet, in press; Rowland and Shanks, 2006b). The conclusion according to which improved performance in IL situation requires attention has been recently supported by studies on statistical learning using continuous speech flow (Toro et al., 2005) or visual displays (Baker et al., 2005; Turk-Browne et al., 2005). This conclusion comes as no surprise, because the major role played by selective attention in acquisition processes is an old and robust empirical finding (for another approach that emphasizes the role of attention, see Frensch et al., 1994).

## 2.32.4.2 Implicitness during the Test Phase

### *2.32.4.2.1 The lack of conscious knowledge about the study material*

Is it possible to improve his/her performance without being conscious of what has been learned? A considerable amount of studies have addressed this question by exploring participants' explicit knowledge through postexperimental tests. Overall, a number of studies report that participants are aware of the knowledge they have acquired. However, other studies report that participants fail in the test of explicit knowledge. The question is: Are those negative results reliable? A number of potential drawbacks have been raised.

### *2.32.4.2.2 The Shanks and St. John information criterion*

The first problem is linked to the fact that exploring whether knowledge is consciously represented primarily requires that the knowledge relevant for performing the task has been correctly identified. In an influential synthesis of the literature, Shanks and St. John (1994) coined this requirement as the 'information criterion.' The information criterion stipulates that the information the experimenter is looking for in the awareness test needs to match the information responsible for the performance change.

Although the cogency of this criterion may seem obvious, it must be realized that it entails that any conclusion about implicitness entirely depends on the response given to the 'what is learned' question raised in the prior sections. Any error in the hypothesized content of knowledge, far from being a "slightly embarrassing methodological glitch" (Reber, 1993, note p. 44, 114-115), has dramatic consequences on the inference that one may drawn about the implicit/explicit status of the acquired knowledge. For instance, Reber and Allen correctly pointed out that:

> . . . clearly a considerable proportion of subjects' articulated knowledge can be characterized as an awareness of permissible and nonpermissible letter pairs. (Reber and Allen, 1978: 210).

However, the authors did not realize that this form of knowledge was sufficient to account for performance. Instead, they attributed performance improvement to rule knowledge, which they concluded to be the result of unconscious abstraction. A large part of the earlier claims for the lack of conscious knowledge about the study material seemingly stems from this problem, also known as the problem of the 'correlated hypotheses' after the seminal studies by Dulany (1961) and Dulany et al. (1984).

### *2.32.4.2.3 The Shanks and St. John sensitivity criterion*

According to Shanks and St. John, a second criterion is that the test of explicit knowledge is sensitive to all of the relevant conscious knowledge. A test of free recall, such as used in the early studies on IL, is notoriously insensitive. For instance, participants may not report some knowledge they have about the material structure, because they have a conservative response criterion that makes them respond only when their knowledge is held with high confidence, or simply because they think this knowledge is irrelevant or trivial. For this reason, most studies now involve a test of recognition, in which participants have to discriminate items belonging to the training materials from new items. However, performing no better than chance in a recognition test is not necessarily a proof that participants lack any explicit knowledge about the task. For instance, Reed and Johnson (1994) used a recognition test after an SRT task and observed that recognition scores were at chance. In an attempted replication involving the same procedure, Shanks and Johnstone (1999) found instead very high levels of recognition. The only difference between the two studies was that participants in Shanks and Johnstone were rewarded by an extra sum of money for each correct decision. Performing the recognition test is somewhat tedious, and presumably participants in the Reed and Johnson study were not motivated enough to make the effort required to perform the task correctly.

#### 2.32.4.2.4 The problems of forgetting

In the standard procedure, the explicit tests are postponed after the task of IL, thus raising the problem of the retention of the knowledge exploited during the implicit test. For instance, Destrebecqz and Cleeremans (2001) reported chance-level recognition in an SRT paradigm (at least for a group of participants). Notably, the test of recognition was administered after participants had performed another task, in which they had to generate sequences under various instructions (see below). Shanks et al. (2003) attempted to reproduce Destrebecqz and Cleeremans' dissociation between RT measures and recognition scores, but in conditions in which the two kinds of measures were taken concurrently. In three experiments, they failed to replicate the Destrebecqz and Cleeremans' dissociation and obtained instead clear evidence of recognition. Note that the problems of forgetting are made especially important due to the fact that a recognition test necessarily includes the exposure to new sequences (generally half of the test items). Because these new sequences are highly similar to old sequences, they are prone to generate interference for the subsequent test trials.

#### 2.32.4.2.5 The problem of the reliability of measures

The scores in implicit and explicit tasks are often found to be correlated. For instance, in SRT tasks, Perruchet and Amorim (1992) reported that Pearson correlations over the sequence trials between RT and recognition scores ranged, in three experiments, from .63 to .98. However, some authors (e.g., Willingham et al., 1993) have argued that evidence for unconscious knowledge was given by the fact that learning could be still observed when the analysis was restricted to the subgroup of items (or the subgroup of participants) for which no evidence of explicit knowledge was gathered. This argument is questionable, however. As discussed in Perruchet and Amorim (1992), the method, in effect, dichotomizes the scores on the implicit measure on the one hand, and on the explicit measure on the other, to assign the items or the participants to a fourfold contingency table. Then inference for dissociation is drawn from the observation that some items or some participants fall into the discordant cells of the contingency table, or in other words, that the correlation is not perfect. The problem with this method is that a prerequisite for obtaining a perfect correlation is perfect reliability of measures. This condition is highly unrealistic for psychological measures, especially for the scores on implicit tests (Meier and Perrig, 2000; Buchner and Brandt, 2003). Shanks and Perruchet (2002) have developed this reasoning into a quantitative model, which assumes that the sources of error plaguing implicit and explicit measure are independent. Although the model involved a single underlying memory variable, it turned out to be able to generate a dissociation between RTs and recognition in SRT tasks that mimics fairly well the dissociation the authors reported themselves (despite the temporal synchrony of measures).

#### 2.32.4.2.6 An intractable issue?

To sum up, the current evidence for the lack of conscious knowledge about the study material is weak at best. There is currently no identified condition allowing one to obtain a reproducible dissociation. Most of the experiments reporting above-chance performance in implicit measures and chance-level performance in explicit tests have been replicated in more stringent conditions, and it turns out that, as a rule, the dissociation no longer appears when appropriate controls are made.

These data do not allow clear conclusions. On the one hand, the preceding discussion makes it clear that it is impossible to conclude to the existence of learning without any conscious counterpart. But, on the other hand, it should be also unwarranted to infer from the current findings that conscious awareness of the material structure is necessary for performance improvement. The first reason is a logical one, which has been met with regard to rule abstraction, namely, it is not possible to prove that something does not exist. There is yet another reason, linked to the fact that no task is process-pure, as has been well documented in the literature on implicit memory. This is especially true for the most sensitive tests, such as recognition. Jacoby (1983), and many others since, have argued that the relative fluency of perception, which relies on implicit process, may be used as a cue for discriminating old from new items in a recognition task, thus making a variable contribution to recognition judgments over and beyond a directed memory search factor. This entails that above-chance recognition after an IL task does not provide a compelling evidence for explicit knowledge. To date, it is not clear how further studies could solve this conundrum. Some authors (e.g., Higham et al., 2000) have suggested that those problems are intractable and should prompt researchers to give up any attempts to demonstrate learning without concurrent consciousness.

#### 2.32.4.2.7 The subjective measures

The measures discussed so far are often called 'objective,' because it is the experimenter that judges the level of awareness of participants from their performance in specific tests. Another way of defining implicitness starts from the consideration of the phenomenal state of the participants such as it may be directly expressed. Two such 'subjective' measures of implicitness have been proposed in the literature, the guessing criterion and the zero-correlation criterion (Dienes et al., 1995). In both cases, participants are submitted to a test of explicit knowledge such as a recognition test, and they have to rate how confident they are about each decision. To check whether the guessing criterion is filled, the scores on the recognition test are restricted to those of the decisions that are accompanied by a subjective experience of guessing. If participants achieve above-chance discrimination while they report to be guessing, the guessing criterion is met. The zero-correlation criterion rests on the idea that, if knowledge is implicit, participants must not be more confident when they are correct than when they are incorrect. As a consequence, if participants have no introspection into the bases of their decisions, the correlation between confidence and accuracy should be null.

Can performances on standard IL tasks be called implicit according to these criteria? The literature again does not provide a clear response, with some studies reporting positive results and others negative results. In fact, the general picture appears similar to that observed with objective measures, with initially positive findings being not replicated when more sensitive measures are used. For instance, Dienes and Altman (1997) reported a zero correlation between confidence and accuracy in an artificial grammar learning task involving a transfer paradigm. Notably, participants had to assess their confidence on a continuous scale ranging from 50 to 100, where 50 was a complete guess and 100 was absolutely sure. Using the same scale, Tunney and Shanks (2003b) replicated this result. However, based on a study by Kunimoto et al. (2001), Tunney and Shanks reasoned that a binary confidence judgment could be more sensitive, maybe because participants might find it easier to express subjective states on a binary than on a continuous scale. When participants had to express their confidence on a binary scale, they were found to be systematically more confident in their correct decision than in their incorrect decision in several independent experiments. To conclude, irrespective of the *a priori* validity that one decides to ascribe to subjective measure of implicitness, it appears that there is to date no identified procedure that fulfills subjective criteria in a reproducible way.

#### 2.32.4.2.8 The lack of control

One possible meaning of 'implicitness' is that of 'automaticity.' One of the key features usually attributed to automatic behavior is that it is irrepressible, irrespective of people's intentions to do so. Although recent literature on automaticity has questioned the possibility that any learned behavior - even reading, which is often construed as prototypical of automaticity – could actually be outside of control (e.g., Tzelgov et al., 1992), the question of whether the expression of knowledge in IL tasks shares this property deserves to be raised. Such a demonstration was provided by Destrebecqz and Cleeremans (2001) in an SRT task. In an application of Jacoby's process dissociation procedure (Jacoby, 1991) to this task, the authors asked participants to generate a sequence under two successive conditions during the test phase of an otherwise standard SRT procedure. In the first condition, they were told to generate the sequences they were previously exposed to, and if they fail to remember them, to generate sequences as they come to their minds (the inclusion instructions). Then participants had to produce a sequence of key-presses that did not overlap with the training sequence (the exclusion instructions). Crucially, participants - at least a subgroup of participants trained without any interval between the response to a target and the appearance of the next target - were influenced by the training sequences despite their intention to prevent this from happening. They performed in the same ways irrespective of the instructions, and under exclusion instructions, they generated the training sequence more than would be expected from an appropriate baseline.

These findings, however, have proven to be difficult to replicate. In the same conditions, Wilkinson and Shanks (2004) found that participants were more influenced by the training sequence under inclusion than under exclusion instructions (see also Destrebecqz and Cleeremans, 2003). In three experiments, Wilkinson and Shanks also failed to replicate the results according to which parts of the training sequence were generated more often under exclusion instructions than in the baseline, even after more extensive training than used by Destrebecqz and Cleeremans (2001) - although they did not get any negative difference either, as it could be expected if participants were able to withdraw the parts of the training sequence from influencing their production. Overall, these and others results (see for instance Dienes et al., 1995; Tunney and Shanks, 2003a) offer only quite limited evidence for the conclusion that knowledge gained in IL settings lies outside of intentional control.

#### 2.32.4.2.9 The lack of intentional exploitation of acquired knowledge

The fact that participants are seemingly able to withdraw the influence of prior training when they are asked to do so does not mean that, under standard conditions, this influence is intentionally mediated. The lack of intentional exploitation of stored knowledge seems to be a hallmark of the real-world examples given at the outset of this chapter. Presumably nobody has the intuition of applying strategically a core of learned knowledge when speaking his maternal language, hearing music, or conforming to physical or social rules. Is this intuition confirmed in experimental studies?

The question is made difficult by the fact that, in most cases, influences expected from the intentional exploitation of conscious knowledge about the relevant aspects of the situation would have the very same effects as those induced by unconscious processes. As a consequence, it has been suggested that performance in IL tests can be accounted for by the use of explicit knowledge about various aspects of the experimental situation (Dulany et al., 1984; Shanks and St. John, 1994). It is certainly impossible to rule out this contention in general. However, it should be unwarranted to generalize it to all IL tasks. Indeed, there are cases in which the conscious exploitation of explicit knowledge does not coincide with the expected results of unconscious processing. One example is provided by the grammar learning studies involving preference judgments. Indeed, there should be *a priori* no reason for the knowledge about the material to be used to guide a preference judgment. However, participants consistently prefer grammatical items (e.g., Manza et al., 1998).

Vinter and Perruchet (2000) proposed a new task of IL that was especially devised to eliminate the potential influence of intentional control. When adults are asked to draw a closed geometrical figure such as a circle, their production exhibits a striking regularity. If they begin the circle in the lower half, they tend to rotate clockwise, and if they begin the circle in the upper half, they tend to rotate counter clockwise. In Vinter and Perruchet experiments, participants were guided to draw geometrical figures in such a way that this natural covariation was inverted. This training induced important and long-lasting modifications of subsequent free drawings. The point of interest is that, even if participants had become aware of the inverted covariation between the starting point and the rotation direction they experienced during the training session, they should have no reason to modify their usual mode of drawing as they did. This study provides clear evidence for an adaptive mode in which subjects' behavior becomes sensitive to the structural features of an experienced situation, without the adaptation being due to the intentional exploitation of subjects' explicit knowledge about these features.

### 2.32.4.3 Processing Fluency and Conscious Experience

Let us now reverse the direction of the potential relation between learning mechanisms and conscious thought, in order to examine the level of dependency of conscious thought with regard to IL.

An influential model of how training in IL settings leads to a change in performance posits that training induces a modification in the subjective experience of the learner. More specifically, the underlying idea is that training improves the fluency of perceptual processing for the studied materials. This account was initially proposed by Servan-Schreiber and Anderson (1990) in the context of their chunking theory. In fact, however, the improved processing fluency can also be attributed to other forms of knowledge, such as rules or memory for specific instances. Thus a fluency theory has been advocated as well by those researchers who maintain a role for rule-based processing (Zizak and Reber, 2004) and by those who consider that statistical computations are sufficient (e.g., Conway and Christiansen, 2005).

Let us examine how this account works in artificial grammar learning paradigms. The assumption is that, after training with a sample of grammatical strings of letters, new grammatical strings are processed fluently, or more precisely, more fluently than expected (Whittlesea and Williams, 2000), hence generating a feeling of familiarity leading itself to endorse the strings as grammatical. The two steps of this hypothesis have received experimental support. The fact that exposure to the training strings improved processing fluency has been shown by Buchner (1994). The test strings were displayed in such a way that they emerged progressively from noise, a procedure known as a perceptual clarification procedure. It turned out that grammatical strings were identified about 200 ms faster than ungrammatical ones. The fact that improved fluency in turn influences grammaticality judgments has been demonstrated using a method well documented in the literature on implicit memory, which consists in artificially enhancing the fluency of processing of selected items. During the test phase of an otherwise standard artificial grammar learning experiments, Kinder et al. (2003) exposed participants to test strings that did not differ in their grammatical status (they were all grammatical). The test strings were displayed in a perceptual clarification procedure as in Buchner (1994), except that some strings were clarified slightly faster than the others. Participants judged the former more often grammatical than the latter.

The fluency account suggests that IL modifies the subjective experience of the learner. However, the induced modifications appear to be quite minor, insofar as they are prompted by a gain of some fractions of second in processing speed. The frequent rapprochement of the concepts of IL and priming (e.g., Cleeremans et al., 1998; Conway and Christiansen, 2006; Kinder et al., 2003) is consonant with the idea that the training-induced modifications are relatively inconsequential. It is also possible to consider that the changes in the conscious experience of the learner are much more striking. For instance, in artificial grammar learning, participants normally learn to perceive the grammatical strings as a sequence of chunks the content of which is consonant with the structure of the grammar (e.g., the sequences of letters composing a recursive loop have high chance of being perceived as chunks, see Servan-Schreiber and Anderson, 1990; Perruchet et al., 2002). Likewise, in word-segmentation studies, the speechflow, which is initially perceived as an unorganized set of syllables, turns out to be perceived as a sequence of units, which match the words composing the language. More generally, an essential function of IL could be that of making the conscious perception and representation of the world isomorphic with world's deep structure. Because this change in subjective experience can be construed as a simple by-product of the attentional processing of the incoming information, Perruchet and Vinter (2002) have suggested the concept of 'self-organizing consciousness' to express the idea that IL shapes new conscious percepts and representations in a way which make them increasingly adaptive (see also Perruchet, 2005; Perruchet et al., 1997).

Neither the fluency account nor Perruchet and Vinter's (2002) self-organizing consciousness model is aimed to account for all behavioral changes observed in IL settings. For instance, although the fluency account is relatively consensual (partly due to the fact that it is mute with regard to the nature of knowledge inducing fluency), this account explains only a part of the performances observed in IL settings. Even in the artificial grammar learning paradigm, which is *a priori* a well-suited field of application, relative processing fluency does not seem to be able to account for the whole pattern of grammaticality judgments (Buchner, 1994; see also Zizak and Reber, 2004, p.23). However, these models point to the possibility of considering IL and consciousness not in terms of dissociation or independence, but rather in terms of dynamic interplay.

### 2.32.4.4 Summary and Discussion

To sum up, research of the last few decades has shown that it is surprisingly difficult to specify in what sense IL is implicit. The notion of unselective, nonattentional learning has vanished in light of studies demonstrating that learning requires at least some forms of attentional processing of the incoming information. Likewise, there are quite limited supports to claim that while they perform the implicit test participants (1) have no conscious knowledge about the study material, (2) have the subjective experience of guessing, or (3) have no control over the expression of their knowledge. Of course, it is possible to include one or the other of these features within a definition of IL, and some authors did so (for a sample of definitions, see Frensch, 1998). However, endorsing this kind of definition leads to the somewhat paradoxical consequence of giving to a research domain the objective of checking whether this domain actually exists. To date, there is no specified paradigm in which one or the other of these criteria can be asserted in a consensual and reproducible way.

A feature that can be retained with higher confidence is the lack of intentional exploitation of stored knowledge. This does not mean, obviously, that this condition is fulfilled in each and every study, but rather that the existence of the phenomenon can be reasonably asserted on the basis of reproducible evidence. Accepting the role of unconscious influences, however, does not lead us to conceive IL and conscious experiences as divorced one from each other. There is indeed extnsive evidence that these unconscious influences primarily affect the conscious experience of the learner.

## 2.32.5 Implicit Learning in Real-World Settings

### 2.32.5.1 Exploiting the Properties of Real-World Situations

Although most of research on IL uses artificial, laboratory situations, natural situations have been used on occasion to shed light on specific issues. In this case, only the test phase is carried out in well-controlled experimental conditions, while implicit training is assumed to have occurred previously in natural settings. For instance, Pacton et al. (2001) exploited the very extended time scale on which real-world learning takes place to examine whether transfer decrement (see the section titled 'The phenomenon of transfer: the interpretations') is a transitory or an enduring phenomenon. The issue is important, because it can be argued that the transfer decrement commonly observed in laboratory settings, which is one of the arguments used against a rule-based view, is simply due to the fact that training is not extensive enough to allow the full development of rule abstraction. Pacton et al. explored the development of the sensitivity to certain orthographic regularities not explicitly taught at school. They showed that the decrement in performance due to transfer persisted without any trend toward fading over the 5 years of experience with printed language that they examined, hence strengthening the claim that IL is not mediated by rule knowledge.

### 2.32.5.2 Exploiting our Knowledge about Implicit Learning

The knowledge gained in laboratory studies is aimed at improving our understanding of world-sized issues. Explicit loans from the IL literature have been made occasionally in a number of domains, including child development (Perruchet and Vinter, 1998b), second-language acquisition (e.g., Ellis, 1994; Robinson, 2002), spelling acquisition (Kemp and Bryant, 2003; Pacton et al., 2005; Pacton and Deacon, in press), and the development of gustatory preferences (Brunstrom, 2004). To various degrees, the concepts and the methodology of laboratory studies have inspired researchers to progress in the understanding of these domains. In regard of the potential relevance of IL mechanisms in these and other domains, much more could be made in this direction, however. The only domain in which a sizeable amount of literature has emerged concerns the relationships between IL and natural language acquisition (e.g., Gomez and Gerken, 2000). This rapprochement is partly due to the fact that research on language has evolved on its own toward methods – the use of artificial languages – and concepts – notably around the notion of statistical learning – that are also at the heart of IL research.

The practical applications of IL, for instance for educative purposes or the reeducation of neurological patients, appear to be still sparser. Some methods have evolved that exploit principles which can be *a posteriori* related to IL principles, such as using conditions as similar as possible to natural learning to teach second language (after Krashen, 1981) or reading (for a review, see Graham, 2000). An extensive literature also concern the use of errorless learning for reeducative purposes in a neuropsychological perspective (see review in Fillingham et al., 2003). But most of these attempts have been conducted without considering the possible contribution of IL research (for a recent exception, see Saetrevik et al., 2006). The explanations for this relative paucity are certainly manifold. One of them may be that learning in real-world situations most often involve some mixture of implicit (or incidental) and explicit (or intentional) learning. Now, the interactions between these forms of learning have not been at focus in the literature on IL, because, except in a few studies (e.g., Matthews et al., 1989), the objective has been to isolate implicit processes to examine them in their maximum state of purity. Further studies are needed to assess how, for instance, the learning of rules in explicit conditions may be combined with implicit statistical learning.

## 2.32.6 Discussion: About Nativism and Empiricism

Let us return to a question raised at the outset of this chapter, which stemmed from the lack of consideration during the behaviorist era of issues such as first-language acquisition, category elaboration, sensitivity to musical structure, acquisition of knowledge about the physical world, and various social skills. It was pointed out that this situation opened the door to the upsurge of a nativist perspective. Where do the studies reported in this chapter leave us?

At first glance, the mechanisms of IL, as they are revealed in laboratory studies, appear as definitely underpowered. The picture given by recent research stands far from the idea of the extraordinarily powerful processes that were imagined once, for instance by Lewicki et al., when they contended that “our non-conscious operating processing algorithms can do instantly and without external help” the same job as our conscious thinking achieves in relying on “notes (with flowchart or lists of if-then statements) or computer” (Lewicki et al., 1992, p.798). In fact, IL processes are probably unable to bring out to genuine rule knowledge, and the possibility of transfer are limited. In addition, the involvement of these processes seems to be dependent on selective attention. As pointed out above, the experimental study of learning around the 1960s was essentially devoted to classical and operant conditioning on the one hand and to the formation of concepts or problem-solving processes on the other hand. To make a long story short, IL mechanisms seem to be much nearer to the former than to the latter.

To be sure, experimental studies show that participants generally perform above chance in complex experimental settings. However, above-chance performance is generally attributable to the learning of some indirect, correlated aspects, which can be easily captured by elementary mechanisms. Everything happens as if IL often captured only nonessential aspects of the task. In experimental contexts, these correlated features are often considered as potential drawbacks, which need to be eliminated to reach the deep substance of the training material. For instance, studies in artificial grammar learning are often designed in such a way that bigram distribution becomes noninformative, studies in invariant learning often are controlled in such a way that the repetition of digits brings out no information about the invariant, and so on.

On the face of it, these data seem to provide fuel for a perspective in which the role of learning is minimized with regard to innate abilities. This is indeed the case if one considers that the knowledge base underlying the mastery of language and of the other high-level abilities alluded to above should be of the same form as the knowledge base that the scientist - for instance the linguist - acquires from an analytic investigation into his or her domain, that is, a formal, rule-based set of principles. This form of knowledge seems indeed to be definitely out of reach of IL processes.

However, a quite different perspective is possible. The general idea consists in assuming that learning in real-world setting proceeds as in the laboratory, that is, through the capture of correlated, apparently secondary aspects that can be grasped by elementary associative processes and that allow a good approximation of the behavior that would result from the knowledge of the formal structure of the domain. In order to be viable, such a perspective requires that the objective analysis of specific domains provides evidence for such correlated features. Quite interestingly, recent research on language has revealed a number of such features. The best-documented example is certainly the past-tense formation in English, in which it has been shown that regular and irregular verbs differ according to the distribution of their phonological and semantic features. Connectionist simulations have shown that exploiting those correlated cues leads to a very good approximation of the performance that would result from the formal knowledge of the *-ed* suffix rule, along with the knowledge of the exceptions (e.g., McClelland and Patterson, 2002). To consider another illustration, it has been shown that simple co-occurrence statistics (e.g., Redington et al., 1998) as well as phonological cues (e.g., Monaghan et al.,

2005) turn out to be highly informative about grammatical categories. These and other studies suggest that, as far as language is concerned, abstract classes and categories are often associated with simple statistical properties that make them tractable by general-purpose statistical learning mechanisms.

If further studies on language corpuses confirm and extend this kind of findings, and if the same kind of analysis proves to be successful in other high-level domains of competence, then IL mechanisms would appear extraordinarily powerful to promote behavioral adaptation. Indeed, those mechanisms are remarkably well-suited to exploit a massive amount of correlated cues. This approach appears to provide the first viable alternative to the nativist perspective that is still prevalent in the cognitive approach starting from Chomsky. The development of a full-blown empiricist alternative depends obviously upon further investigations on human learning processes, but also on the development of a nonconventional mode of description of the world humans are faced with.

# 2.33 Implicit Memory and Priming

**W. D. Stevens, G. S. Wig, and D. L. Schacter**, Harvard University, Cambridge, MA, USA

## 2.33.1 Introduction

Priming refers to an improvement or change in the identification, production, or classification of a stimulus as a result of a prior encounter with the same or a related stimulus (Tulving and Schacter, 1990). Cognitive and neuropsychological evidence indicates that priming reflects the operation of implicit or nonconscious processes that can be dissociated from those that support explicit or conscious recollection of past experiences. More recently, neuroimaging studies have revealed that priming is often accompanied by decreased activity in a variety of brain regions (for review, see Schacter and Buckner, 1998; Wiggs and Martin, 1998; Henson, 2003), although conditions exist in which priming-related increases are also observed (e.g., Schacter et al., 1995; Henson et al., 2000; Fiebach et al., 2005). Various terms have been used to describe these neural changes, including adaptation, mnemonic filtering, repetition suppression, and repetition enhancement. These terms often refer to subtly distinct, though related, phenomena, and in some cases belie a theoretical bias as to the nature of such neural changes. Thus, throughout the present review, the term neural priming will be used to refer to changes in neural activity associated with the processing of a stimulus that result from a previous encounter with the same or a related stimulus.

When considering the link between behavioral and neural priming, it is important to acknowledge that functional neuroimaging relies on a number of underlying assumptions. First, changes in information processing result in changes in neural activity within brain regions subserving these processing operations. A second assumption underlying positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) is that these changes in neural activity are accompanied by changes in blood flow, such that the energy expenditure that accompanies increased neuronal processing elicits the delivery of metabolites and removal of by-products to and from active regions, respectively. It is these local vascular changes that are measured: PET measures changes in cerebral blood flow and oxygen or glucose utilization, while fMRI measures the ratio of oxygenated to deoxygenated hemoglobin (i.e., the blood-oxygen-level dependent, or BOLD, signal). Related techniques such as event-related potentials (ERP) and magnetoencephalography (MEG), by contrast, measure the electrophysiological responses of neural populations more directly, although at a cost of decreased spatial resolution. While this chapter will focus on fMRI and to a lesser extent PET studies of priming, ERP and MEG studies will be discussed when they are of special interest to the discussion of a particular topic.

Neuroimaging studies have provided new means of addressing cognitive theories that have traditionally been evaluated through behavioral studies. The primary goal of the present chapter is to examine how neuroimaging evidence has informed, influenced, and reshaped cognitive theories about the nature of priming. We focus on five research areas where such interaction has occurred: influences of explicit versus implicit memory, top-down attentional effects, specificity of priming, the nature of priming-related activation increases, and correlations between brain activity and behavior.

## 2.33.2 Influences of Explicit Versus Implicit Memory

Priming is typically defined as a nonconscious or implicit form of memory. This characterization is supported by numerous observations of spared priming in amnesic patients with severe disorders of explicit memory. However, starting with the earliest cognitive studies of priming in healthy volunteers, researchers have been concerned with the possibility that subjects may use some type of explicit retrieval to perform a nominally implicit task. This concern has led to the development of various cognitive procedures for estimating and removing the influences of explicit retrieval (e.g., Schacter et al., 1989; Jacoby, 1991). Two forms of such explicit 'contamination' have received attention in cognitive studies: (1) subjects realize that their memory is being tested, and intentionally retrieve study list words while performing a priming task to augment performance; (2) subjects follow task instructions, and therefore do not engage in intentional retrieval, but nonetheless unintentionally recollect that they had studied target items on the previous study list. With respect to the latter type of contamination, it has been noted that explicit memory often takes the form of unintentional or involuntary recollections of previous experiences in which there is no deliberate, effortful attempt to think back to the past; one is spontaneously 'reminded' of a past event that is accompanied by conscious recollection (e.g., Schacter, 1987; Schacter et al., 1989; Richardson-Klavehn et al., 1994; Richardson-Klavehn and Gardiner, 1998; Bernsten and Hall, 2004). We now consider findings from neuroimaging studies that provide insights into the nature of and relation between implicit and explicit influences on priming.

The explicit contamination issue arose in the first neuroimaging study of priming (Squire et al., 1992). In this experiment, subjects semantically encoded a list of familiar words prior to PET scanning and were then scanned during a stem completion task in which they provided the first word that came to mind in response to visual three-letter word stems. During one scan, subjects could complete stems with study list words (priming), and during another, they could complete stems only with new words that had not been presented on the study list (baseline). In a separate scan, subjects were provided with three-letter stems of study-list words, and were asked to think back to the study list (explicit cued recall).

Priming was associated with decreased activity in the right extrastriate occipital cortex compared with baseline, but there was also increased activity in the right hippocampal formation during priming compared with the baseline condition. In light of previous results from amnesic patients indicating that normal stem-completion priming can occur even when the hippocampal formation is damaged, it seemed likely that the observed activation of the hippocampal region reflects one of the two previously mentioned forms of 'contamination': subjects intentionally retrieved words from the study list or, alternatively, they provided the first word that comes to mind and involuntarily recollected its prior occurrence.

Schacter et al. (1996) attempted to reduce or eliminate explicit influences by using a nonsemantic study task (counting the number of t-junctions in each of target words), which in previous behavioral studies had supported robust stem-completion priming together with poor explicit memory for the target items (e.g., Graf and Mandler, 1984; Bowers and Schacter, 1990). Consistent with the idea that the priming-related hippocampal activation previously observed by Squire et al. reflects contamination from explicit memory that is not essential to observing priming, following the t-junction encoding task there was no evidence of priming-related increases in the vicinity of the hippocampal formation during stem completion performance relative to the baseline task, but there were priming-related decreases in bilateral extrastriate occipital cortex and several other regions.

Using PET, Rugg et al. (1997) found greater left hippocampal activity after deep encoding than after shallow encoding during both intentional (old/new recognition) and unintentional (animate/inanimate decision) retrieval tasks. They also observed greater right anterior prefrontal activity during intentional retrieval than during unintentional retrieval after both deep and shallow encoding. These results suggest that increases in hippocampal activity during explicit retrieval, unaccompanied by corresponding increases in anterior prefrontal activity, reflect the presence of involuntary explicit memory.

A more recent event-related fMRI study by Schott et al. (2005) extends the findings of these early studies. During the study phase, subjects made nonsemantic encoding judgments in which they counted the number of syllables in each word. During the test phase, Schott et al. used a stem completion task and directly compared performance during intentional retrieval (i.e., try to remember a word from the list beginning with these three letters) and incidental retrieval (i.e., complete the stem with the first word that comes to mind). Importantly, they used a behavioral procedure developed by Richardson-Klavehn and Gardiner (1996, 1998) in which participants indicate whether or not they remember that the item they produced on the completion task had appeared earlier during the study task. This procedure could be applied to both the incidental and intentional tests, because on the intentional test subjects were told to complete stems even when they could not recall a study-list item. In the scanner, subjects used a button press to indicate whether they had covertly completed a stem; between these test trials, they provided their completions orally and indicated whether or not they remembered having seen the item during the study task. Stems completed with study-list words that were judged as nonstudied were classified as primed items, whereas stems completed with study-list words judged as studied were classified as remembered items. Both primed and remembered items were compared with baseline items that subjects judged correctly as nonstudied.

Similar to previous studies, Schott et al. (2005) documented activation reductions for primed items compared with baseline items in a number of regions, including extrastriate visual cortex. However, because the primed items in this study were, by definition, ones that subjects did not consciously remember having encountered previously, these data show more convincingly than earlier studies that priming-related activation decreases can reflect strictly nonconscious or implicit memory. Moreover, the authors also reported that their findings concerning priming-related reductions during the incidental tests were largely replicated during the intentional test. Thus, the results support the idea that priming effects can occur during both intentional and unintentional retrieval. Several other regions, including the right prefrontal cortex, showed greater activity during the intentional than the incidental task. In contrast to prior studies, the hippocampus showed greater activity during baseline than during priming, which the authors attributed to novelty encoding. Overall, these neuroimaging results support earlier behavioral distinctions between strategic controlled retrieval (i.e., intentional vs. incidental) and conscious recollection of the occurrence of previously studied items and show clearly that priming-accompanied activation reductions can occur without conscious recollection.

While the foregoing studies attempted to distinguish implicit and explicit aspects of priming by focusing on retrieval, other studies have done so by examining brain activity during encoding. Schott et al. (2006) examined subsequent memory effects, where neural activity during encoding is sorted according to whether items are subsequently remembered or forgotten (e.g., Brewer et al., 1998; Wagner et al., 1998). This study reported fMRI data from the encoding phase of the aforementioned stem completion experiment reported by Schott et al. (2005), where participants counted the number of syllables in each word. Consistent with results from earlier subsequent memory studies that examined explicit retrieval, Schott et al. found greater activation during encoding for subsequently remembered than for forgotten items in left inferior prefrontal cortex and bilateral medial temporal lobe. By contrast, encoding activity in these areas was not associated with subsequently primed items. Instead, subsequent priming was associated with activation decreases during encoding in bilateral extrastriate cortex, left fusiform gyrus, and bilateral inferior frontal gyrus. These regions were distinct from those that showed priming-related decreases during the stem completion test. Schott et al. suggest that their data indicate that priming, in contrast to explicit memory, is associated with sharpening of perceptual representations during encoding, an idea that is consistent with previous theories emphasizing the differential role of a perceptual representation system in priming and explicit memory (Schacter, 1990, 1994; Tulving and Schacter, 1990).

While the combined results from Schott et al.'s (2005, 2006) encoding and retrieval phases highlight clear differences between priming and explicit memory, a related study by Turk-Browne et al. (2006), also using a subsequent memory paradigm, uncovered conditions under which the two forms of memory are associated with one another. Subjects made indoor/outdoor decisions about a series of novel scenes. Each scene was repeated once, at lags ranging from 2 to 11 items. Fifteen minutes after presentation of the final scene, subjects were given a surprise old/new recognition test. Turk-Browne et al. focused on a region of interest in the parahippocampal place area (PPA) that responds maximally to visual scenes (e.g., Epstein and Kanwisher, 1998). The critical outcome was that repeated scenes produced behavioral priming and reduced activation in the PPA, but only for those scenes that were subsequently remembered. Forgotten items did not produce either behavioral or neural priming. A whole-brain analysis revealed similar effects – neural priming for remembered items only – in bilateral PPA as well as in left inferior temporal gyrus and bilateral angular gyrus. However, forgotten items were associated with neural priming in the anterior cingulate.

Given the general trend that behavioral and neural priming both depended on subsequent explicit memory, Turk-Browne et al. suggested that their data reveal a link between implicit and explicit memory that involves some aspect of shared encoding processes – most likely that selective attention during encoding is required for both subsequent priming and explicit memory.

The neuroimaging evidence considered thus far reveals some conditions under which priming can occur independently of explicit memory and others where dependence exists. An experiment by Wagner et al. (2000) showed that priming can sometimes hinder explicit memory. They made use of the well-known spacing or lag effect, where reencoding an item after a short lag following its initial presentation typically produces lower levels of subsequent explicit memory than reencoding an item after a long lag (though in both cases, explicit memory is higher than with no repetition). Using an incidental encoding task (abstract/concrete judgment) and old/new recognition task, Wagner et al. documented greater explicit memory following a long- than a short-lag condition, consistent with previous behavioral findings. By contrast, they showed greater behavioral priming, indexed by reduced reaction time, and greater neural priming, indexed by reduced activity in the left inferior frontal lobe, following a short lag than a long lag. Moreover, there was a negative correlation between the magnitude of neural priming in the left inferior frontal region and the level of subsequent explicit memory. Thus, the short-lag condition that maximized priming also reduced explicit memory. Although the exact mechanism underlying the effect is still not known, Wagner et al. suggested that priming may impair new episodic encoding and later explicit memory by reducing encoding variability, that is, encoding different attributes of repeated items on different trials. To the extent that encoding variability normally enhances subsequent memory by providing multiple retrieval routes to an item (e.g., Martin, 1968), priming might reduce explicit memory because it biases encoding toward sampling the same item features on multiple trials. Whatever the ultimate explanation, these results highlight the role of a previously unsuspected interaction between priming and explicit memory in producing a well-known behavioral effect.

## 2.33.3 Top-Down Attentional Effects on Priming

Priming is often considered to be an automatic process (e.g., Jacoby and Dallas, 1981; Tulving and Schacter, 1990; Wiggs and Martin, 1998). However, recent neuroimaging evidence has revealed that, to some extent, behavioral and neural priming may be affected by top-down cognitive processes such as attention or task orientation.

### 2.33.3.1 Priming: Automatic/Independent of Attention?

Early evidence supported the notion that perceptual priming effects occur independent of manipulations of attention (for review see Mulligan and Hartman, 1996). However, subsequent findings from behavioral studies began to reveal that some perceptual priming effects do depend to some degree on attention at study (e.g., Mulligan and Hornstein, 2000).

In a seminal review that linked behavioral priming with the phenomenon of repetition suppression, Wiggs and Martin (1998) stated that this process "happens automatically in the cortex" and "is an intrinsic property of cortical neurons," and that "perceptual priming is impervious to . . . attentional manipulations" (Wiggs and Martin, 1998: 231). Indeed, there is some compelling evidence from studies with monkeys to suggest that repetition-related neural priming can occur independent of attention (e.g., Miller et al., 1991; Miller and Desimone, 1993; Vogels et al., 1995), but these findings do not speak directly to neural priming in humans. Some neuroimaging evidence shows that conditions exist under which both behavioral and neural priming are unaffected by manipulations of attention. A PET study by Badgaiyan et al. (2001) investigated the effects of an attentional manipulation during the study phase of a cross-modal priming task. Target words were aurally presented among distracter words at study under either full attention or under a divided-attention task. At test, visual word stems were presented in separate blocks for both target word types. Behavioral priming (faster reaction times) and neural priming (reduced regional cerebral blood flow in superior temporal gyrus) were of similar magnitude for words presented under full and divided attention conditions (see also Voss and Paller, 2006).

An fMRI study that we reviewed earlier (Schott et al., 2005) further demonstrated that changing the nature of the task to be performed during the test phase did not affect the level of behavioral or neural priming. Following shallow encoding of words at study, word stems were presented in separate blocks of either an implicit or an explicit memory task at test. Although the explicit task elicited a higher rate of explicit recollection of previously studied words, there were no differences in behavioral priming effects between the two conditions – i.e., subjects produced an equivalent number of previously studied words when cued with word stems in both test conditions. Moreover, an equivalent degree of neural priming was documented in left fusiform, bilateral frontal, and occipital brain regions in both implicit and explicit conditions. Thus, this experiment demonstrated that changing the task orientation at test had no effect on behavioral or neural priming.

Hasson et al. (2006) demonstrated comparable neural priming in some brain regions despite a change of task orientation across separate sessions (i.e., separate experiments with different tasks). In the first of two experiments, subjects listened to spoken sentences, some grammatically sensible, some nonsensible, and decided whether each sentence was sensible or not. In the second experiment, subjects passively listened to spoken sensible sentences only, making no judgments or responses. A direct contrast between the two tasks indicated that neural priming in temporal regions was equivalent across conditions. However, neural priming was also observed in inferior frontal regions, but only in the active condition in which subjects made sensible/nonsensible judgments. This finding suggests that attentional manipulations have variable effects on different brain regions.

The foregoing studies have demonstrated that behavioral and/or neural priming can occur independent of shifts in attentional demands or task orientation at study (Badgaiyan et al., 2001; Voss and Paller, 2006), at test (Schott et al., 2005), or between different tasks (Hasson et al., 2006). However, consistent with the latter finding by Hasson et al. of concurrent attenuation of priming in prefrontal regions associated with changing task demands, these null results do not rule out the possibility that under different task conditions, and in different brain regions, top-down attentional effects may play an important role in priming. We consider now (and also later in the chapter) recent evidence that supports this claim.

### 2.33.3.2 Priming: Modulated by Attention

Henson et al. (2002) reported one of the first neuroimaging studies to demonstrate that neural priming is modulated by top-down cognitive factors. Subjects viewed pictures of famous and nonfamous faces, each presented twice at random intervals within one of two separate, consecutive task sessions. During the implicit task session, subjects performed a continuous famous/nonfamous face discrimination task; during the explicit task session, subjects performed a continuous new/old face recognition task. Neural priming was observed in a face-responsive region in the right fusiform gyrus for repeated famous faces only, consistent with previous findings (Henson et al., 2000), as well as for both famous and nonfamous faces in a left inferior occipital region. Neural priming in these regions occurred only in the implicit task. As stimuli were identical across the different task conditions, the modulation of neural priming was attributed to top-down effects of task orientation.

Although there were effects of attention on neural priming, behavioral priming seemed to be unaffected by top-down factors. Rather, behavioral priming, as indexed by reduced reaction time to respond to repeated presentations of famous faces relative to initial presentations, was equivalent in the implicit and explicit tasks. This result implies a dissociation between behavioral priming and neural priming observed in these brain regions. Further, attentional modulation varied only between sessions, i.e., the same task was performed on each stimulus during the initial and repeated presentations, leaving open the question of whether attentional factors exert an influence at study, at test, or on both occasions.

A subsequent fMRI study tested the hypothesis that attentional factors, specifically at study, have an impact on neural priming (Eger et al., 2004). During fMRI scanning, subjects performed a task at study in which two objects were simultaneously presented, one to the left and one to the right of a central fixation point. Importantly, subjects were cued to attend to either the left or right of center by a visual cue presented onscreen 100 ms prior to presentation of the 'prime' stimuli. A single 'probe' stimulus was subsequently presented in the center of the screen that matched the previously attended stimulus, matched the previously unattended stimulus, was the mirror image of one of these two stimuli, or was novel. Analyses of repetition-related behavioral facilitation (faster reaction times) and neural response reductions (fMRI BOLD signal decreases in fusiform and lateral occipital regions) revealed that behavioral and neural priming occurred only for probes that matched (or mirrored) the attended prime. Conversely, no behavioral or neural priming was documented when the probe stimulus matched (or mirrored) the unattended prime. Thus, this study showed that modulation of spatial attention affects behavioral as well as neural priming in object selective perceptual processing regions, and that these top-down attentional effects exert an influence specifically at the time of study.

In a face-repetition priming study, Ishai et al. (2004) reported that neural priming occurred only for repeated faces that were task relevant. Subjects were presented with a target face and then were shown a series of faces, including three repetitions of the target face, three repetitions of a nontarget face, and seven distracter faces. Participants were required to push a button each time the target face appeared, and thus were required to attend to all faces, although only the target face was task relevant. Significant neural priming (reduced BOLD response for the third relative to the first repetition) was observed in face-responsive regions, including inferior occipital gyri, lateral fusiform gyri, superior temporal sulci, and amygdala, but only for the target face repetitions; no neural priming was associated with repetition of nontarget faces.

Yi and colleagues (Yi and Chun, 2005; Yi et al., 2006) used overlapping scene and face images to also demonstrate that task-relevant attention has an effect even for simultaneously viewed stimuli. In one experiment, participants were presented with overlapping face and scene images and instructed to attend only to the face or the scene on a given trial (Yi et al., 2006). Neural priming in a face-responsive fusiform region was documented only for repeated faces that were attended, and not for scenes or unattended faces. Similarly, neural priming in a scene-responsive parahippocampal region occurred only for repeated scenes that were attended, and not for faces or unattended scenes. Surprisingly, even after sixteen repetitions of a stimulus every 2 s within a block, no trace of neural priming was observed for unattended stimuli in these respective regions (Yi et al., 2006).

Thus, while a number of neuroimaging studies have shown that both behavioral and neural priming can remain constant across study and test manipulations of attention or between different tasks with common stimuli, several studies reviewed here indicate that top-down effects of attention can have an impact on behavioral and/or neural priming, both at the time of study (Henson et al., 2002) and at test (Ishai et al., 2004), and have been shown to involve both spatial attention (Eger et al., 2004) and task-relevant selective attention (Ishai et al., 2004; Yi and Chun, 2005; Yi et al., 2006). To reconcile these ostensibly incongruent conclusions requires a more detailed consideration of the nature of subtle differences in various manipulations of attention, and importantly, of the particular brain regions involved.

Accordingly, recent studies (e.g., Hassan et al., 2006) have begun to dissociate various brain regions that are differentially sensitive to various attentional manipulations. In a study by Vuilleumier et al. (2005), participants viewed overlapping objects drawn in two different colors at study and were instructed to attend only to objects of a specified color. At test, these objects were presented singly among novel real and nonsense objects, and subjects indicated whether each object was a real or nonsense object. Behavioral priming was documented both for previously attended and ignored objects, with a relative boost in performance for objects that were attended. However, different brain regions showed differential sensitivity to the effects of attention on neural priming. A group of regions that comprised right posterior fusiform, lateral occipital, and left inferior frontal regions demonstrated neural priming only for attended objects presented in the original view. By contrast, bilateral anterior fusiform regions were insensitive to changes of viewpoint (original vs.

mirrored), but showed neural priming for unattended objects in addition to more robust neural priming for attended objects. Finally, neural priming in the striate cortex was view specific and more robust for attended than ignored objects.

In keeping with the latter findings, O'Kane et al. (2005) reported a similar dissociation between brain regions differentially sensitive to manipulation of top-down processes. Subjects were presented with words at study and performed a judgment of either size, shape, or composition in separate task blocks. At test, subjects performed a size judgment for all studied words presented among novel words. Behavioral facilitation, as measured by faster reaction times for size judgments at test, was observed for repeated relative to novel words, with an additional benefit when the judgment was the same at study and test (size/size) relative to when the judgment was switched (shape/size or composition/size). Neural priming in left parahippocampal cortex tracked the behavioral trend, showing reduced BOLD responses for repeated relative to novel words, with an additional trend toward increased priming when the task was the same across repetition. In left perirhinal cortex, however, neural priming occurred for repeated words only when the judgment was the same at study and test. The finding that perirhinal cortex is sensitive to semantic but not perceptual repetition provides evidence that this region is involved in conceptual processing.

Considered together, the neuroimaging studies reviewed here suggest that behavioral and neural priming are indeed modulated by top-down cognitive factors of attention or task orientation, but that this modulation exerts differential effects across different brain regions depending on the nature of the task. Neural priming within a given brain region may occur only to the extent that the processing of a stimulus reengages this region in a qualitatively similar manner across repetitions.

### 2.33.3.3 Neural Mechanisms of Top-Down Attentional Modulation

Although the effects of attention on priming have now been well documented, little is known about the neural mechanisms that underlie these top-down effects. Efforts to understand these mechanisms have been at the forefront of recently emerging neuroimaging research.

Increased attention at the time of study has been suggested as an important factor in priming. Turk-Browne et al. (2006), as previously reviewed in this chapter, reported that neural priming occurred only for repeated scenes that were later remembered, but not for those scenes that were later forgotten. They found that tonic activation, a general measure of regional neural activity, was elevated for scenes that were later remembered and that also elicited neural priming upon repeated presentation. While previous evidence indicates that increased attention results in increased neural firing rates within process-relevant brain regions, a recent fMRI study suggests that attention may also increase selectivity of the neural population representing an attended stimulus (Murray and Wojciulik, 2004).

Other neuroimaging approaches, including MEG and EEG, have been used to further characterize the nature of attentional modulations of neural priming as well. Evidence supporting the hypothesis that attention serves to increase specificity of perceptual representations was reported by Duzel and colleagues (2005) in a study using MEG. By investigating neural activity at study, they compared words that showed subsequent behavioral priming (faster reaction times) to those that did not show subsequent priming. They reported relatively decreased amplitude, but increased phase alignment, of beta and gamma oscillations for words that showed later priming, indicating increased specificity of the neural response for these words at the time of study. Further, they reported increased coordination of activity between perceptual and higher brain regions for words that showed subsequent priming, as measured by increased interareal phase synchrony of alpha oscillations. Importantly, this increased synchrony between perceptual and higher brain regions was detected immediately prior to the initial presentation of the subsequently primed stimuli, indicating an anticipatory effect. These results suggest that top-down processes, through anticipatory coordination with perceptual brain regions, increase specificity of perceptual representations at study. Such a process may also be necessary at test for successful priming. Gruber et al. (2006) reported that 'sharpening' of the neural response in cell assemblies (as measured by suppression of induced gamma band responses in ERPs) occurred for repeated visual stimuli only when the task was the same at both study and test, but not when the task was switched.

Therefore, through a combination of various neuroimaging techniques, researchers have begun to characterize the neural mechanisms that underlie attentional modulation of priming. These mechanisms may constitute a link between the cognitive functions that are accessible to our conscious awareness and under our volitional control and the unconscious systems that facilitate fluency of mental processing.

## 2.33.4 Specificity of Priming

Priming effects vary in their specificity, that is, the degree to which priming is disrupted by changes between the encoding and test phases of an experiment. When study/test changes along a particular dimension produce a reduction in priming, the inference is that the observed priming effect is based to some extent on retention of the specific information that was changed; when level of priming is unaffected by a study/test change, the inference is that priming reflects the influence of an abstract representation, at least with respect to the changed attribute. Questions concerning the specificity of priming have been prominent since the early days of priming research in cognitive psychology, when evidence emerged that some priming effects are reduced when study/test sensory modality is changed (e.g., Jacoby and Dallas, 1981; Clarke and Morton, 1983) and can also exhibit within-modality perceptual specificity, shown by the effects of changing typeface or case for visual words (e.g., Roediger and Blaxton, 1987; Graf and Ryan, 1990), or speaker's voice for auditory words (e.g., Schacter and Church, 1992). Considerable theoretical debate has focused on the key issue raised by studies of specificity effects, namely whether priming reflects the influence of nonspecific, abstract preexisting representations or specific representations that reflect perceptual details of an encoding episode (for review and discussion of cognitive studies, see Roediger, 1990; Schacter, 1990, 1994; Roediger and McDermott, 1993; Tenpenny, 1995; Bowers, 2000).

Considering the early cognitive research together with more recent neuropsychological and neuroimaging studies, Schacter et al. (2004) recently proposed a distinction among three types of specificity effects: stimulus, associative, and response. Stimulus specificity occurs when priming is reduced by changing physical properties of a stimulus between study and test; associative specificity occurs when priming is reduced because associations between target items are changed between study and test; and response specificity occurs when priming is reduced because subjects make different responses to the same stimulus item at study and test. We will review here evidence from neuroimaging studies concerning each of the three types of priming specificity and consider how the imaging data bear on the kinds of theoretical questions that have been of interest to cognitive psychologists.

### 2.33.4.1 Stimulus Specificity

Most neuroimaging research has focused on stimulus specificity, which is observed by changing physical features of a stimulus between study and test. As mentioned earlier, cognitive studies have shown that priming effects are sometimes modality specific, that is, reduced when study and test sensory modalities are different compared with when they are the same. Such effects are most commonly observed on tasks such as word or object identification, stem completion, or fragment completion, which require perceptual or data-driven processing (Roediger and Blaxton, 1987). Amnesic patients have shown a normal modality-specific effect in stem completion priming (e.g., Carlesimo, 1994; Graf et al., 1985), suggesting that this effect is not dependent on the medial temporal lobe structures that are typically damaged in amnesics.

Early neuroimaging studies of within-modality visual priming that compared brain activity during primed and unprimed stem completion showed that priming is associated with decreased activity in various posterior and prefrontal cortical regions, but the decreases were observed most consistently in the right occipitotemporal extrastriate cortex (e.g., Squire et al., 1992; Buckner et al., 1995; Schacter et al., 1996). These and related findings raised the possibility that priming-related reductions in extrastriate activity are based on a modality-specific visual representation, perhaps reflecting tuning or sharpening of primed visual word representations (Wiggs and Martin, 1998). Consistent with this possibility, Schacter et al. (1999) directly compared within-modality visual priming to a cross-modality priming condition in which subjects heard words before receiving a visual stem completion task. They found priming-related reductions in extrastriate activity during within- but not cross-modality priming. Surprisingly, however, other neuroimaging studies of within-modality auditory stem completion priming also revealed priming-related activity reductions near the extrastriate region that was previously implicated in visual priming (Badgaiyan et al., 1999; Buckner et al., 2000; Carlesimo et al., 2004). These results remain poorly understood, but it has been suggested that one part of the extrastriate region (V3A, within BA 19) is involved in multimodal functions, perhaps converting perceptual information from one modality to another (Badgaiyan et al., 1999).

Although the results of imaging studies comparing within- and cross-modality priming are not entirely conclusive, studies of within-modality changes in physical properties of target stimuli have provided clear evidence for stimulus-specific neural priming, which in turn implicates perceptual brain mechanisms in the observed priming effects. Studies focusing on early visual areas have provided one source of such evidence. Grill-Spector et al. (1999) found that activation reductions in early visual areas such as posterior lateral occipital complex (LOC) exhibit a high degree of stimulus specificity for changes in viewpoint, illumination, size, and position. By contrast, later and more anterior aspects of LOC exhibit greater invariance across changes in size and position relative to illumination and viewpoint. Evidence from a study by Vuilleumier et al. (2005) considered in the previous section likewise indicates a high degree of stimulus specificity in early visual areas, as indicated by viewpoint-specific neural priming in these regions.

Later visual regions can also show stimulus-specific neural priming, but several studies indicate that this specificity effect is lateralized. In a study by Koutstaal et al. (2001), subjects judged whether pictures of common objects were larger than a 13-inch-square box, and later made the same judgments for identical objects, different exemplars of objects with the same name, and new objects. Behavioral priming, indicated by faster response times, occurred for both identical objects and different exemplars, with significantly greater priming for identical objects. Reductions in activation were also greater for same than for different exemplars in the bilateral middle occipital, parahippocampal, and fusiform cortices. These stimulus-specific activation reductions for object priming were greater in the right than in the left fusiform cortex. Simons et al. (2003) replicated these results and further demonstrated that left fusiform cortex shows more neural priming for different exemplars compared with novel items relative to right fusiform cortex, indicating more nonspecific neural priming in the left fusiform. Also, left but not right fusiform neural priming was influenced by a lexical-semantic manipulation (objects were accompanied by presentation of their names or by nonsense syllables), consistent with a lateralized effect in which right fusiform is modulated by specific physical features of target stimuli and left fusiform is influenced more strongly by semantic features. In a related study by Vuilleumier et al. (2002), subjects decided whether pictorial images depicted real or nonsense objects, and subsequently repeated stimuli were identical, differed in size or viewpoint, or were different exemplars with the same name. Neural priming in the right fusiform cortex was sensitive to changes in both exemplar and viewpoint.

A similar pattern has also been reported for orientation-specific object priming by Vuillemer et al. (2005) in the overlapping shape paradigm described earlier, and Eger et al. (2005) reported a stimulus-specific laterality effect using faces. In the latter experiment, subjects made male/female judgments about famous or unfamiliar faces that were preceded by the identical face, a different view of the same face, or an entirely different face. Behavioral priming, indexed by decreased response times, was greater for same than different viewpoints for both famous and unfamiliar faces. Collapsed across famous and unfamiliar faces, neural priming was more viewpoint dependent in right fusiform gyrus than in left fusiform gyrus. In addition, for famous faces, priming was more nonspecific in anterior than more posterior fusiform cortex. Similarly, Vuillemer et al. (2005) report some evidence for greater stimulus-specific neural priming in posterior compared with anterior fusiform gyrus. Other studies indicate that later perceptual regions can exhibit largely nonspecific priming, both for visual stimuli such as scenes (Blondin and Lepage, 2005) and auditory words (Orfanidou et al., 2006; see also Badgaiyan et al., 2001). However, evidence provided by Bunzeck et al. (2005) suggests that effects in later perceptual regions are characterized by category specificity. In their study, subjects made male/female judgments about faces and indoor/outdoor judgments about scenes. Subjects responded more quickly to repeated faces and scenes compared with initial presentations, thus demonstrating behavioral priming. Face-responsive regions in fusiform and related areas showed selective activation reductions for repeated faces, whereas place-responsive regions in parahippocampal cortex showed decreases for repeated scenes.

By contrast, regions of inferior frontal gyrus and left inferior temporal cortex appear to respond invariantly to an item's perceptual features and are instead sensitive to its abstract or conceptual properties – even when the degree of perceptual overlap between initial and subsequent presentations of a stimulus is minimal to nonexistent. Neural priming has been observed in these regions during reading of mirror-reversed words initially presented in a normal orientation (Ryan and Schnyer, 2006) and also when silently reading semantically related word pairs, but not for pairs that are semantically unrelated (Wheatley et al., 2005). Consistent with this observation, neural priming in these regions is independent of stimulus modality (Buckner et al., 2000) and has even been observed when the modality differs between the first and second presentations of a stimulus (e.g., visual to auditory; Badgaiyan et al., 2001; Carlesimo et al., 2003).

Overall, then, the foregoing studies reveal a fairly consistent pattern in which neural priming in early visual regions exhibits strong stimulus specificity, whereas in later visual regions, right-lateralized stimulus specificity is consistently observed (for a similar pattern in a study of subliminal word priming, see Dehaene et al., 2001). These effects dovetail nicely with previous behavioral studies using divided-visual-field techniques that indicate that visually specific priming effects occur to a greater extent in the left visual field (right hemisphere) than in the right visual field (left hemisphere) (e.g., Marsolek et al., 1992, 1996).

The overall pattern of results from neuroimaging studies of stimulus specificity suggests that, consistent with a number of earlier cognitive theories (e.g., Roediger, 1990; Schacter, 1990, 1994; Tulving and Schacter, 1990), perceptual brain mechanisms do indeed play a role in certain kinds of priming effects.

### 2.33.4.2 Associative Specificity

Research concerning the cognitive neuroscience of associative specificity began with studies examining whether amnesic patients can show priming of newly acquired associations between unrelated words. For example, amnesic patients and controls studied pairs of unrelated words (such as window–reason or officer–garden) and then completed stems paired with study list words (window–rea___) or different unrelated words from the study list (officer–rea___). Mildly amnesic patients and control subjects showed more priming when stems were presented with the same words from the study task than with different words, indicating that specific information about the association between the two words had been acquired and influenced priming, but severely amnesic patients failed to show associative priming (Graf and Schacter, 1985; Schacter and Graf, 1986). A number of neuropsychological studies have since examined associative specificity in amnesics with mixed results (for review, see Schacter et al., 2004), and it has been suggested that medial temporal lobe (MTL) structures play a role in such effects. Some relevant evidence has been provided by a PET study that used a blocked design version of the associative stem completion task (Badgaiyan et al., 2002). Badgaiyan et al. found that, as in previous behavioral studies, priming was greater when stems were paired with the same words as during the study task than when they were paired with different words. The same pairing condition produced greater activation in the right MTL than did the different pairing condition, suggesting that associative specificity on the stem completion task may indeed be associated with aspects of explicit memory. Given the paucity of imaging evidence concerning associative specificity, additional studies will be needed before any strong conclusions can be reached.

### 2.33.4.3 Response Specificity

While numerous behavioral studies had explored stimulus specificity and associative specificity prior to the advent of neuroimaging studies, the situation is quite different when considering response specificity, where changing the response or decision made by the subject about a particular item influences the magnitude of priming (note that we use the terms 'response specificity' and 'decision specificity' interchangeably, since behavioral data indicate that the effect is likely not occurring at the level of a motor response; see Schnyer et al., in press). Recent interest in response specificity has developed primarily as a result of findings from neuroimaging research. Dobbins et al. (2004) used an object decision priming task that had been used in studies considered earlier (Koutstaal et al., 2001; Simons et al., 2003), but modified the task so that responses either remained the same or changed across repeated trials. In the first scanning phase, pictures of common objects were either shown once or repeated three times, and subjects indicated whether each stimulus was bigger than a shoebox (using a 'yes' or 'no' response). Next, the cue was inverted so that subjects now indicated whether each item was 'smaller than a shoebox'; they made this judgment about new items and a subset of those that had been shown earlier. Finally, the cue was restored to 'bigger than a shoebox,' and subjects were tested on new items and the remaining items from the initial phase.

If priming-related reductions in neural activity that are typically produced by this task represent facilitated size processing, attributable to 'tuning' of relevant aspects of neural representations, then cue reversal should have little effect on priming (though it could disrupt overall task performance by affecting both new and primed items). According to the neural tuning account, the same representations of object size should be accessed whether the question focuses on 'bigger' or 'smaller' than a shoebox. By contrast, if subjects perform this task by rapidly recovering prior responses, and this response learning mechanism bypasses the need to recover size representations, then the cue reversal should disrupt priming-related reductions. When the cue is changed, subjects would have to abandon the learned responses and instead reengage the target objects in a controlled manner in order to recover size information.

During the first scanning phase, standard priming-related activation reductions were observed in both anterior and posterior regions previously linked with priming: left prefrontal, fusiform, and extrastriate regions. But when the cue was reversed, these reductions were eliminated in the left fusiform cortex and disrupted in prefrontal cortex; there was a parallel effect on behavioral response times. When the cue was restored to the original format, priming-related reductions returned (again there was a parallel effect on behavioral response times), suggesting that the reductions depended on the ability of subjects to use prior responses during trials. Accordingly, the effect was seen most clearly for items repeated three times before cue reversal.

Although this evidence establishes the existence of response-specific neural and behavioral priming, there must be limitations on the effect, since a variety of priming effects occur when participants make different responses during study and test. For instance, priming effects on the stem completion task, where subjects respond with the first word that comes to mind when cued with a three-letter word beginning, are typically observed after semantic or perceptual encoding tasks that require a different response (see earlier discussion on top-down attentional influences). Nonetheless, the existence of response specificity challenges the view that all activation reductions during priming are attributable to tuning or sharpening of perceptual representations, since such effects should survive a response change. Moreover, these findings also appear to pose problems for theories that explain behavioral priming effects on object decision and related tasks in terms of changes in perceptual representation systems that are thought to underlie object representation (e.g., Schacter, 1990, 1994; Tulving and Schacter, 1990), since these views make no provisions for response specificity effects. By contrast, the transfer appropriate processing view (e.g., Roediger et al., 1989, 1999) inherently accommodates such effects. According to this perspective, priming effects are maximized when the same processing operations are performed at study and at test. Although this view has emphasized the role of overlapping perceptual operations at study and at test to explain priming effects on tasks such as object decision, to the extent that the subject's decision or response is an integral part of encoding operations, it makes sense that reinstating such operations at test would maximize priming effects.

However, there is one further feature of the experimental paradigm that Dobbins et al. (2004) used to produce response specificity that complicates any simple interpretation. Priming in cognitive studies is usually based on a single study exposure to a target item, but neuroimaging studies of priming have typically used several study exposures in order to maximize the signal strength. As noted earlier, Dobbins et al. found that response specificity effects were most robust for items presented three times during the initial phase of the experiment (high-primed items), compared with items presented just once (low-primed items).

A more recent neuropsychological investigation of response specificity in amnesic patients highlights the potential theoretical importance of this issue (Schnyer et al., 2006). Schnyer et al. compared amnesics and controls on a variant of the object decision task used by Dobbins et al. (2004). Objects were presented either once (low primed) or thrice (high primed), and then responses either remained the same ('bigger than a shoebox?') or were switched ('smaller than a shoebox?'). Consistent with Dobbins et al. (2004), controls showed greater response specificity for high-primed objects compared with low-primed objects. Amnesic patients showed no evidence of response specificity, demonstrating normal priming for low-primed items and impaired priming for high-primed items. That is, healthy controls showed greater priming for high- than for low-primed objects in the same response condition, but amnesics failed to show this additional decrease in response latencies.

These results raise the possibility that different mechanisms are involved in priming for objects presented once versus those presented multiple times. Perhaps single-exposure priming effects on the object decision task depend primarily on perceptual systems that operate independently of the MTL and thus are preserved in amnesic patients. In neuroimaging experiments, such effects might reflect tuning or sharpening of perceptual systems, independent of the specific responses or decisions that subjects make regarding the object. But for items presented several times, subjects may learn to associate the object with a particular response, perhaps requiring participation of medial temporal and prefrontal regions. These considerations also suggest that response or decision specificity in the object decision paradigm used by Dobbins et al. (2004) is better described in terms of stimulus-response or stimulus-decision specificity – that is, the formation of a new link between a particular stimulus and the response or decision. This idea is supported by recent behavioral data showing that response-specific priming occurs only for the exact object that was studied, and not for a different exemplar with the same name (Schnyer et al., in press). In any event, the overall pattern of results suggests that a single-process model is unlikely to explain all aspects of these neural or behavioral priming effects, a point to which we return later in the chapter.

## 2.33.5 Priming-Related Increases in Neural Activation

Our review so far has focused on behavioral facilitation and corresponding repetition-related reductions of neural activity associated with priming. However, under some conditions, priming has been associated with decrements in stimulus processing, such as slower responses to previously ignored stimuli relative to novel stimuli (i.e., the 'negative priming' effect – a term coined by Tipper, 1985) and poorer episodic encoding for highly primed items (Wagner, et al., 2000). Further, while repetition-related increases in neural activity have long been associated with explicit memory processes, neural increases associated with priming have also been documented, although less frequently. Neuroimaging studies have begun to investigate the nature of such neural increases and the conditions that elicit them. This research suggests a link between performance decrements and increased neural responses associated with priming and provides new evidence that speaks to competing cognitive theories of implicit memory.

### 2.33.5.1 Negative Priming

Negative priming (NP) occurs when a stimulus is initially ignored, and subsequent processing of the stimulus is impaired relative to that of novel stimuli. An early example of identity NP was demonstrated by Tipper (1985); overlapping drawings of objects drawn in two different colors were presented, and subjects were instructed to attend to and identify objects of only one specified color. At test, identification of previously presented objects that were ignored was significantly slower than identification of novel objects. The NP effect has since been documented across a diverse range of experimental tasks and stimuli (for review, see Fox, 1995; May et al., 1995). Efforts to characterize the nature of this processing have sparked a number of theoretical debates within the cognitive psychology literature. One of these debates has centered on the cause of NP (e.g., whether it relies on processes during encoding or later retrieval), while another has focused on determining the level of processing that ignored items undergo in order to elicit NP (e.g., perceptual vs. semantic processing).

Competing accounts of the cause of NP are offered by two theories. The selective inhibition model (Houghton and Tipper, 1994) proposes that representations of ignored stimuli are initially activated but are immediately inhibited thereafter by selective attention. Thus, upon subsequent presentation of a previously ignored stimulus, this inhibition must be overcome, resulting in slowed processing relative to novel stimuli. The episodic retrieval model (Neill and Valdes, 1992; Neill et al., 1992) proposes that ignored stimuli are fully encoded into an episodic representation, as are attended stimuli. Upon repeated presentation of a stimulus, episodic information from the initial presentation can provide a 'shortcut' to the previous response associated with that stimulus. Whereas this would facilitate processing of previously attended stimuli that were associated with a particular response, it is detrimental to processing of ignored stimuli with which no response was associated at study. Behavioral experiments have failed to produce unambiguous support for either of these models (Fox, 1995; May et al., 1995; Egner and Hirsch, 2005).

Neuroimaging can provide a useful way to test these theories, because they predict the involvement of different brain regions supporting either inhibitory or episodic processes. Egner and Hirsch (2005) reported data from an fMRI experiment using a color-naming Stroop task that provide support for the episodic retrieval model. A region in the right dorsolateral prefrontal cortex (DLPFC) demonstrated increased activation for probe trials that were subject to NP relative to probe trials that had not been primed. The authors noted that this right DLPFC region has been associated with processes related to episodic retrieval (for review, see Stevens and Grady, 2007). Importantly, across individual subjects, activity in right DLPFC was positively correlated with response times during NP trials, but not nonprimed trials. These data support the theory that ignored stimuli, rather than being actively inhibited, are fully encoded at study, and that episodic retrieval at test contributes to the NP effect.

Another recent fMRI study investigated the level at which ignored stimuli are processed (i.e., perceptual vs. semantic/abstract) (Zubicaray et al., 2006). The authors reasoned that, if ignored stimuli elicit automatic activation of semantic representations at study, then brain regions that have been implicated in the storage and/or processing of these representations, such as the anterior temporal cortex (for review, see McClelland and Rogers, 2003) should be active during study of ignored stimuli. Overlapping drawings of different-colored objects elicited NP (slower reaction time for object identification at test) for previously ignored objects relative to novel objects. Analysis of fMRI data from the study session revealed a positive relationship between the magnitude of BOLD activity in the left anterolateral temporal cortex, including the temporal pole, and the magnitude of the subsequent NP effect. In agreement with Egner and Hirsch (2005), these data suggest that ignored stimuli are actively processed at study, and further indicate that this processing occurs at the level of abstract/semantic representations in higher conceptual brain regions.

### 2.33.5.2 Familiar Versus Unfamiliar Stimuli

There has been a long-standing debate in the cognitive psychology literature concerning priming of familiar versus unfamiliar stimuli (for review, see Tenpenny, 1995). According to modification/abstractionist theories (Morton, 1969; Bruce and Valentine, 1985), preexisting representations are required in order for priming to occur; these abstract representations are modified in some way upon presentation of familiar stimuli. According to acquisition/episodic theories (Jacoby, 1983; Roediger and Blaxton, 1987; Schacter et al., 1990), priming does not rely on a preexisting representation; rather, both familiar and unfamiliar stimuli can leave some form of a trace that can facilitate subsequent priming (although there may be limits; see Schacter et al., 1990; Schacter and Cooper, 1995). Neuroimaging studies have produced data relevant to this debate.

In a PET study, Schacter et al. (1995) reported behavioral priming for repeated unfamiliar objects, as shown by increased accuracy of possible/impossible judgments for structurally possible three-dimensional objects. However, in contrast to the more common finding of concomitant reduction in neural activity associated with behavioral priming reviewed earlier in the chapter, the authors reported increased activation in a left inferior fusiform region that was associated with priming of the possible objects.

In a more recent event-related fMRI study, Henson et al. (2000) reported data from four experiments using familiar and unfamiliar faces and symbols that directly tested the hypothesis that repetition-related neural priming entails reduced neural activity for familiar stimuli, but increased neural activity for unfamiliar stimuli. Behavioral priming (faster reaction times for familiarity judgments) was documented for repetition of both familiar and unfamiliar faces and symbols (although priming was greater for familiar than for unfamiliar stimuli). However, in a right fusiform region, repetition resulted in decreased activation for familiar faces and symbols, but increased activation for unfamiliar faces and symbols.

Henson et al. (2000) offered an account of their findings in terms of both modification and acquisition: while priming of familiar stimuli involves modification of preexisting representations, resulting in repetition suppression, priming also occurs for unfamiliar stimuli as a new representation is formed, resulting in repetition enhancement (for a generalized theory, see Henson, 2003). This suggestion is supported by evidence from a study by Fiebach et al. (2005), who concluded that neural decreases accompanying repeated words, in contrast to neural increases accompanying repeated pseudowords, reflect the sharpening of familiar object representations and the formation of novel representations for unfamiliar objects, respectively. Further, data from a previously reviewed study by Ishai et al. (2004) support this hypothesis as well; for unfamiliar faces, neural activation increased for the first repetition, but decreased in a linear trend thereafter, possibly reflecting the initial acquisition of an unfamiliar face representation, followed by subsequent modification of this newly formed representation. Henson et al. (2000) further hypothesized that the repetition enhancement effect for unfamiliar stimuli would only occur in "higher visual areas, such as the fusiform cortex, where the additional processes such as recognition occur" (Henson et al., 2000: 1272). However, in a recent study using event-related fMRI, Slotnick and Schacter (2004) reported increased activation in early visual processing regions (BA 17/18) for repeated, relative to novel, unfamiliar abstract shapes. This finding suggests that earlier perceptual regions may also demonstrate activation attributable to processes involved in acquisition of new representations of unfamiliar stimuli.

### 2.33.5.3 Sensitivity Versus Bias

In number of studies by Schacter and colleagues (Schacter et al., 1990, 1991a; Cooper et al., 1992; Schacter and Cooper, 1993) participants studied line drawings of structurally possible and impossible objects and then made possible/impossible judgments at test to repeated presentations of the objects. Behavioral priming is measured as increased accuracy (and/or faster reaction time) for identifying an object as possible or impossible upon repeated presentations; significant priming is consistently observed for possible, but not impossible, objects. As mentioned earlier, a PET study of priming on the possible/impossible decision task revealed that increased activation in a left inferior/fusiform region was associated with priming of possible objects only (Schacter et al., 1995).

Schacter and Cooper proposed that such priming depends on the structural description system (SDS), a subsystem of the more general perceptual representation system (Tulving and Schacter, 1990). The proposal of an SDS was based on evidence of dissociations between priming (for possible, but not impossible, objects) and explicit tests of memory, across study-to-test object transformations (Cooper, et al., 1992; Schacter et al., 1993b), manipulations at encoding (Schacter and Cooper, 1993; Schacter et al., 1990), and in studies with elderly populations and amnesic patients (Schacter et al., 1991b, 1992, 1993b; and for review, see Soldan et al., 2006). In this view, priming of repeated objects reflects increased sensitivity (i.e., accuracy) on the part of the SDS, which is only capable of representing structurally possible objects.

An alternative theory is the bias account of priming in the possible/impossible object-decision task proposed by Ratcliff and McKoon (McKoon and Ratcliff, 1995, 2001; Ratcliff and McKoon, 1995, 1996, 1997, 2000). In this view, an encounter with an object, regardless of whether it is structurally possible or impossible, results in a subsequent bias to classify that object as 'possible,' leading to increased accuracy (i.e., positive priming) for repeated possible objects but decreased accuracy (i.e., negative priming) for impossible objects. However, this account also posits that explicit processes play a role in object-decisions, such that explicit memory of the study episode cues subjects as to whether the object is possible or impossible. It is argued, then, that this combination of bias and episodic information leads to robust positive priming for possible objects. By contrast, for impossible objects, the two factors cancel each other out, resulting in zero priming. Ratcliff and McKoon (1995) reported data from seven experiments that supported their hypothesis (for criticism of their conclusions, see Schacter and Cooper, 1995; for response, see McKoon and Ratcliff, 1995). Other bias accounts of object-decision priming have been proposed as well, such as the structure-extraction bias (Williams and Tarr, 1997).

Behavioral studies relevant to this debate continue to emerge, supporting either the sensitivity account of priming (e.g., Zeelenberg et al., 2002) or the bias account (e.g., Thapar and Rouder, 2001), but behavioral investigations alone have been inconclusive (Soldan et al., 2006). However, neuroimaging studies have recently produced evidence that speaks to the ongoing debate.

In a recent event-related fMRI study (Habeck et al., 2006), subjects performed a continuous possible/impossible object-decision task on structurally possible and impossible objects repeated four times each. Although the behavioral results did not correspond to sensitivity or bias models, or to previous findings (priming, as measured by faster reactions times, was documented for both possible and impossible objects), neural priming was documented for possible objects only. A multivariate analysis of the fMRI data revealed a pattern of brain regions in which activation covaried in a linear fashion (areas showing both repetition suppression and repetition enhancement) with repetition of possible objects only. No such pattern was observed for repetition of impossible objects. Further, there was a correlation between behavioral (faster reaction times) and neural priming for possible objects only.

Similarly, a recent ERP study by Soldan et al. (2006) reported data from two possible/impossible object-decision priming experiments using unfamiliar objects that provide compelling evidence that the visual system differentially encodes globally possible versus globally impossible structures. In the first experiment, subjects made structural decisions (right/left orientation-decision task) about possible and impossible objects at study. In the second experiment, a functional decision (tool/support function-decision task) was performed at study. The behavioral results of the experiments were inconclusive with respect to sensitivity versus bias theories. However, the ERP data clearly failed to support bias theories, which hold that possible and impossible objects are processed similarly in the visual processing system. Rather, two early ERP components (the N1 and N2 responses) showed repetition enhancement for possible objects, but no neural effect for repetition of impossible objects, in both the structural and functional encoding experiments. Moreover, the magnitude of repetition enhancement in the N1 ERP component was correlated with behavioral priming for possible objects. These data support the theory that priming is supported by an SDS that encodes structurally possible objects only.

## 2.33.6 Correlations between Behavioral and Neural Priming

While neuroimaging studies have provided considerable evidence bearing on the neural correlates of priming, caution is warranted when interpreting the causal nature of such effects. Although a number of studies have documented the close overlap between neuronal activity and BOLD activity in the primate (Logothetis et al., 2001; Shmuel et al., 2006; for a human analogue see Mukamel et al., 2005), it is critical to determine whether functional neuroimaging data reflect the neural underpinnings of cognitive processes or index spurious activations that are epiphenomenal to the process of interest.

Initial studies used methodologies where blocks during which participants viewed repeated items were contrasted with blocks during which participants viewed novel items (e.g., Squire et al., 1992; Raichle et al., 1994; Buckner et al., 1995; Schacter et al., 1996; Wagner et al., 1997). The introduction of event-related fMRI (Dale and Buckner, 1997) later allowed researchers to intermix old and new items and delineate activity associated with individual trial-types, providing evidence that the neural priming that accompanies repeated items is not simply due to a blunting of attention or vigilance that may permeate extended periods of cognitive processing (e.g., Buckner et al., 1998). Together, studies of this sort have consistently documented the co-occurrence of behavioral priming and neural priming in a subset of the brain regions that are engaged during task performance with novel material (see **Figure 1**).

In order to establish a link between neural priming and behavioral priming, neuroimaging studies have attempted to demonstrate a relationship between the magnitude of both effects. That is, if neural priming is indeed related to behavioral priming, then the two should not only co-occur but should be directly correlated. A number of studies have reported a positive correlation between the magnitudes of behavioral priming and neural priming in frontal regions during tasks of a semantic or conceptual nature. Maccotta and Buckner (2004) showed that behavioral priming for repeated words in a living/nonliving classification task was significantly correlated with the magnitude of neural priming in regions of the left inferior frontal gyrus and pre-supplementary motor areas. Using the same task, Lustig and Buckner (2004) documented significant correlations between behavioral and neural priming in the left inferior frontal gyrus for young adults, healthy older adults, and patients with Alzheimer's disease (also see Golby et al., 2005). A similar pattern has been documented in the auditory domain: Orfanidou et al. (2006) found that the degree of auditory word priming on a lexical decision task was predicted by the extent of neural priming in left inferior frontal gyrus and supplementary motor areas. Others have found that the correlation between behavioral priming and prefrontal neural priming can be category specific. Using a classification task, Bunzeck et al. (2006) provided evidence that the correlations between neural and behavioral priming were specific for scenes in left inferior prefrontal cortex, but for faces in left middle frontal gyrus.

Consistent with the foregoing findings, in the aforementioned study by Dobbins et al. (2004), multiple regression analysis revealed that left prefrontal activity predicted the disruptive effects of response switching on behavioral priming for individual subjects: greater initial reductions in prefrontal activity were associated with greater subsequent disruptions of behavioral response times when the response was changed. To the extent that activation reductions in prefrontal cortex indicate less reliance on controlled processing and greater reliance on automatic processing, these data suggest that performance disruptions attributable to response switching reflect a need to

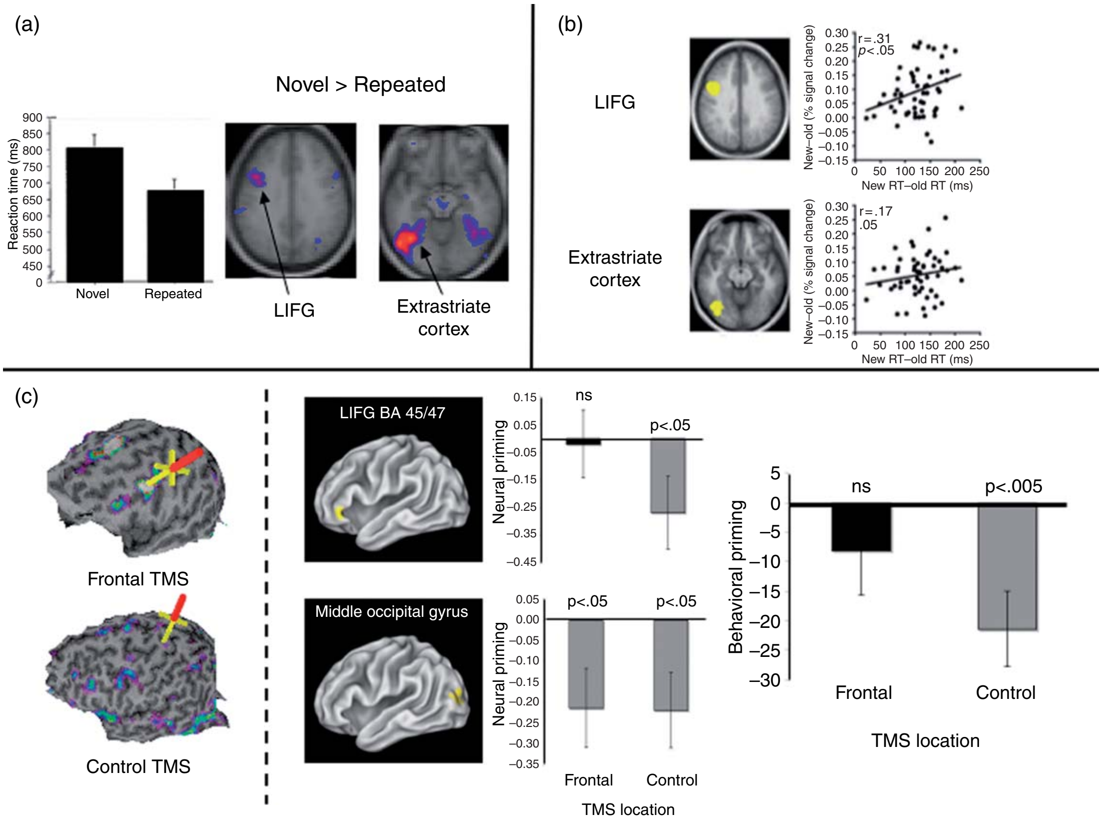

**Figure 1** Correlations between behavioral and neural priming. (a) Semantic classification of visual objects using event-related fMRI reveals that the decrease in response time (behavioral priming) that accompanies classification of repeated items co-occurs with decreased activity (neural priming) in regions of the left inferior frontal gyrus (LIFG) and extrastriate cortex. (b) During semantic classification of words, the magnitude of behavioral priming is directly correlated with the magnitude of neural priming in the LIFG, but not the extrastriate cortex. (c) Transcranial magnetic stimulation (TMS) applied to a region of the LIFG (but not of a control location) during semantic classification of visual objects disrupts subsequent behavioral priming and the neural priming in LIFG during fMRI scanning. Neural priming in the middle occipital gyrus is unaffected by frontal or control TMS. Adapted from (a) Buckner RL, Goodman J, Burock M, et al. (1998) Functional-anatomic correlates of object priming in humans revealed by rapid presentation event-related fMRI. *Neuron* 20: 285–296, with permission from Elsevier; (b) Maccotta L and Buckner RL (2004) Evidence for neural effects of repetition that directly correlate with behavioral priming. *J. Cogn. Neurosci.* 16: 1625–1632, with permission from MIT Press; (c) Wig GS, Grafton ST, Demos KE, and Kelley WM (2005) Reductions in neural activity underlie behavioral components of repetition priming. *Nat. Neurosci.* 8: 1228–1233, with permission from the authors.

reengage slower controlled processes in order to make object decisions. This idea is consistent with the further finding that reductions in fusiform activity did not predict behavioral costs of switching cues, suggesting that these reductions may be incidental to behavioral priming during conceptual tasks.

Other evidence indicates that behavioral priming can correlate with neural priming in regions outside the prefrontal cortex as well. Bergerbest et al. (2004) found that behavioral priming for environmental sound stimuli correlated with neural priming in right inferior prefrontal cortex and also in two secondary auditory regions: bilateral superior temporal sulci and right superior temporal gyrus. Using a stem completion task, Carlesimo et al. (2003) found that the magnitude of behavioral cross-modality priming (auditory-to-visual) was correlated with the extent of activation reduction at the junction of the left fusiform and inferior temporal gyrus.

Turk-Browne et al.'s (2006) study of the relation between priming and subsequent memory effects, (where, as discussed earlier, neural activity during encoding is sorted according to whether items are subsequently remembered or forgotten) provided a different perspective on the correlation issue. Repeated scenes produced behavioral and neural priming, but only for those scenes that were subsequently remembered. For these scenes only, there was also a correlation between the magnitude of behavioral and neural priming in the fusiform gyrus; this relationship approached significance in right inferior prefrontal cortex. As discussed earlier, the finding that the degree of behavioral and neural priming depended on subsequent memory points toward a link between implicit and explicit memory, perhaps involving shared attentional processes.

Together, these studies provide evidence for a relationship between behavioral priming and neural priming (also see Zago et al., 2005; Habeck et al., 2006). Correlations between the two variables generalize across paradigms (e.g., semantic classification, stem-completion) and are restricted to regions thought to mediate the cognitive operations engaged during the task. Although these correlations have been consistently reported with respect to neural priming in frontal cortices and to a lesser extent temporal cortex, few studies thus far have provided evidence for a correlation between behavioral priming and neural priming in earlier perceptual cortices – even though neural priming in the latter regions frequently accompanies item repetition.

The relationship between behavioral priming and neural priming in early visual regions was explicitly explored by Sayres and Grill-Spector (2006). Participants were scanned using fMRI in an adaptation paradigm during a semantic classification task on objects. Repetition of objects was accompanied by reductions in activity in regions of the LOC and posterior fusiform gyrus. However, in contrast to the correlations that have been observed between neural and behavioral priming in frontal and temporal regions, neural priming in earlier visual regions was unrelated to the facilitation in response time that accompanied repeated classification, thus providing more evidence that these two phenomena may be less tightly associated in these regions.

Although these correlations suggest that neural priming effects in prefrontal and temporal regions may support behavioral priming on a number of tasks, they do not allow conclusions regarding a causal role. It is possible that neural priming in these regions is necessary for behavioral priming. Alternatively, neural priming in other areas of the brain (e.g., regions of perceptual cortex) may subserve behavioral priming, and the neural priming observed in prefrontal and temporal cortex may simply reflect a feedforward propagation of the changes occurring in these other regions. In order to establish a causal relationship between behavioral priming and neural priming in frontal and temporal cortex, one would have to provide evidence of a disruption of behavioral and neural priming in these regions, accompanied by intact neural priming in perceptual cortices.

Wig et al. (2005) provided such evidence by combining fMRI with transcranial magnetic stimulation (TMS). TMS allows for noninvasive disruption of underlying cortical activity to a circumscribed region, thus inducing a reversible temporary virtual lesion (Pascual-Leone et al., 2000). In the study by Wig and colleagues, for each participant, regions of the left prefrontal cortex (along the inferior frontal gyrus) that demonstrated neural priming were first identified during semantic classification (living/nonliving) of repeated objects using fMRI. Each participant was then brought back for a TMS session where they classified a new set of objects using the same task. Short trains of TMS were applied to the previously identified prefrontal region during classification of half of these objects; classification of the remaining half of objects was accompanied by TMS applied to a control region (left motor cortex). Immediately following the TMS session, subjects were rescanned with fMRI while performing the semantic classification task on objects that were previously accompanied by prefrontal stimulation, objects previously accompanied by control-site stimulation, and novel objects. Results revealed that classification of objects that had been previously accompanied by left frontal TMS failed to demonstrate subsequent behavioral priming and neural priming in the left inferior frontal gyrus and lateral temporal cortex. By contrast, neural priming in early visual regions remained intact. Critically, these effects were not due to generalized cortical disruption that accompanied TMS; control-site stimulation had no disruptive effects on either behavioral or neural markers of priming. Consistent with this finding, Thiel et al. (2005) provided evidence for a disruptive effect of left-frontal TMS on behavioral priming during a lexical decision task. Together, these results provide evidence that behavioral and neural markers of priming in frontal and temporal regions are causally related, not just correlated.

In summary, correlations between behavioral and neural priming are observed consistently in prefrontal, and to some extent temporal, regions on priming tasks that include a conceptual component, such as semantic classification and stem completion. Although studies using such tasks have failed to demonstrate a relationship between behavioral priming and neural priming in perceptual regions, behavioral demonstrations of perceptual priming are well documented (e.g., Tulving and Schacter, 1990; Schacter et al., 1993a). A key hypothesis to be evaluated in future investigations is that neural priming in perceptual cortices subserves perceptual priming. Establishing a causal relationship between the two necessitates careful consideration of the behavioral tasks used to demonstrate such effects. Further, it is likely that the behavioral advantage for repeated processing of an item is mediated by multiple processes and components of priming – both conceptual and perceptual – that contribute in an aggregate fashion to facilitate task performance (e.g., Roediger et al., 1999). Neuroimaging research can be helpful in attempting to tease apart the components of such effects and link them with the activity of specific brain regions.

## 2.33.7 Summary and Conclusions

Our review demonstrates that neuroimaging research has shed new light on cognitive theories of priming that were originally formulated and investigated through behavioral approaches within the field of cognitive psychology. The contributions of this research include advances with respect to long-standing theoretical debates about the nature of priming, as well as new lines of investigation not previously addressed by cognitive studies.

As alluded to earlier, evidence across several domains of neuroimaging research on priming is inconsistent with a single process account of the phenomenon, and instead supports the idea that multiple processes are involved in different types of behavioral priming and corresponding neural priming. Schacter et al. (2007) recently proposed a multiple-component view of priming, as depicted in **Figure 2**.

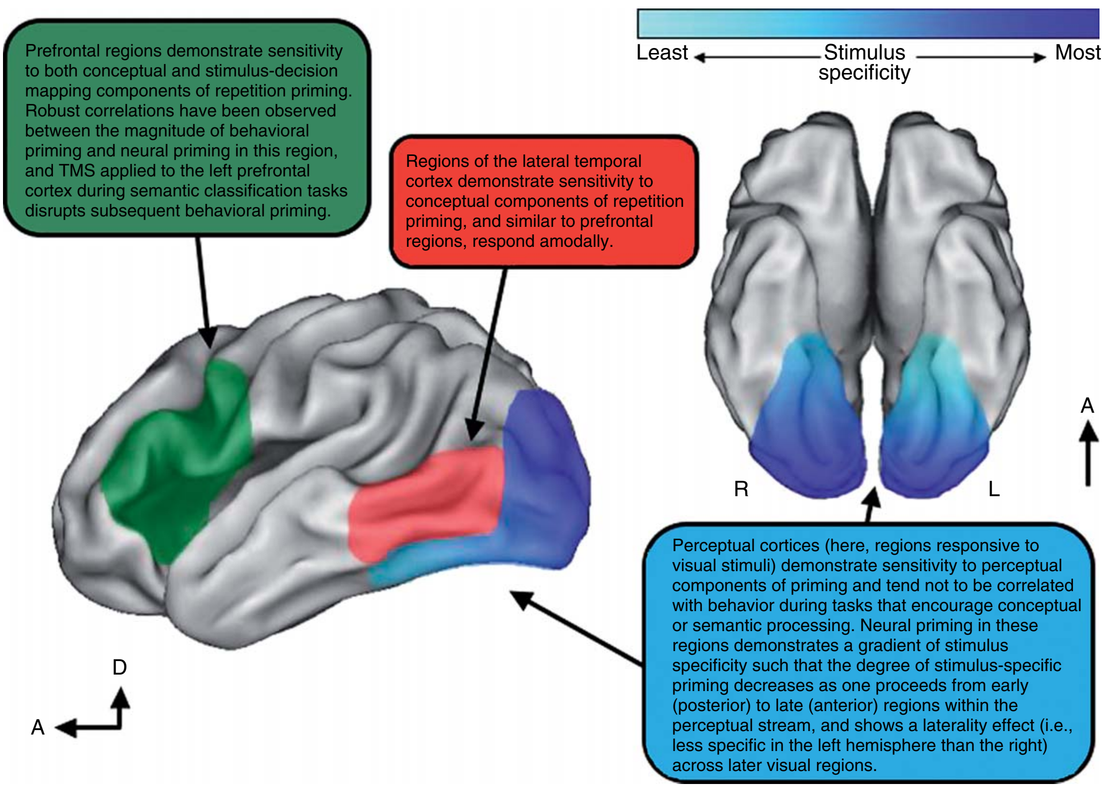

**Figure 2** Schematic of proposed components of priming. Figure depicts partially inflated lateral view of the left hemisphere and ventral view of the left and right hemispheres. Lateral view is tilted in the dorsal-ventral plane to expose the ventral surface ('A' denotes anterior direction, 'D' denotes dorsal direction, 'L' and 'R' denote left and right hemispheres, respectively). Color-coding of anatomical regions is meant to serve as a heuristic for the proposed components. The color gradient within the ventral visual stream (blue) is meant to represent approximately the gradient of stimulus specificity that has been observed within these regions. TMS, transcranial magnetic stimulation. Adapted from Schacter DL, Wig GS, and Stevens WD (2007) Reductions in cortical activity during priming. *Curr. Opin. Neurobiol*. 17: 171–176, with permission from Elsevier.

This view suggests that there are at least two distinct mechanisms involved in neural priming. One corresponds roughly to what Wiggs and Martin (1998) called *sharpening* or *tuning*, which occurs when exposure to a stimulus results in a sharper, more precise neural representation of that stimulus (*See* Chapter 3.12; see also Grill-Spector et al. (2006) for more detailed consideration of sharpening and related ideas). Such tuning effects are likely to predominate in posterior regions that code for the perceptual representations of items, and perhaps in anterior regions that underlie conceptual properties of these items. Tuning effects, however, are unable to account for response-specific priming effects (e.g., Dobbins et al., 2004) and appear to be less correlated with behavioral priming observed during tasks that are semantic or conceptual in nature. The second proposed mechanism primarily reflects changes in prefrontal cortex that drive behavioral priming effects in a top-down manner, as initially controlled processes become more automatic (Logan, 1990; Dobbins et al., 2004).

While the view proposed by Schacter et al. (2007) suggests two possible components of priming, this is a preliminary model that needs to be extended, elaborated, and related more fully to distinctions among types of priming (e.g., perceptual, conceptual, associative) that have been long discussed in the cognitive literature. Traditional theories of priming laid the groundwork for understanding these components, and neuroimaging research will likely play a crucial role in resolving the questions that remain, in suggesting new lines of inquiry not previously conceived of, and in expanding our understanding of the nature of priming and implicit memory more generally.

# 2.34 Motor Learning and Memory

**T. D. Lee**, McMaster University, Hamilton, ON, Canada

**R. A. Schmidt**, University of California at Los Angeles, Los Angeles, CA, USA

## 2.34.1 Introduction and Definition of the Field

Most of us have marveled at the extreme levels of movement skill shown by champion athletes, musicians and dancers, or artisans. Certainly, we almost take for granted our capabilities to drive a car, type on our computer keyboard, or play golf, as the many skills we seem to possess make life productive at work and enjoyable at play. But the capability for production of actions is far more important and fundamental than this. A moment's reflection will reveal that the capability to move our limbs is an essential aspect of life for, without movement capabilities, we could not feed ourselves, locomote to find food or shelter, or, for that matter, even reproduce or survive after birth. Viewed in this way, the capability to move purposefully and efficiently is a critical aspect of life itself, and its study requires little justification.

The study of movement capabilities is very broad, spanning many levels of analysis and touching many different fields or departments within the typical university. Researchers frequently study these phenomena by focusing on such varied levels of analysis as the biochemical changes with muscle contractions or brain activity, the neural underpinnings of actions, the biomechanics of skilled activities, the learning of new actions, the changes in movement with age, and even the role of movements for societies (migrations or wars). For our purposes here, we narrow the focus to areas of study that are closely related to experimental psychology where, as with other areas within psychology, the concern is with observable behavior in individuals (mainly humans) and for the understanding of how this behavior is organized and produced. This focus has, in the past few decades, been called various names such as kinesiology, motor neuroscience, human performance, or motor control. This field is defined by the scientific study of movements by humans and animals, with attempts to understand the actions' characteristics and fundamental underpinnings and ultimately organizing the many variables' experimental effects into testable theory.

A part of the field of motor control has, since the earliest days of experimental psychology, been the focus on how skills are learned with practice and experience. The study of learning in general has always been a core focus for experimental psychology and, as we discuss later, the study of skill learning has undergone many changes in popularity over the years as well. The label motor learning is the one most often associated with the field directed at understanding the acquisition of skill (or movement capability) with practice or experience. This chapter focuses on this area directly.

## 2.34.2 Motor Learning: Acquisition of Procedural Knowledge

It is useful to make an important distinction about the kind of knowledge that is the product of motor learning, as it helps to set the field of motor learning apart from the larger field of human learning as it is studied in experimental psychology. Roughly speaking, knowledge can be thought of in two ways (or perhaps, as two ends of a continuum). Declarative knowledge is the capability to know that, as in knowing that the first American president was George Washington, or that $2+2=4$. A distinctly different kind of knowledge is procedural knowledge, which is the capability to know how to. . ., as in knowing how to ride a bicycle, how to type on a keyboard, or how to use a machine tool.

We suggest that, for the much of research efforts concerning human and animal learning in experimental psychology, the laboratory subject is acquiring declarative knowledge. For example, in verbal learning, the participant already knows how to say the proper answer or press the correct response key; what is learned is the selection of an existing behavior out of a large number of existing behaviors. In animal learning, the animal may learn to press the bar in the cage after some stimulus information is presented; learning how to press the bar is not of much interest. Also, learning to run a maze seems to be, at first glance, a highly motor activity; but running and learning to turn corners are not what is learned in the experiment – rather when and which way to turn are the critical issues.

For motor learning, on the other hand, the problem for the learner is how to produce a particular action, e.g., a dislocate-shoot-handstand on the still rings; the choice of which action to do is not the issue, as it is clear that this particular action is the goal. Now, the problem for the learner is to develop a way to control the musculature and limbs so that the designated action can be performed. Thus, motor learning does not seem to involve learning which previously acquired action to make, but rather it involves how to produce a given action. This is emphasized in motor-learning experiments, where tasks for which subjects have not had any previous experience are typically used (see Schmidt and Lee, 2005: Chapter 2).

We can probably think of counter-examples for animal learning. One might be the circus bear who has learned to ride a bicycle, or the dog who rides a surfboard, behaviors that are almost certainly not genetically acquired and must have been learned. If these kinds of behaviors were studied in animal-learning laboratories, we would be forced to call the product of this practice motor learning. But tasks like this are rarely studied in the laboratory, where the preferred method seems to be to use already acquired actions (e.g., bar presses) so that what is learned is when, or under what conditions, to press the bar – declarative knowledge. Even with these possible exceptions, the declarative/procedural distinction seems to be the chief factor that separates the field of motor learning from many other forms of learning examined in the laboratory. How procedural knowledge is acquired with practice is the defining feature of motor-learning research.

## 2.34.3 Brief Historical Background of Motor Learning Research

Historians owe a debt of gratitude to the work of McGeoch (1927, 1929, 1931), Irion (McGeoch and Irion, 1952; Irion, 1966), and Adams (1987), who provided detailed reviews of motor learning research during the past century. Like those reviews, the present chapter does not detail closely related areas of research such as the neurophysiology of motor control, or human factors and ergonomics research. Rather, we focus on studies of motor behavior, and how the permanent capability to achieve a goal-oriented action improves as the direct result of practice – the study of motor learning.

Early experimental investigations of motor learning were concerned with real-world skills, and the problems associated with their acquisition, retention, and transfer. For example, Bryan and Harter (1897, 1899) studied telegraphy (sending and receiving Morse code), documenting the changes that occur with improvements in skill (see also Taylor, 1911/1967). The acquisition (Book, 1908/1925) and retention (Hill et al., 1913; Hill, 1934, 1957) of typewriting skills represented another focus of study of learning real skills.

The initial stage or period of skill acquisition provided important information about the motor learning process, which was unavailable to the experimenter if the participant had already acquired some skill in the task to be learned. So, similar to the use of nonsense syllables as the unit of study in verbal memory experiments, psychologists created new tasks to examine how learning proceeded in the absence of previously acquired skill. Very simple tasks such as blindfolded line-drawing (Thorndike, 1927; Elwell and Grindley, 1938) and more complex tasks such as mirror tracing (Snoddy, 1926) and pursuit tracking (Koerth, 1922) were frequently used motor learning tasks.

The use of novel motor tasks also facilitated the study of various practice variables, as these variables were believed to have their most significant impact during the early stage(s) of skill acquisition. During the first half of the twentieth century, the most commonly studied motor learning variables included the effects of practice distribution (Bourne and Archer, 1956) and knowledge of results, or KR (Thorndike, 1927; MacPherson et al., 1948, 1949; Dees and Grindley, 1951). Like all behavioral science disciplines, certain topics in motor learning have gone through periods of intense scrutiny, during which considerable research was conducted and their results archived. Much of this work was driven by theories that, at the time, generated a great deal of interest. A good example in early motor learning research was the study of distribution of practice. A large volume of research was produced during the 1940s and 1950s concerning the effects of rest period durations between work periods, almost always using continuous tasks (such as pursuit tracking or mirror tracing). Much of this work was conducted with the purpose of testing the tenets of Hull's (1943) theory of habit strength and drive reduction. Practice distribution using continuous motor skills was viewed as a good behavioral vehicle to study Hull's theory in humans. So, when interest in Hull's theory waned, so too did experiments on practice distribution in motor learning (Adams, 1987; for a review of this work see Lee and Genovese, 1988). The study of KR suffered a similar fate. Augmented feedback, such as KR, was important to theorists who studied conditioning as a means to shape behavior.

The cognitive psychology revolution in the 1950s and 1960s ended most of the motor learning research undertaken in psychology departments. The new hot topics were memory and attention. By the 1970s, research output in the study of learning, such as paired associate learning and motor skills learning, was significantly reduced. Disinterest in motor-learning research continued in psychology departments through the end of the century and largely remains so today (Rosenbaum, 2005). However, motor learning research has become revitalized since the 1970s due mainly to four key factors.

## 2.34.4 Four Factors Contributing to the Modern Era of Motor Learning Research

### 2.34.4.1 Technology

By the early 1980s, researchers had generally become dissatisfied with simple measures of performance, such as reaction time or unidirectional error scores. Everyday actions involve complex movements, usually requiring the coordination of multiple degrees of freedom. The rapid advancements in computers and digital technology in the latter part of the century gave rise to more sophisticated methods to examine complex movements and the ability to record and analyze much more data than had previously been possible. Digital recording devices allowed the simultaneous recording of multiple actions and computers enabled the power and flexibility to put them to work. The elegance of motor control could now be studied in detail, and relatively cheaply and easily so.

### 2.34.4.2 Relevance to Other Disciplines

A second factor that gave rise to the rebirth of motor learning research was the expansion of interest to other disciplines. Motor learning had always been relevant to physical educators who studied sport skills, and this interest continued to grow as technology facilitated the examination of specific sport skills in experiments (Williams and Hodges, 2004). Motor learning also grew as an area of research interest to scientists in other disciplines. Specialists in human factors and ergonomics found motor learning to be a fruitful area for understanding the learning process in occupation-related settings (e.g., Agruss et al., 2004). Various health-related disciplines discovered important relationships between motor learning and factors of direct relevance to them, such as stroke rehabilitation in physical therapy (Boyd and Winstein, 2003; Krakauer, 2006), voice rehabilitation (Verdolini and Lee, 2004; Yiu et al., 2005), and the acquisition of chiropractic (Descarreaux et al., 2006), dental (Wierinck et al., 2006), and surgical skills (Dubrowski et al., 2005; Brydges et al., 2007).

### 2.34.4.3 Two Important Papers

Although interest in motor skills research among psychologists waned, the role of psychological and cognitive processes as key components of the motor learning process became a motivating factor for renewed interest, and this interest can be localized to the publication of two important papers. The papers were important because they reported findings that were counterintuitive to popular thinking at the time. Shea and Morgan (1979) reported the findings of two groups of subjects who practiced three versions of a task that required subjects to learn patterns of arm movements and to perform them as rapidly as possible. A blocked group practiced the patterns in a drill-type order, which minimized the interference that practice of one task could exert on another task; all trials on one pattern were completed before trials began on a new pattern. Performance of this blocked group was very good: They achieved an asymptote level of reaction time and movement time

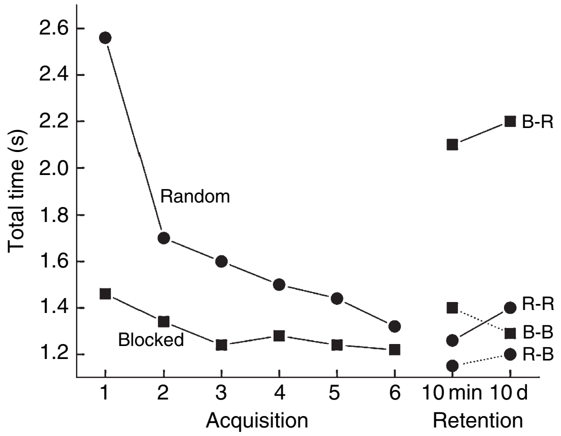

**Figure 1** Blocked practice produces better performance during the acquisition trials than random practice. However, the random group performs better than the blocked group in immediate (10-min) and delayed (10-day) retention tests, regardless of how the retention tests are ordered (e.g., R–B = performance of the random group in blocked-ordered retention tests). Data from Shea JB and Morgan RL (1979) Contextual interference effects on the acquisition, retention, and transfer of a motor skill. *J. Exp. Psychol. Hum. Learn. Mem.* 5: 179–187.

very quickly (presented as total time in **Figure 1**). In contrast, performance of the random group, which never received practice trials on the same pattern more than twice in a row, was poor, never reached asymptote, and generally was worse than the blocked group throughout acquisition. These findings were consistent with well-known principles of the effects on interference on performance: Less interference produced better performance and vice versa.

The counterintuitive nature of Shea and Morgan's findings were revealed in retention and transfer tests conducted after delays of 10 min and 10 days. In these tests (conducted in both random and blocked orders), performance of the random group was superior to that of the blocked group on the blocked-ordered retention tests (compare the R-B and B-B symbols in **Figure 1**). And the effects of random practice were far superior in the randomly ordered retention tests (compare the R-R and B-R symbols in **Figure 1**). Apparently, the very same interference effects that resulted in performance deficits in acquisition also resulted in learning benefits as revealed in the retention tests. This finding was called the contextual interference effect (cf. Battig, 1979; Battig and Shea, 1980) and remains a topic of continued interest today (see the section titled 'Contextual interference').

The other important paper, published around the same time, was a review of the extant literature regarding the effects of KR in motor learning (Salmoni et al., 1984). The message delivered in this review paper was consistent in many respects to the message of the Shea and Morgan (1979) paper. Specifically, if one were to make an assessment about the efficacy of learning variables on the basis of performance during an acquisition session (i.e., when the manipulations were ongoing), then a very different conclusion would emerge compared to an assessment that was based on performance in a retention or transfer test (i.e., when the conditions of performance are equated). In their review of the KR literature, Salmoni et al. reported several instances in which the effects of a KR variable in acquisition were reversed in a retention or transfer test. Similar to the Shea and Morgan findings, these conclusions highlighted the important distinction between performance and learning and caused researchers to reassess their thinking about the factors and theoretical issues underlying the learning of motor skills.

We discuss these research areas in detail later. However, it is interesting to note that much of the interest in motor learning for researchers in other disciplines grew directly out of the counterintuitive nature of the findings reported in the new studies of contextual interference and KR effects. For some, it was the relative ineffectiveness of practice regimes in these specific, applied research areas that motivated this interest in motor learning research (e.g., Dubrowski et al., 2005).

#### 2.34.4.4 Theory

The last factor that has spirited the growth of motor learning research concerns the product of skill acquisition – memory for motor skill – which is the domain of motor control. Perhaps this factor, more than any other, has resulted in the growth of motor learning from a theoretical perspective. Movement is the result of neural mechanisms that interact to result in action. At any one time, the true capability for motor skill is a concatenation of the current state of these interactions in memory, which is the direct result of practice. Two formalized theories of motor control, published in the 1970s, provided a strong rationale regarding how motor control is represented in memory. We begin by reviewing these theories and how they influenced motor learning research.

## 2.34.5 Motor Control: The Memory (Product) of Motor Learning

Over the years, there have been many separate statements or suggestions concerning what is learned in motor learning, that is, what is the product of practice? Two of these more formalized attempts are described next.

### 2.34.5.1 Adams's Theory

In the late 1960s, Jack Adams emphasized that learning could be conceptualized in terms of feedback-based, closed-loop processes, both for verbal learning (Adams and Bray, 1970) and motor learning (Adams, 1971). His motor-learning theory was based on the large body of empirical literature that used slow, self-paced, linear-positioning tasks, with the numerous practice variables that had been studied in this way. For these skills, the learner's task was to move a lever (or other manipulandum) to a particular goal location, and practice with KR was typically used.

For Adams, practice created what he called the perceptual trace – a memory structure that was the product of learning. After each attempt at positioning the lever, the subject receives KR about his or her error, which provides a basis for a more correct action on the next trial, and so on. Thus, for Adams, the function of KR was to guide the action toward the target over trials. Experience at the target location generated movement-produced (chiefly kinesthetic) feedback about that position, which was stored as a perceptual trace. With repeated trials increasingly near the target position, the most frequently experienced perceptual trace came to represent the sensory qualities of being at the target location. The process of reinforcing an increasingly narrow range of perceptual traces near the correct trace is illustrated in the three panels in **Figure 2**. Once this perceptual trace was sufficiently strong, on a subsequent attempt the subject would move to a position such that the difference (error) between his or her actual feedback at the moment and the acquired perceptual trace was minimal, using closed-loop processes. Thus, variations of KR that produced a faster approach to the target, or more accuracy at the target, were thought to be beneficial for learning because they made the perceptual trace more distinctive or reliable. This process also improved the subject's capability to detect his or her own errors (the difference between concurrent sensory feedback and the perceptual

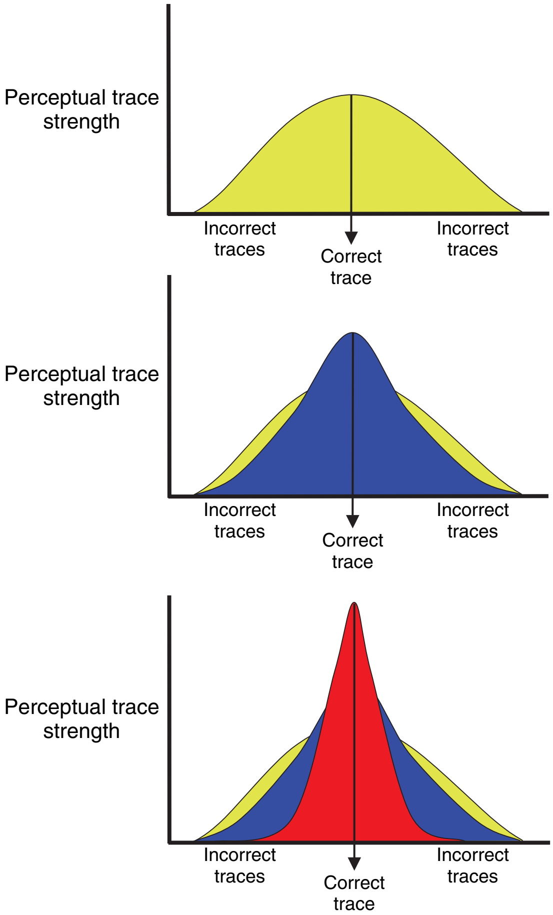

**Figure 2** A conceptualization of Adams's (1971) theory. As repetitions accumulate, the representation strength of the correct perceptual trace becomes more fine-tuned in memory. With many repetitions, the correct perceptual trace becomes the dominant modal representation.

trace). In this manner, a strong perceptual trace would facilitate continued learning in the absence of external KR from the experimenter.

Adams's theory had a powerful effect on the field, generating considerable empirical activity in providing tests of the various predictions. As a result of this activity, research identified a number of shortcomings in the theory.

#### *2.34.5.1.1 No open-loop processes*

Adams intended his theory to be an account of slow, linear positioning tasks, and he made no attempt to explain the control of rapid actions. For rapid tasks, such as throwing, striking, or other brief movements of the limbs, evidence has mounted showing that feedback acts too slowly for it to be the basis for movement control. Alternatively, centrally generated, open-loop processes were proposed that were presumably responsible for producing such fast actions without requiring movement-produced feedback (Henry and Rogers, 1960; Keele, 1968). These open-loop processes have been described under the general heading of motor programs, about which we will provide additional discussion later. But, in short, the inability for Adams's theory to account for rapid actions was taken as a limitation.

#### *2.34.5.1.2 Novelty*

One logical problem with the theory was the inability to account for novel actions: Actions that the subject had never produced previously. If the basis for the perceptual trace was experience with the correct action, then how could the person ever make a variation of a skill that he or she had never practiced before, such as positioning a weighted limb in a new location? Perceptual traces, in this view, were limited to the actions that had actually been performed or practiced previously. A further implication is that, in order to perform the many varieties of actions that we do, we must have a very large number of perceptual traces in memory. This naturally brought up the concern regarding how the central nervous system could store and retrieve all of the traces necessary to allow us to move with the ease and efficiency that we can.

#### *2.34.5.1.3 Generality*

Another concern was the fact that skills seemed to demonstrate a particular kind of generality. That is, when we throw, we can throw in a very large number of ways, many of which have not been experienced before. It is as if the skill of throwing, for example, could be generalized to a wide number of similar but nonidentical throwing actions. Adams's theory did not provide a way for this kind of generalization to occur.

### 2.34.5.2 Schema Theory

Schema theory, proposed by Schmidt (1975), grew out of the several drawbacks to Adams's theory. In particular, the concern was to provide an account of learning in rapid as well as slower actions, to provide a way for novel actions to be performed, and to account for the generality that seemed to be shown in so-called classes of actions (such as throwing). As with Adams's theory, the concern was for discrete actions only, as other kinds of processes seem to operate in continuous tasks (e.g., swimming, steering a car).

#### 2.34.5.2.1 Open-loop processes

Schmidt proposed that discrete actions such as overarm throwing are really a collection of actions that fall into the same class. Each member of the class is different in nearly countless ways (e.g., speed, trajectory, object size, throwing distance), but each member of the class had certain features that were invariant (Schmidt, 1985) across the members of the class. The idea was that this class of actions was governed by what was termed a generalized motor program (GMP), which had certain invariant features structured rigidly in it. The debate about what these invariant features are, and whether they are sufficiently invariant, has raged for several decades.

Chief among these invariants are sequencing and relative timing. Sequencing of the parts of an action simply refers to the order in which various events occur: For example, activity in Muscle 1 precedes Muscle 2, and both precede Muscle 3. It was assumed that all members of a class of actions have the same sequencing of elements. Relative timing refers to the temporal structure, or temporal pattern, of the action. If various muscle contractions were recorded, then we would see a temporal regularity in these elements. Specifically, for an action with several muscles participating, relative timing is invariant if the ratios among the contraction durations are constant across changes in, say, the overall duration of the action. Also, invariance requires that the duration of any contraction divided by the overall duration of the action must be constant across changes in overall duration. Another feature of the class of actions is relative force. Relative force refers to the patterning of forces among the various muscles: Muscle 1 always contracts with twice the force as Muscle 2, etc. This is another invariant feature structured in the GMP for the action.

According to the theory, when the performer attempts an action in the class, he or she retrieves the GMP for that class and then adds parameters to the program to suit the particular environmental demands. These parameters are proposed to be the overall duration of the action (throwing rapidly or slowly), the overall amplitude of the action (as in writing one's signature in different sizes), and the particular limbs to be used (writing with the fingers on a check, or with the arm/shoulder ten times larger on a blackboard). The selection of the parameters occurs prior to the action, and the GMP is initiated so that the invariant features of the movement emerge but with different surface features (such as amplitude or speed). Note that this kind of model helps to solve the problem of novelty, mentioned earlier, as a novel set of parameters will produce an action that the performer has never produced before. Also because there is only one program needed for the class, this eliminates the need to have a separate program for every different way that the action can be produced, and helps to solve the problem of storage. Note however, that the theory assumes the existence of the GMPs and is silent about how the programs are learned. This latter question remains one of the largest challenges facing schema theory (Shea and Wulf, 2005).

The theory does, however, provide a way for the parameter-selection process to be learned. When the performer produces an action such as throwing, he or she stores information from four sources: (1) the initial conditions (e.g., the required distance to throw, the weight of the object to be thrown, etc.), (2) the parameters that were used (absolute amounts of force, time, etc.), (3) the outcome in terms of the environmental (e.g., distance thrown) as provided by KR, and (4) the sensory consequences of the movement (how it looked, felt, sounded, etc.). This information is stored only long enough for the performer to update two schemas – rules or relationships among these stored values. The schemas are continuously updated with new information over many parameterizations for the class of actions.

The two schemas are the recall schema and the recognition schema. The recall schema is the relationship between the past parameters used and the past outcomes of the action, whereas the recognition schema is the relationship between the past sensory consequences of the action and the past outcomes. Given these schemas, when the person wants to produce a particular, perhaps novel, outcome with the action-class, he or she uses the recall schema to select the parameters based on the desired outcome. The recognition schema is used so that the performer can select the expected sensory consequences based on the desired outcome; this forms the basis for recognizing errors in performance after the action is produced. For example, knowing that on this occasion I want to throw 20 m, the recall schema estimates the parameter values needed (based on past experience with this class of tasks but with different outcomes), they are supplied to the GMP, and the action is triggered.

#### 2.34.5.2.2 Fast versus slow actions

Finally, schema theory proposes that rapid actions (e.g., throwing, say 100 ms in duration) and slow actions (e.g., linear positioning, say 3 s in duration) are produced systematically differently. Fast actions are produced by executing the GMP in an open-loop manner. After the action, the performer can compare the actual sensory consequences (response-produced feedback) with the expected sensory consequences from the recognition schema, providing a basis for the performer knowing about errors in movement production.

Slow actions are produced in a way analogous to Adams's (1971) proposal. When a slow action is required, the subject generates the expected sensory consequences from the recognition schema and then moves to that position such that the actual sensory consequences (movement-produced feedback) match the expected sensory consequences; the GMP is not involved. This leaves no capability for the performer to detect postperformance errors, as this error-detection process is used to produce the movement in the first place (see Schmidt and White, 1972). Thus, the overall generalization is that closed-loop processes produce slow actions and open-loop processes produce fast actions. There is considerable evidence supporting the distinction between motor control processes involved in fast and slow actions (see Schmidt and Lee, 2005: Chapter 13).

#### 2.34.5.2.3 Variability-in-practice effects

One interesting implication of schema theory is that variability in practice among members of a class of actions, as compared to an equal amount of practice on any one of them, should be beneficial for learning (i.e., transfer performance on a novel variant). This is so because the schema for the class of actions – analogous to a regression line – is built up more reliably as the learner gains more variability in prior experiences. In this manner, the theory predicts that transfer performance to a novel variant is more accurate because the schema-rule is better defined. This somewhat counterintuitive prediction has been tested many times over the past 25 years, and the evidence generally supports it (McCracken and Stelmach, 1977; Shapiro and Schmidt, 1982; Lee et al., 1985; Van Rossum, 1990; see Schmidt and Lee, 2005: Chapters 11 and 13, for a summary and discussion). Another, even more counterintuitive prediction is that, for a task with, say, five variants (A, B, C, D, and E along some dimension such as speed), practice at A, B, D, and E is more beneficial for transfer to Variant C than is an equal amount of practice at Variant C itself. This prediction was supported in research by Shea and Kohl (1991), which is

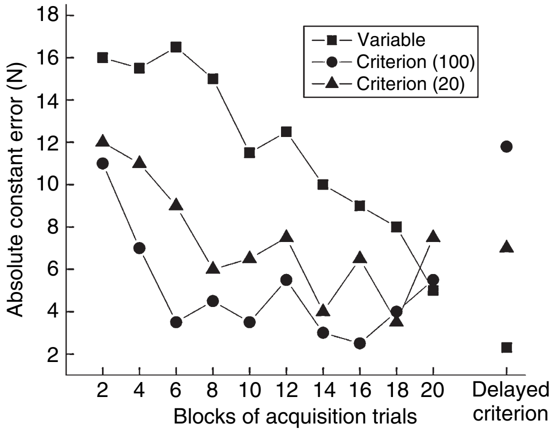

**Figure 3** Variable practice (at goals surrounding and including a criterion target force) produces increased accuracy on a delayed criterion test than equal amounts of criterion-only task performance when controlling both for the number of criterion task trials (Criterion 20 group) and the total number of practice trials (Criterion 100 group). Data from Shea CH and Kohl RM (1991) Composition of practice: Influence on the retention of motor skills. *Res. Q. Exerc. Sport* 62: 187–195.

illustrated in **Figure 3**. In their research, Shea and Kohl asked participants to learn a force-production task, providing them with 100 trials to learn a criterion force of 150 N. The variable practice group received only 20 of these trials at the criterion force, and 80 trials were practiced at goals that were 50 or 100 N above or below the criterion force. Two control groups were included that received either 20 or 100 practice trials 'only' at the criterion force. A delayed retention test at the criterion force revealed that the variable practice group performed with less mean error than both the two criterion-only practice groups, supporting the schema-theory prediction. This variability-in-practice evidence is seen as contradictory to Adams's theory. The findings have strong implications for the structure of real-world practice.

#### 2.34.5.2.4 Learning parameters versus learning programs

In another line of research, investigators have found that movement errors arising from two sources can be separated. Errors stemming from the specification of parameters can be dissociated from errors resulting from the generation of the GMP itself (Wulf et al., 1993). Being able to separate these two kinds of errors makes it possible to study how various practice conditions affect these two theoretical processes. For example, increased relative frequency of KR enhances parameter learning but degrades program learning (Wulf et al., 1993; Wulf and Schmidt, 1996). Several of the dissociations between factors that affect program versus parameter learning have been shown recently, and they tend to support the separation of these two constructs in memory (Wulf and Shea, 2002). Much more needs to be done in this area, in our view.

#### 2.34.5.2.5 Especial skills

Recent findings by Keetch et al. (2005) seem to provide some difficulties for the schema view, however. One prediction arising from schema theory is that practice at any one variant of a class of actions exerts its effect by strengthening the schema for the whole class, not just for that particular variant. Thus, extensive practice at one of these members should not be evident on this particular member, but rather on the class as a whole. Keetch et al. studied set shots (where the feet do not leave the floor) made by skilled basketball players across various shot distances. They found that accuracy at the foul line (15 ft), which has had massive amounts of practice, was far better than predicted by performance at shot distances longer than or shorter than 15 ft (i.e., 9, 11, 13, 17, 19, and 21 ft). This effect can be seen in **Figure 4**. Keetch et al. interpreted these findings in terms of what they called an especial skill – an individual variant of a class of actions that, because it has received massive amounts of practice, stands out from other seemingly similar variants of the same class. These kinds of results suggest that learning is manifested not only in processes of generalization (as suggested by schema theory), but also by specificity in terms of these especial skills. Newer theories of motor learning will have to recognize both types of effects.

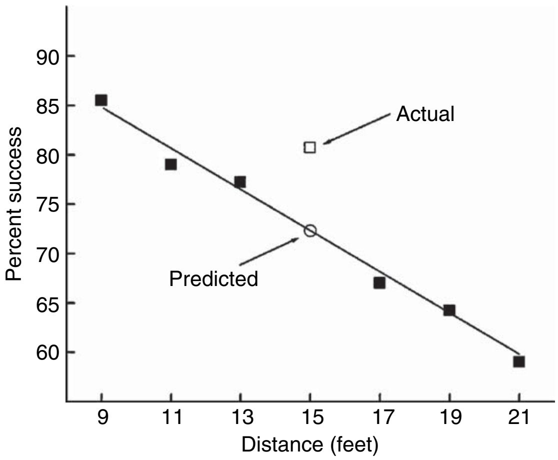

**Figure 4** Shooting accuracy data at the free-throw line (open square symbol) exceeds predicted free-throw performance (unfilled circle symbol) based on set shot data from adjacent locations (filled square symbols). Data from Keetch KM, Schmidt RA, Lee TD, and Young DE (2005) Especial skills: Their emergence with massive amounts of practice. *J. Exp. Psychol. Hum. Percept. Perform.* 31: 970–978.

## 2.34.6 Cognitive Operations During Motor Learning

Motor control, the product in memory about which both Adams (1971) and Schmidt (1975) theorized, was critically dependent upon the interaction of movement and feedback (both sensory and augmented feedback). What was not considered important in these theories, however, was the role that cognitive operations served in the development of motor memories. As we mentioned earlier, it was the prominence of these theories, combined with their failure to explain the effects of cognitive operations during practice, that set the stage for the impact on learning research of the Shea and Morgan (1979) and Salmoni et al. (1984) papers.

### 2.34.6.1 Contextual Interference

The findings by Shea and Morgan (1979) on the effects of blocked and random practice were unexpected, given the views about memory that had been presented by Adams (1971) and Schmidt (1975). There was every reason to expect that blocked practice would be superior to random practice for learning, and this was confirmed by the acquisition data collected during practice. The reversal seen in retention and transfer might have been considered a set of data outliers, if it were not for the plausible theoretical rationale that was proposed to explain the results. Shea and Morgan found an ally in William Battig, and they relied heavily on some of Battig's ideas regarding elaborative and distinctive processing mechanisms to explain their results.

Battig had long been a proponent that learning comes at a cost. Earlier, he had suggested that "intertask facilitation is produced by intratask interference" (Battig, 1966: 227), referring to the finding that the difficulty in acquiring various items within the same category actually facilitated transfer when learning a different category of items. An expanded view (Battig, 1979), which he termed contextual interference, further developed his stance regarding the relationship between interference and facilitation.

#### 2.34.6.1.1 Elaborative and distinctive processing

An important part of Shea and Morgan's explanation for the differences in learning due to random and blocked practice was similar to Battig's (1979) views regarding elaborative and distinctive processing mechanisms. Consider first a typical trial in a blocked practice schedule. The learner prepares to perform one of the tasks to be learned, executes the action when cued to do so, and then evaluates the completed performance on the basis of movement-produced feedback and KR (if provided). By the very nature of blocked practice, the next trial requires essentially that same movement preparation and execution as the previous trial. In contrast, a typical random practice trial requires that the learner prepare, execute, and evaluate performance for a task that has a different goal on consecutive trials. Shea and Morgan (1979) proposed that the operations completed for one task, in the context of operations that may still reside in memory for a different task, provide more comparative and contrastive information about the tasks to be learned, compared to a blocked practice schedule.

In Shea and Morgan's view, the comparative and contrastive information during random practice would be explicit and verbalizable, and therefore should be available to report. This prediction was supported in a subsequent study by Shea and Zimny (1988), who found that subjects in a random-practice condition were more likely than those in blocked practice to provide information about the just-completed task in ways that set the task apart from the other tasks to be learned. Such information was argued to have made the explicit recall of the tasks more memorable, thus facilitating performance in retention tests.

The views of Shea and Morgan (1979) also suggest that any practice schedule (not necessarily a random schedule) that promotes comparative and contrastive processing should facilitate learning compared to a blocked schedule. A study by Wright (1991) provided strong support for this argument by combining different between-trial processing activities with a blocked practice schedule. One group of subjects was asked to describe the task that had just been performed, while another group was asked to describe a different task. A third group rested during the interval, and a fourth group was asked to explicitly describe the differences in task demands for the just-performed trials compared to one of the other tasks to-be-learned. The explicit processing of this latter group resulted in retention that was far superior to that of the other three groups, even though all groups had physically performed the tasks in a blocked schedule. The findings supported the proposition that random practice places more demands on the learner to prepare and evaluate performance in a manner that makes the information that has been learned about each of the tasks more memorable and distinctive.

#### 2.34.6.1.2 Action reconstruction processing

An alternative view of the random/blocked effects emerged from research performed by Lee and Magill (1983). In their view, the differences between random and blocked practice schedules were similar to the effects seen in verbal memory when item repetitions are spaced during study, which has the effect of increasing performance in a retention test. According to Jacoby (1978; Cuddy and Jacoby, 1982), the spacing effect results from processing a repetition when the memory for the initial presentation has been forgotten (or at least degraded). Lee and Magill (1983, 1985) modified Jacoby's rationale to explain the contextual-interference effect. The processing requirements to learn a motor skill in a blocked-practice schedule are minimized because all repetitions of the task follow immediately after having just performed the same task. Processes associated with movement planning, execution, and evaluation all concern the very same goal-oriented action. Therefore, these processes need not be fully undertaken on each subsequent trial because the previous plan remains in memory. In contrast, a repetition of any single task in a random schedule may not occur until several trials later, during which the learner is required to abandon any previously constructed action plans in favor of an action plan that is appropriate for the current task demands. When a repetition of that earlier task is again required, the previously constructed action plan for that task is no longer in memory, thereby requiring that the learner reconstruct the action plans anew. It is practice at (re)constructing the action that gives random practice its benefits, according to this view.

Note that these processing requirements for random practice should be undermined if the action planning activities are obviated at the time that a repetition is performed. Such a prediction was tested by Lee et al. (1997) in which modeled augmented information about the temporal components of a timing task was presented to the learner prior to each random practice trial. The powerful advantage of the modeled timing information was clearly evident in the acquisition trial blocks: This random group performed as well as the blocked group throughout acquisition, and both were better than a random group that did not have the modeled timing information. However, the fate of this random group that received modeled information during practice was revealed in learning tests. Despite having received random practice, the modeled information resulted in retention and transfer performance that was as poor as blocked practice, and was much worse than the random group that did not receive the modeled information. In terms of the reconstruction view, these data provided evidence that external reinstatement or augmentation of the action-plan information prior to a practice trial facilitates performance and is detrimental to learning, likely because it eliminates (or at least reduces) the need for the learner to practice the reconstruction of the action by him- or herself.

The findings of Lee et al. (1997) were replicated and extended in an experiment by Simon and Bjork (2002). In their study, groups of blocked and random subjects received modeled information that either matched the task to be performed or was appropriate for the timing requirements of one of the other tasks (mismatched). Their results appear in **Figure 5** and are straightforward. Matched timing models facilitated performance of both blocked and random practice groups (the filled symbols in **Figure 5**), relative to mismatched models (the unfilled symbols). Retention performance, however, benefited from the mismatched models, regardless of the physical order in which the practice trials were undertaken.

Note that the Simon and Bjork (2002) data do not distinguish between the elaboration and reconstruction views of contextual interference. Although the matching models may have provided important planning information that undermined learning, the information from the mismatching models could also have provided contrastive information that benefited both the random and blocked practice groups. Similarly, other studies reveal that processing activities are elevated in random practice relative to blocked, although these findings could be accounted for by either an elaboration or a reconstruction account. For instance, Immink and Wright (1998) showed that preparation times taken prior to action are longer in random than in blocked practice schedules. As well, secondary tasks that are inserted into the interval during which a learner would be planning for an upcoming actions revealed longer probe reaction times for random than for blocked practice (Li and Wright, 2000). These data suggest that planning operations are likely to be elevated during random practice, although these could be result of enhanced elaboration or reconstruction processes.

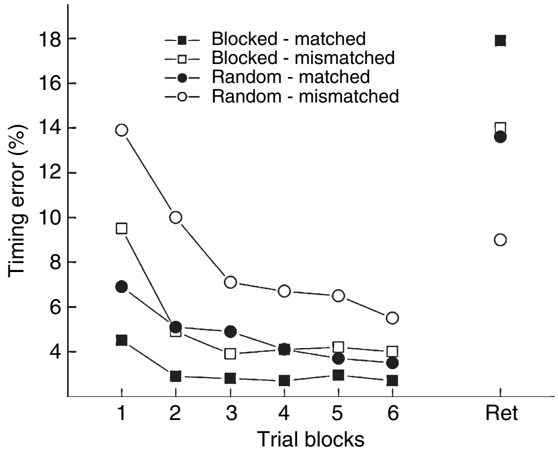

**Figure 5** Matched timing models facilitate acquisition performance (relative timing error from target), but mismatched timing models facilitate retention performance, for both blocked and random groups. Data from Simon DA and Bjork RA (2002) Models of performance in learning multisegment movement tasks: Consequences for acquisition, retention, and judgments of learning. *J. Exp. Psychol. Appl.* 8: 222–232.

More recent studies have identified more precisely what types of processing activities are likely to be affected by random and blocked practice schedules. Specifically, these studies have been designed to tease apart the nature of motor programming activities that have been undertaken in random and blocked schedules. In one experimental manipulation, Immink and Wright (2001) examined motor-programming operations using Morse code responses (dit and dah) within the experimental paradigm developed by Klapp (1996). According to Klapp, two programming operations are involved for this task: (a) organizing the internal components of motor program “chunks,” and (b) sequencing the chunks. Further, it was argued that the internal process can be preprogrammed in advance, especially so if repeated trials on the same task are performed. In their experiments, Immink and Wright (2001) found that random practice facilitated the learning of the internal programming process (relative to blocked practice), but not the sequencing process. They argued that, since the internal process can be preprogrammed, blocked practice required no practice at reconstructive processing, which degraded learning relative to random practice, as measured in retention tests.

An alternative view of the motor-programming process that is influenced by the effects of random and blocked practice was examined in an experiment by Lee et al. (1992). In this study, the nature of the reconstruction process was examined specifically using tasks that differed in terms of their relative timing structure. The rationale was that a set of tasks that shared the same underlying relative timing is based on a common GMP. Regardless of whether the practice sequence order was blocked or random, no reconstruction of the GMP would be required as long as the task variations that were practiced shared the common relative timing. In contrast, for a set of tasks that each had a distinct relative timing, random-practice schedules would require a new reconstruction of the programming process on each trial, but of course, not for blocked practice. Thus, based on reconstructive programming, the authors predicted, and found, large random-blocked differences for a set of different relative timing tasks, but no differences for tasks that shared a common relative timing (see also Magill and Hall, 1990). Although these findings supported the action-reconstruction view, other data suggest that task variations involving same GMPs can also result in a contextual interference effect (Sekiya et al., 1994; Hall and Magill, 1995; Sekiya et al., 1996). These latter findings suggest that simply reconstructing the parameterization of the GMP (same relative timing, but different overall duration) is sufficient to produce random versus blocked differences in learning.

#### *2.34.6.1.3 Cognitive effort*

The effect of task variations in blocked and random practice schedules have also been examined relative to the overall concept of cognitive effort – that random practice is overall, more effortful practice, which works optimally for tasks that are simple and which leads to boredom during practice (Guadagnoli and Lee, 2004). Tasks that are inherently more interesting, or perhaps more complex in nature, should be less amenable to contextual-interference effects because blocked practice engages the learner in more cognitive effort than would be the case for simple tasks. These predictions were supported in research by Albaret and Thon (1998), who found large contextual-interference effects for two simple versions of an arm-movement task, but no differences for the most complex task. Indeed, Wulf and Shea (2002) have suggested that contextual-interference effects are sometimes reversed for very complex tasks, and blocked practice can facilitate learning more than random practice. These suggestions are controversial, however, as large random-practice advantages have been found for complex tasks such as baseball batting (Hall et al., 1994) and handwriting skills in young children (Ste-Marie et al., 2004).

#### *2.34.6.1.4 Meta-memory misattributions*

We mentioned earlier that some of the attraction to this area of research might be attributed to the often-misunderstood distinction between performance and learning, and the counterintuitive conclusions about learning that resulted from these experiments. Two recent lines of research have continued to explore this issue directly. In one experiment, Simon and Bjork (2001) examined the effects of random and blocked practice on actual levels of performance and retention and contrasted these results with the participants' predicted levels of performance and retention. **Figure 6** illustrates their findings. The left panel reveals typical random/blocked effects in acquisition and retention. The right panel illustrates what the learners had predicted would be their level of performance. The findings are clear;

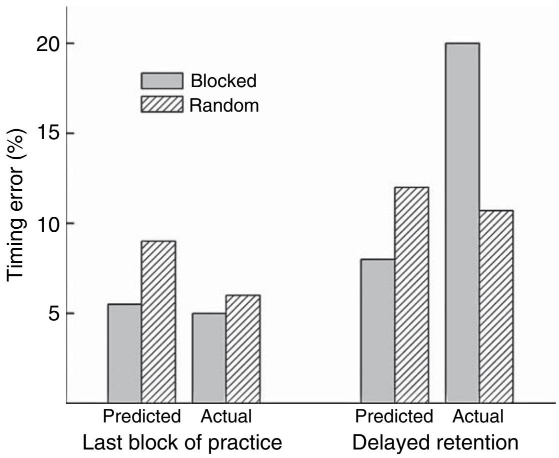

**Figure 6** Blocked and random groups accurately predicted timing error performance at the end of acquisition. In retention, the blocked groups overestimated performance and the random group underestimated performance. Data from Simon DA and Bjork RA (2001) Metacognition in motor learning. *J. Exp. Psychol. Learn. Mem. Cogn.* 27: 907–912.

most importantly, the subjects in the blocked group overestimated their retention performance while the subjects in the random group underestimated retention.

These findings on self-estimations of learning are difficult to reconcile with recent research concerning the self-determination of practice schedules. Almost all studies of practice schedules in the modern era of motor learning research have investigated experimenter-determined schedules, in which the order of practice trials is beyond the learner's control. One would suspect, given the Simon and Bjork (2001) results, that learners would feel more confident with their progress in learning under a blocked schedule and would therefore self-select a schedule of practice that undermines their potential for learning. Surprisingly, such is not the case. New research is emerging (e.g., Keetch and Lee, in press), which suggests that self-determined schedules facilitate learning (relative to yoked controls), regardless of the degree to which the self-selected order is blocked or randomized. This finding might suggest that individual difference variables, in addition to the trial order, combine to influence the effectiveness of practice. We see this new paradigm on practice schedules as a having considerable potential in future motor-learning research.

### 2.34.6.2 Knowledge of Results

The role of knowledge results (KR) in the theories of Adams (1971) and Schmidt (1975) was rather mechanistic: KR served to guide the learner toward making correct movements, and these movements served to strengthen either the correct perceptual trace (in Adams's theory) or the schemas (in Schmidt's theory). This view was termed the guidance role by Salmoni et al. (1984) because KR served as a tool that guided the learner toward the target goal and therefore facilitated learning. However, in their reanalysis of the KR literature, Salmoni et al. discovered that the beneficial role of guidance could only be found in experiments when performance during acquisition trials was considered, i.e., during those trials in which the KR manipulation was ongoing. However, the effects on retention of these same variables were rather different. Salmoni et al. found a number of instances in which a KR variable that guided the learner to strong performance during acquisition was actually detrimental to learning as measured in retention. The conclusion that the guidance function of KR played a detrimental role in learning initiated a new round of research that continues today. Importantly, the guidance role of KR highlighted some cognitive factors that intervene during motor learning, which will be discussed in more detail later. First, we describe two KR variables that illustrate both the positive and negative roles for the guidance function of KR.

#### *2.34.6.2.1 Timing of knowledge results*

One of the most frequently studied variables in this area of motor learning research concerns the timing of the KR delivery following the performance of a task. Because augmented feedback refers to information about performance, it is delivered to the learner either concurrently with ongoing performance or following the completion of a performance. Typically, concurrent delivery of KR occurs when the performance of the task is of sufficiently long duration that perception and utilization of the provided information are possible (say, 0.5 s or longer). For tasks in which the movement duration is less than 0.5 s or so, KR is typically delivered after the completion of the movement. If the KR is not delivered instantaneously upon movement completion, then two variables may intercede; there is a time delay and the opportunity for other activities (e.g., motor, cognitive) to be conducted prior to the delivery of the KR. We highlight some research that documents the effects of the timing of KR.

A study by Schmidt and Wulf (1997) illustrates the guidance effects of concurrent feedback. The movement task was to displace a lever by making flexion and extension arm movements that matched precise spatial and temporal requirements. The overall movement time goal was almost 1 s, providing sufficient time for the learner to use concurrent augmented feedback to perform the task. A video monitor was used to provide one group with concurrent feedback by overlapping a trace of the learner's movement production with a template of the perfect (goal) movement. Discrepancies between the actual and goal movements were explicit from the images presented on the monitor. A second group received an image of the produced movement trace together with the goal trace 3 s after the movement had been completed; the monitor was blank during the movement. Schmidt and Wulf (1997) reported a number of spatial and temporal measures of average performance and performance variability. In general, these measures showed advantages during practice that favored the concurrent augmented feedback group. This general trend was reversed in retention: the removal of KR resulted in drastic declines in performance for the concurrent feedback group, but not so for the delayed KR group.

A similar finding for acquisition and retention has been found when the augmented feedback is not presented concurrently, but rather is presented instantaneously on completion of the movement (Swinnen et al., 1990). These researchers found that a delay of 8 s prior to the delivery of KR improves retention, especially if learners are requested to estimate their feedback during this delay period prior to KR delivery. Thus, simply delaying the KR was sufficient to reduce the negative guidance effects of the instantaneous KR, and the estimation procedure provided an additional boost to the learning effect.

Another method by which the timing of augmented feedback can be manipulated has been termed the trials-delay method (Bilodeau, 1956). By this method, the presentation of KR for any specific trial may be delayed for a time period during which one or more intervening trials of the task are practiced. As illustrated in **Figure 7**, studies of this type (Lavery, 1962; Anderson et al., 2001, 2005) have typically found that the immediate delivery of KR (no trials-delay) resulted in superior acquisition performance compared to a trials-delay condition (e.g., Anderson et al., 2001, 2005, used a two-trials-delay condition). However, no-KR retention tests again support the efficacy for learning of the delayed KR practice conditions; in this case, the trials-delay condition typically produces better retention than the immediate KR conditions.

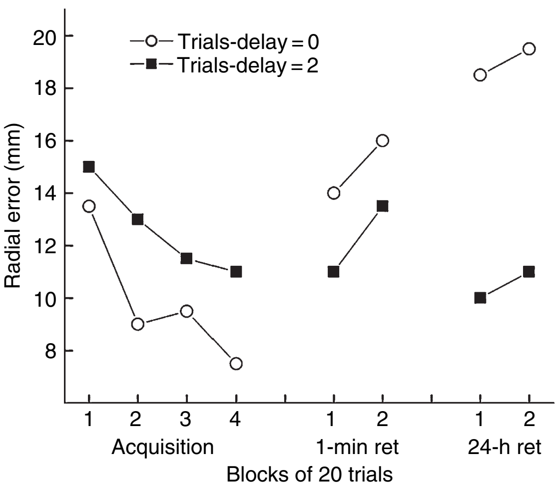

**Figure 7** Immediate delivery of KR produces superior performance in acquisition (error in distance from target) but inferior retention (ret) compared to a KR trials-delay condition. Data from Anderson DI, Magill RA, and Sekiya H (2001) Motor learning as a function of KR schedule and characteristics of task-intrinsic feedback. *J. Mot. Behav.* 33: 59–66.

### 2.34.6.2.2 Frequency of knowledge results

Augmented feedback can also be manipulated by varying the relative frequency of its presentation in relation to the total number of trials practiced. One manipulation is to withhold KR after some trials (reduced relative frequency) and compare the effects in acquisition and retention to a condition that provides KR after every trial (100% relative frequency). The effects of a reduced relative frequency tend to be small, if any, in acquisition. However, retention performance is often enhanced by reduced relative frequency (compared to 100% frequency conditions; e.g., Winstein and Schmidt, 1990).

A variation of the feedback frequency manipulation provides information about every trial, but not directly after every trial. In this manner, the same amount of information is presented but it is done in such a manner that statistically summarizes KR over a series of previous trials. Studies have varied the manner in which summaries are presented: some have used graphs that plot performance for the previous series of trials; other studies have used statistical averages that summarize the average performance tendency for the series of trials. The effects are similar and produce contrasting effects in acquisition and retention, relative to a trial-by-trial KR delivery method. Relative to every-trial KR, summary KR degrades performance in practice but enhances retention (e.g., Schmidt et al., 1989). There appears to be a limit to the benefit of the size of summaries, however, with the optimal summary size dependent on the task demands (Schmidt et al., 1990; Guadagnoli et al., 1996). Yao et al. (1994) provided a convincing demonstration of the effect of both summary size and summary type; their results are illustrated in **Figure 8**. However, retention performance was facilitated by moderately sized (five-trial) summaries, compared to both the every-trial KR and larger (15-trial) summaries. This finding was present regardless of whether the summary information was presented as a graph of the individual trials or as a statistical average of the summarized trials.

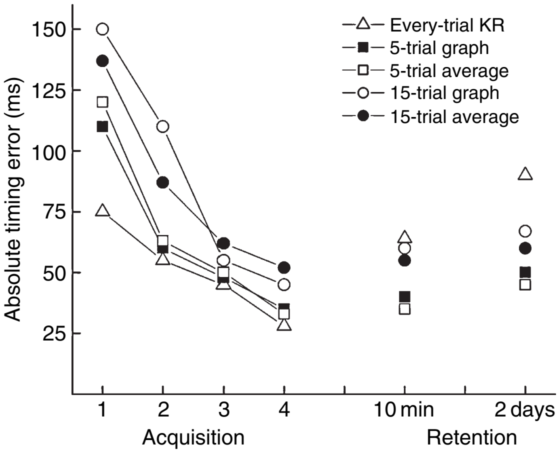

**Figure 8** Moderately-sized (5-trial) summaries facilitated timing error in retention, relative to every-trial KR and larger (15-trial) summary sizes. Data from Yao W, Fischman MG, and Wang YT (1994) Motor skill acquisition and retention as a function of average feedback, summary feedback, and performance variability. *J. Mot. Behav.* 26: 273–282.

The product of learning under these conditions of the temporal delivery of KR suggests that memory is affected in different ways. Conditions of practice during which KR is delivered such that it guides the learner toward producing the correct, or optimal, movement solution, are suboptimal to performance in retention. Providing KR concurrently or instantaneously upon movement completion are both conditions that fulfill the guiding role of KR. In contrast, delaying the delivery of KR is likely to lessen its immediate guidance function and, possibly, allow time for other learning factors to intervene. Such factors include a better understanding of one's movement-produced feedback, which is enhanced under conditions where the learner is encouraged to produce magnitude estimates of feedback during the delay period prior to KR delivery.

#### 2.34.6.2.3 The roles of knowledge results

Until the review of Salmoni et al. (1984), researchers had been content with the view that augmented information serves three roles in the acquisition of motor skills (Schmidt and Lee, 2005): (1) KR can be used as information by the learner to make permanent corrections in the actions being learned, (2) KR serves a motivating function that helps to maintain interest in the task and encourage continued practice, and (3) KR can provide a means to learn associations between motor commands and the sensory consequences of those commands. However, the finding that KR can serve a guidance role that has both positive effects (during practice) and negative learning consequences (i.e., in retention tests) suggested that the KR might be serving roles that had previously gone unnoticed.

Salmoni et al. (1984) and Schmidt (1991) speculated about two processes that might underlie these guidance effects. One idea is that successful motor learning involves the capability to understand and use the intrinsic feedback information that results from movement (such as proprioceptive and visual feedback). When KR is presented instantaneously and/or frequently, that information actively blocks or overshadows the processing of intrinsic feedback. Consequently, learning how to use intrinsic feedback when it is the only available source of information is degraded (e.g., when KR is removed in retention or otherwise is no longer available). An alternative view of these KR guidance effects suggests that the capability of a learner to correct errors is limited because of the natural, inherent variability of the motor system. However, often KR is provided without regard to what capabilities the learner possesses to use the information to make corrections to movement errors. In other words, the KR may encourage the learner to attempt to correct errors smaller than the learner's actual ability to control them; such attempts produce so-called maladaptive short-term corrections that may be beneficial for performance in practice, but are not beneficial for learning as measured on retention tests (Schmidt and Bjork, 1992).

In the previous section, we mentioned that one of the exciting, new directions in research concerns individual differences and the effects of self-determined schedules of practice. A similar line of investigation has also been undertaken with regard to the delivery of augmented feedback, and some intriguing findings are emerging. An early study (Janelle et al., 1997) revealed that retention was facilitated if learners were provided the control over the decision about whether or not to receive augmented feedback after a trial, relative to a yoked group (that controlled for the frequency, but not the decision to deliver feedback) and a group that received five-trial summaries. The benefit to learning for this self-determined group has been replicated in several experiments (e.g., Chiviacowsky and Wulf, 2002, 2005) and represents a curious effect. For example, in postexperiment interviews Chiviacowsky and Wulf (2002) found that individuals preferred to receive KR after trials on which they perceived that their performance had been relatively good. Additionally, Chiviacowsky and

Wulf (2005) found that the decision to receive feedback was more effective when made after the performance of a trial than when decided before a trial.

According to the guidance hypothesis, KR will have a detrimental effect on learning if it blocks or overshadows the learner's attempt to interpret his or her own movement-produced feedback relative to the information provided in the KR. The effects of self-determined KR are consistent with the guidance hypothesis to the extent that providing control of when KR is delivered gives the learner the opportunity to maximize the contrast between perceived KR and actual KR. However, these findings also contradict some basic theoretical arguments regarding how KR works. One consistent finding in the literature suggests that the usefulness of KR is optimized when it informs the learner about errors that had been made, not when it confirms to the learner that a trial had been performed well (Sherwood, 1988). Thus, similar to the research on practice schedules, individual differences in the learner's perception of ongoing performance, as well as their metacognitive strategies for how the delivery of KR is best suited to facilitate learning, are all likely to be important determiners of the effectiveness of augmented feedback.

## 2.34.7 Summary

Motor learning is the process by which the capability for skilled motor control becomes represented in memory. Motor memory is the product of learning. In this chapter, we have reviewed two theories regarding how memory for skill is developed. Both theories explain how the interaction of movement and feedback results in permanent representations that influence motor control. We suggest that future work needs to be done that further develops theories of motor learning that account for how and why cognitive factors influence the qualitative representations in memory.

# 2.35 The Role of Sleep in Memory Consolidation

**J. D. Payne**, Beth Israel Deaconess Medical Center, Harvard Medical School, Harvard University, Boston, MA, USA

**J. M. Ellenbogen**, Beth Israel Deaconess Medical Center, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

**M. P. Walker and R. Stickgold**, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

## 2.35.1 The Role of Sleep in Memory Consolidation

We spend about a third of our lives sleeping, yet in spite of decades of scientific inquiry, the function of sleep remains an enigma. This is not to say that progress has not been made. From antiquity until the 1950s, sleep was generally believed to be a state of inactivity where the brain was turned off and the body rested, but we now know that the sleeping brain can be equally, and sometimes more, active than the brain in its awake state. Even during deep or slow wave sleep, when the brain is relatively quiescent compared to rapid eye movement sleep or wakefulness, it is still roughly 80% activated and thus capable of elaborate information processing (Steriade, 1999; Hobson, 2005).

Numerous hypotheses have been put forward to explain the functions of sleep, including energy conservation, brain detoxification, immune regulation, tissue restoration, and predator avoidance. More recently, the hypothesis that sleep plays a key role in the consolidation of memories has gained considerable attention (Smith, 1985; Maquet, 2001; Smith, 2001; Stickgold et al., 2001). Following two seminal papers in 1994 (Karni et al., 1994; Wilson and McNaughton, 1994), the publication rate on this topic increased fivefold over the next 10 years (Stickgold and Walker, 2005).

Despite this resurgence of attention, the question of how sleep contributes to memory consolidation is actually quite old. In the first century AD, the Roman rhetorician Quintilian, commenting on the benefits of sleep, noted that "what could not be repeated at first is readily put together on the following day; and the very time which is generally thought to cause forgetfulness is found to strengthen the memory."

In this chapter, we review the accumulating evidence supporting a sleep–memory connection, which converges from studies at the molecular, cellular, physiological, and behavioral levels of analysis (Maquet, 2001; Smith, 2001; McNaughton et al., 2003; see also Gais and Born, 2004a; Stickgold, 2005; but see Vertes and Siegel, 2005). We begin with a précis of the field's history before turning to a review of its present status. We attempt to operationally define the terms sleep and memory, and offer our opinions on the field's strengths and shortcomings. In the first half of this chapter, we examine sleep's role in the strengthening of perceptual and procedural skills, and in the second half, we devote our attention to sleep's role in the consolidation of episodic memories. Our primary intention is to alert memory researchers to the growing field of sleep and memory, as well as to spark enthusiasm for a new way of researching memory systems that holds much promise for understanding both sleep and memory.

Although our review covers mainly behavioral and physiological evidence in humans, we point the interested reader to a growing animal literature on this topic. Numerous studies have examined the reactivation of neuronal patterns during post-training sleep, which show that neuronal activation sequences associated with various memory tasks are replayed during subsequent sleep. We touch briefly upon these studies toward the end of the chapter, but we refer the reader to the following articles for a deeper understanding of this fascinating topic (Wilson and McNaughton, 1994; Qin et al., 1997; McNaughton et al., 2003; Sirota et al., 2003; Ribeiro and Nicolelis, 2004). Other studies have begun to illuminate the molecular aspects of sleep-dependent memory consolidation, which we will not discuss here, but which certainly deserve attention as well (Smith et al., 1991; Nakanishi et al., 1997; Ribeiro et al., 1999; Graves et al., 2001; Benington and Frank, 2003).

## 2.35.2 Definitions of Sleep and Memory

Before turning to a discussion of the relationship between sleep and memory, we will first attempt to define both terms, as confusion has often arisen due to oversimplifications of one or both. We thus begin the chapter with a brief overview of the neurobiological characteristics associated with the various stages of sleep, and the different types of memory.

## 2.35.3 Stages of Sleep

Sleep progresses through a series of stages, which can be divided broadly into rapid eye movement or REM sleep (also called paradoxical sleep, due to the many wake-like features seen in this sleep stage), and non-rapid eye movement or NREM sleep. NREM sleep can be further subdivided into four NREM stages (1–4) corresponding, in that order, to increasing depth of sleep (Rechtschaffen and Kales, 1968). Slow wave sleep (stages 3 and 4) is the deepest of the NREM phases, and is the phase from which people have the most difficulty awakening.

In healthy adults, NREM and REM sleep alternate in approximately 90-min cycles throughout the night (so-called ultradian cycles). However, the relative contributions of NREM and REM sleep to these cycles varies across the night, with more of NREM stages 3 and 4 (slow wave sleep, SWS) early in the night, and more REM sleep late in the night. Thus, more than 80% of a night's SWS is concentrated in the first half of the night, while the second half of the night contains roughly twice as much REM sleep as the first half. This distribution of sleep stages has implications for some of the research paradigms described later in this chapter.

As NREM sleep progresses from stage 1 through stages 3 and 4 (SWS), electroencephalographic (EEG) activity steadily slows. In stage 1 sleep (drowsiness) there is an attenuation of the normally occurring alpha rhythm (8–13 Hz). In its place, a mixture of frequencies with a slower theta frequency (4–7 Hz) begin to emerge. Stage 2 NREM sleep is characterized by a continued reduction in EEG frequencies combined with two signature waveforms: large electrical sharp waves called K complexes and short synchronized bursts of 11- to 16-Hz oscillations called sleep spindles. Slow wave sleep is characterized by high-voltage, low-frequency (<4 Hz) EEG oscillations, which are an expression of underlying synchrony between the thalamus and cerebral cortex (Amzica and Steriade, 1995).

REM sleep, on the other hand, is characterized by low-amplitude, mixed-frequency EEG oscillations that are similar to the EEG patterns seen in wake. Periodic bursts of rapid eye movement also occur, along with a nearly complete loss of muscle tone.

As the brain passes through these sleep stages, it undergoes marked neurochemical alterations. In NREM sleep, acetylcholine neurons in the brainstem and forebrain become strikingly less active (Hobson et al., 1975) and serotonergic and noradrenergic neurons also reduce their firing rates relative to waking levels. In REM sleep, both of these aminergic systems are strongly inhibited, while acetylcholine neurons become intensely active, in some cases more active than in wake (Marrosu et al., 1995). The brain in REM sleep is thus largely devoid of aminergic modulation and dominated by acetylcholine. Thus, sleep consists of myriad physiological states and many neurochemical and neurohormonal mechanisms. When considering the role of sleep in memory consolidation, one must take this dynamic model of sleep into account (Payne and Nadel, 2004; Walker and Stickgold, 2004).

## 2.35.4 Types of Memory

Like sleep, memory can be subdivided into different types. In contrast to earlier perspectives, in which memory was viewed as a single system subserved by a restricted part of the brain, most modern views posit several types of memory, each obeying different rules of operation, and each drawing on distinct neural systems that interact to produce the subjective sense of remembering. This insight is critical if we are to understand the role of sleep in human memory consolidation because it raises the possibility of many complex interactions among the dynamic processes of sleep and memory, where the neurochemistry associated with distinct sleep/brain states differentially influences the various types of memory.

Various taxonomies are used to classify the different memory systems (Schacter and Tulving, 1994), most of which agree on a distinction between two broad classes of memory. First, there are memories of the events in our lives and the knowledge of the world that we obtain from these events. Typically, this class of memories can be explicitly retrieved, and for this reason it is often referred to as explicit or declarative (i.e., that which can be declared). Second, there are memories for the various skills, procedures, and habits we acquire through experience – so-called 'how-to' memories. These memories are not so easily made explicit and are usually only evident through performance improvements in various behaviors. Thus, this class of memories is referred to as procedural or implicit. The neural mechanisms that support these memory systems appear to be partially dissociable; however, it is important to remember that they interact as well.

Explicit memory can be further subdivided into episodic and semantic memories (Tulving, 1972). Episodic memory concerns those aspects of explicit remembering that incorporate the specific context of an experienced event, including the time and place of its occurrence. Semantic memory, on the other hand, is concerned with the knowledge one acquires during events, but is itself separated from the specific event in question. Thus, our knowledge about the meaning of words and facts about the world, though acquired in the context of some specific experience, appears to be stored in a form that is context-independent (e.g., not bound to the originating context).

Beyond these, there is also evidence for an emotional memory system that mediates the encoding and consolidation of emotionally charged events (McGaugh et al., 1993; Cahill and McGaugh, 1996; McGaugh et al., 1996; Cahill, 2000; Packard and Cahill, 2001). This system is particularly concerned with learning about fearful and unpleasant stimuli, although growing evidence suggests it plays a role in memory for pleasant information as well (Hamann et al., 1999; Hamann et al., 2002; Hamann, 2003; Kensinger, 2004).

The explicit memory system is governed by the hippocampus and surrounding medial temporal areas, while procedural and implicit memory are thought to be independent of the hippocampal complex, relying instead on various subcortical and neocortical structures (Squire, 1992; Schacter and Tulving, 1994). The emotional memory system is critically modulated by the amygdala, a limbic structure located deep in the subcortical brain and richly connected to the hippocampus. It is important to note that because each of these memory systems is subserved by different brain areas, information dependent on each is open to differential processing during sleep. Thus, when attempting to answer the seemingly straightforward question – how does sleep influence memory? – we find that it quickly branches into numerous questions, depending on what kind of sleep and what kind of memory we are talking about.

Although memory consolidation is a complex, multistep process, we define it here as a slow process that converts a still-labile memory trace into a more stable or enhanced form (e.g., Dudai, 2004). As such, the benefits of sleep are sometimes seen as a reduction in the normal decay of a memory (assessed via performance on a memory task), while other times they are seen as actual enhancements in performance.

## 2.35.5 Procedural and Implicit Memory

Sleep appears to benefit both procedural/implicit and explicit memory. Since most of the recent work has focused on sleep and procedural memory, we begin our review here. A wide range of perceptual, motor, and cognitive abilities are gradually acquired through continuous interactions with the environment, and in many cases this occurs in the absence of conscious awareness. Converging data suggest that these abilities are acquired slowly and are not attained solely during the learning episode. While some learning certainly develops quickly, performance on various tasks improves further, and without additional practice, simply through the passage of time (so-called off-line improvement), suggesting that memory traces continue to be processed over long periods of time. Importantly for our purposes, these longer periods often contain sleep, and the consolidation occurring during them may be dependent on this sleep.

### 2.35.5.1 Visual Discrimination Learning

Early work investigating the effect of sleep on implicit learning used a visual texture discrimination task (VDT) that was originally developed by Karni and Sagi (1991). The task requires participants to determine the orientation (vertical or horizontal) of an array of diagonal bars that is embedded in one visual quadrant against a background of exclusively horizontal bars (**Figure 1**). At the center of the screen is the fixation target, which is either the letter T or L. This target screen is succeeded first by a blank screen for a variable interstimulus interval (ISI), and then by a mask (a screen covered with randomly oriented V letters, with a superimposed V and L in the center). Subjects must determine the orientation of the array, and the performance is estimated by the ISI corresponding to 80% correct responses (Karni and Sagi, 1993; Karni et al., 1994).

Amnesic patients with damage to the hippocampal complex, who cannot acquire knowledge explicitly, show normal performance improvements on the VDT. This was shown using a group of five densely amnesic patients. All five had extensive medial temporal lobe damage, including damage to the hippocampal formation. These patients were trained on the task on day 1 and retested on days 2 and 5. In spite of having no conscious recollection of having taken the test before, they showed substantially improved performance (Stickgold, 2003).

In neurologically normal subjects, improvement on the VDT develops slowly after training (Karni and Sagi, 1993; Stickgold et al., 2000a), with no improvement when retesting occurs on the same day as training (**Figure 2(a)**, open circles). Instead, improvement is only observed after a night of sleep (**Figure 2(a)**, filled circles).

This was true even for a group of subjects that were retested only 9 h after training. Importantly, there was not even a trend to greater improvement when the training–retest interval was increased from 9 to 22.5 h, suggesting that additional wake time after the night of sleep provided no additional benefit. While further wake time provided no benefit, additional nights of sleep did produce incremental improvement. When subjects were retested 2–7 days after training, 50% greater improvement was observed than after a single night of sleep (**Figure 2(b)**, green bars). Critically, another group of subjects was sleep-deprived on the first night after training. These subjects were allowed two full nights of recovery sleep before being retested 3 days later. They failed to show any residual learning, suggesting that performance enhancements are dependent on a normal first night of sleep (**Figure 2(b)**, red bar). Time alone is clearly not enough to produce

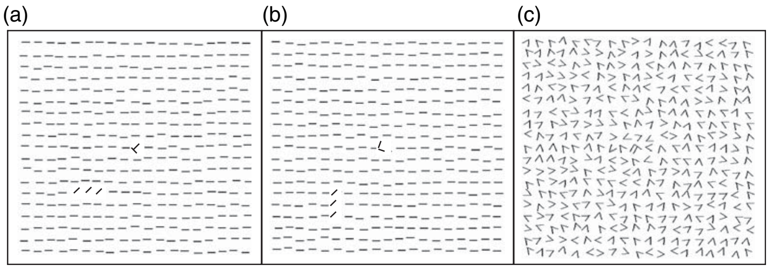

**Figure 1** Sample screens from the visual texture discrimination task (VDT). See text for explanation.

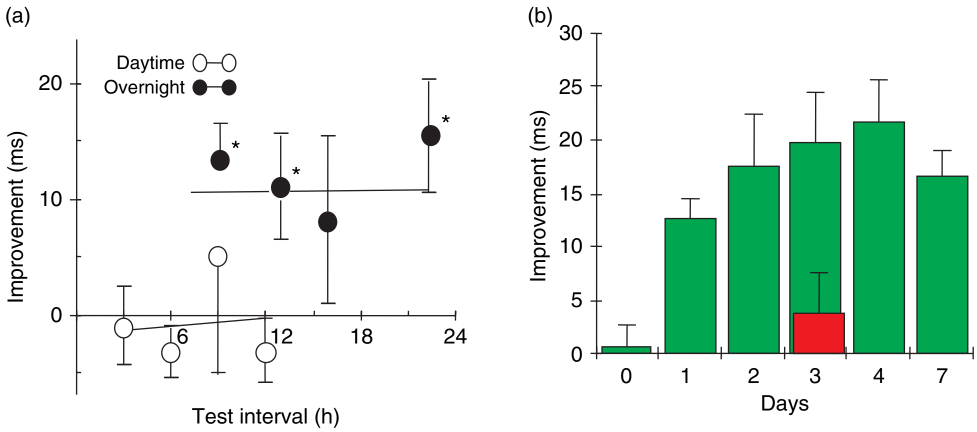

**Figure 2** Sleep-dependent improvement on the VDT. All subjects were trained and then retested only a single time. Each point in (a) and each bar in (b) represents a separate group of subjects. Error bars in (a) and (b) are S.E.M.s. From Stickgold R, James L, and Hobson A (2000a) Visual discrimination learning requires post-training sleep. *Nat. Neurosci.* 2(12): 1237–1238; Stickgold R, Whidbee D, et al. (2000b) Visual discrimination task improvement: A multi-step process occurring during sleep. *J. Cogn. Neurosci.* 12: 246–254.

long-term benefits from VDT training. It appears that sleep is also required (Stickgold et al., 2000a).

Initially, improvement on this task appeared to depend solely on REM sleep, because subjects who underwent selective deprivation of REM sleep showed no improvement on the task (Karni et al., 1994). Later studies, however, showed that optimal performance on this task requires both SWS and REM sleep (Stickgold et al., 2000b).

When subjects were trained and their subsequent sleep monitored in the sleep laboratory, the amount of improvement was proportional to the amount of SWS during the first quarter of the night (**Figure 3(a)**), as well as to the amount of REM sleep in the last quarter (**Figure 3(b)**). Indeed, the product of these two sleep parameters explained more than 80% of the intersubject variance (**Figure 3(d)**). No significant correlations were found for sleep stages during other parts of the night (**Figure 3(c)**) or for the amount of Stage 2 sleep at any time during the night.

Gais et al. (2000) came to a similar conclusion by examining improvement after 3 h of sleep either early or late in the night. They found that 3 h of early night sleep, which was rich in SWS, produced an 8-ms improvement; but after a full night of sleep, which added REM-rich sleep late in the night, a 26-ms improvement was observed, three times that seen with early sleep alone. Interestingly, however, 3 h of REM-rich, late-night sleep actually produced deterioration in performance (Gais et al., 2000).

Daytime naps also lead to performance benefits on the VDT. To lay the groundwork for the nap studies, Mednick et al. (2002) showed that VDT performance suffers from repeated, same-day testing. When subjects were trained on the task and then tested at numerous time points throughout the day, their performance deteriorated (i.e., their ISI threshold was higher). **Figure 4** depicts tests given at 9.00 a.m., 12.00 p.m., 4.00 p.m., and 7.00 p.m., with performance worsening significantly on each successive test. However, if subjects are allowed to take an afternoon nap after the second test, their performance improves. Interestingly, 30-min naps prevented the normal deterioration seen during sessions 3 and 4 (Mednick et al., 2002), and longer naps ranging from 60 to 90 min, and containing both SWS and REM sleep, actually enhance performance (Mednick et al., 2003). Taken together, these studies suggest that both SWS and REM sleep play roles in the sleep-dependent memory consolidation of this task.

At this point, sleep's role in visual discrimination learning (as measured by VDT performance) is clear. But the VDT represents a very specific type of sensory memory that may or may not share its sleep dependency with other procedural tasks. This raises the question of whether the sleep effects observed with the VDT generalize to other forms of procedural memory. Studies of sleep-dependent auditory and motor skill learning strongly suggest that they do.

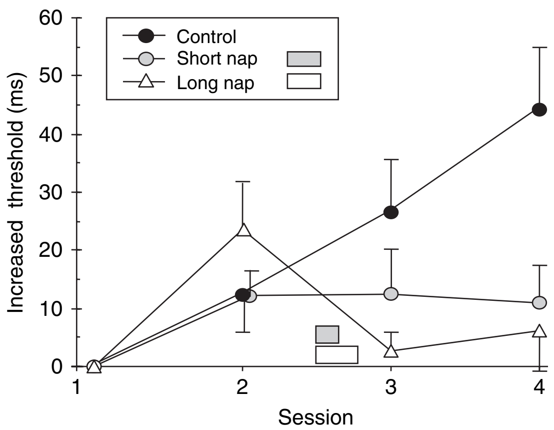

**Figure 4** Deterioration in VDT performance with repeated same-day testing and recovery following napping. Note that the ordinate reflects changes in ISI threshold and, as such, higher values indicate worse performance. From Mednick SC, Nakayama K, Cantero JL, et al. (2002) The restorative effect of naps on perceptual deterioration. *Nat. Neurosci.* 5: 677–681.

### 2.35.5.2 Auditory Learning

Gaab et al. (2004) have shown that delayed performance improvements in memory for pitch develop only across periods of sleep and not across similar periods spent awake. Atienza and colleagues (Atienza et al., 2002, 2004) have also presented evidence of both time- and sleep-dependent auditory memory consolidation, including sleep-dependent changes in brain-evoked response potentials (ERPs). Although post-training sleep deprivation did not prevent continued behavioral improvements, ERP changes associated with the automatic shift of attention to relevant stimuli, which normally develop in the 24–72 h after training, failed to develop following a posttraining night of sleep deprivation. These findings highlight the danger of presuming that a lack of behavioral improvement is equivalent to an absence of beneficial plastic changes in the brain, and they demonstrate the importance of using combined behavioral and physiological analyses (Gaab et al., 2004; Walker and Stickgold, 2006).

Finally, Fenn et al. (2003) have demonstrated that sleep benefits learning on a synthetic speech-recognition task. Training on a small set of words improved performance on novel words that used the same phoneme but a different acoustic pattern.

Importantly, sleep benefited this ability to generalize phonological categories across different acoustic patterns. Time spent awake after initial training resulted in a degradation of performance on this task, but a subsequent night of sleep restored it. This suggests a process of sleep-dependent consolidation capable of reestablishing previously learned complex auditory skill memory, as well as a form of sleep-dependent generalization of learning, which is a hallmark of flexible learning in humans (Fenn et al., 2003). These studies suggest that, as with visual discrimination learning, sleep provides an important benefit to auditory skill learning. In the next section, we show that motor memory benefits from sleep as well.

### 2.35.5.3 Motor Memory

Numerous studies have demonstrated a relationship between sleep and various types of motor memory (Smith and MacNeill, 1994; Fischer et al., 2002; Walker et al., 2002; Maquet et al., 2003). As an example, Walker et al. (2002) have demonstrated sleep-dependent improvements on a finger-tapping task. The task requires subjects to type the numeric sequence 4-1-3-2-4 as quickly and accurately as possible. Training consisted of twelve 30-s trials, separated by 30-s rest periods. All subjects show considerable improvement during the 12 trials of the training session (a fast learning component), but 12 h later, subjects performed very differently depending on whether the 12-h interval was filled with time spent sleeping or time spent awake. When trained in the morning and retested 12 h later, only an additional nonsignificant 4% improvement was seen in performance, but when tested again the next morning, a large and robust (14%) improvement was seen (**Figure 5(a)**). The failure to improve during the daytime could not be due to interference from related motor activity because subjects who were required to wear mittens and refrain from fine motor activities during this time showed a similar pattern of wake/sleep improvement (**Figure 5(b)**).

In contrast, when subjects were trained in the evening, improvement was observed the following morning (after sleep), but not across an additional 12 h of wake (**Figure 5(c)**). Thus, improved performance resulted specifically from a night of sleep, as opposed to the simple passage of time. Curiously, unlike the findings for the VDT, overnight improvement on this task correlated with the amount of stage 2 NREM during the night, especially during the last quarter of the night. These findings are in agreement with those of Smith and colleagues (Smith and MacNeill, 1994; Tweed et al., 1999; Fogel et al., 2001), who have also shown that stage 2 sleep, and possibly the sleep spindles which reach peak density

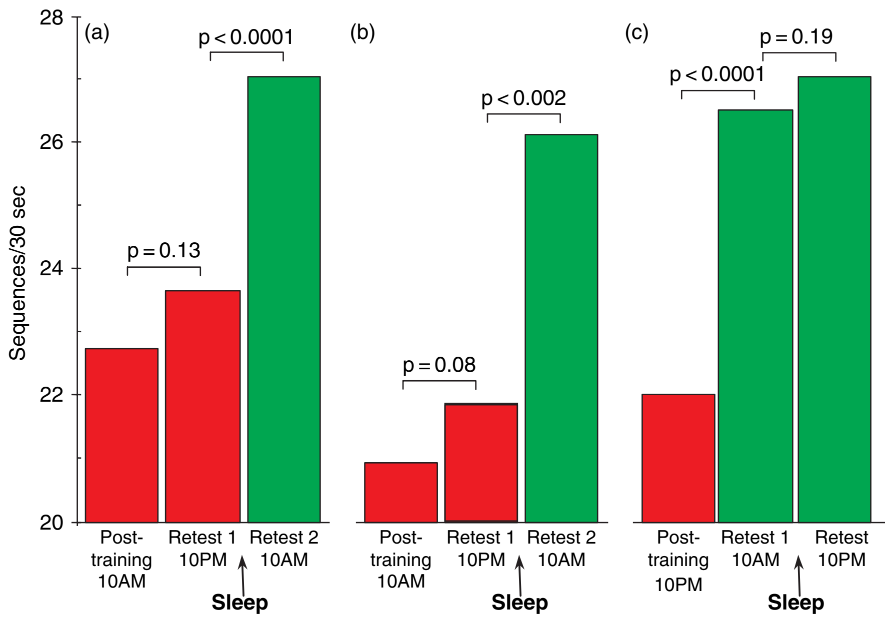

**Figure 5** Sleep-dependent motor learning. Improvement in speed was seen in all three groups over a night of sleep, but not over 12 h of daytime wake. From Walker MP, Brakefield T, Hobson JA, and Stickgold R (2002) Practice with sleep makes perfect: Sleep dependent motor skill learning. *Neuron* 35(1): 205–211.

during late night stage 2 sleep, are critical for simple motor memory consolidation. This seems plausible, as sleep spindles have been proposed to trigger intracellular mechanisms that are required for synaptic plasticity (Sejnowski and Destexhe, 2000).

It is important to note that this sleep-based improvement was not due to a speed/accuracy trade-off. When the number of errors per 30-s trial was compared between evening and morning, the number of errors actually decreased, although not significantly (Walker et al., 2002). However, when error rates (i.e., errors per sequence) were calculated, a highly significant 43% decrease inthe error rate was seen overnight (**Figure 6**), while a 20% increase in the error rate was found across 12 h spent awake (Walker et al. 2003).

At least for a simple motor task then, sleep appears to benefit both speed and accuracy. More recent studies have shown that these sleep-dependent benefits appear to be specific to both the motor sequence learned and the hand used to perform the task (Fischer et al., 2002; Korman et al., 2003).

This motor sequence task has been examined to determine where precisely in the motor program the sleep-dependent improvement occurs (Kuriyama et al., 2004). In the sequence mentioned above (4-1-3-2-4), there are four unique key-press transitions; 4 to 1, 1 to 3, 3 to 2, and 2 to 4. When the speed between transitions was analyzed for individual subjects prior to sleep, sticking points emerged. While some transitions were easy (i.e., fast), others were problematic (i.e., slow), as if the sequence was being parsed or chunked into smaller bits during presleep learning (Walker and Stickgold, 2006). After a night of sleep, these problematic points were preferentially improved, whereas transitions that had already been mastered prior to sleep did not change. Subjects who were trained and retested after a daytime wake interval showed no such improvements.

These findings suggest that the sleep-dependent consolidation process involves the unification of smaller motor memory units into a single motor memory representation, thereby improving problem points in the sequence. This overnight process would therefore offer a greater degree of performance automation, effectively optimizing speed across the motor program, and would explain the sleep-dependent improvements in speed and accuracy previously reported (Walker and Stickgold, 2006). But importantly, it suggests that the role of sleep is subtle and complex and does more than simply strengthen memories; sleep may encourage the restructuring and reorganization of memories – an important and often overlooked aspect of memory consolidation. We will return to this idea later in the chapter.

Fisher et al. (2002), using a different sequential finger-tapping task, which involves finger-to-thumb movements instead of keyboard typing, have shown

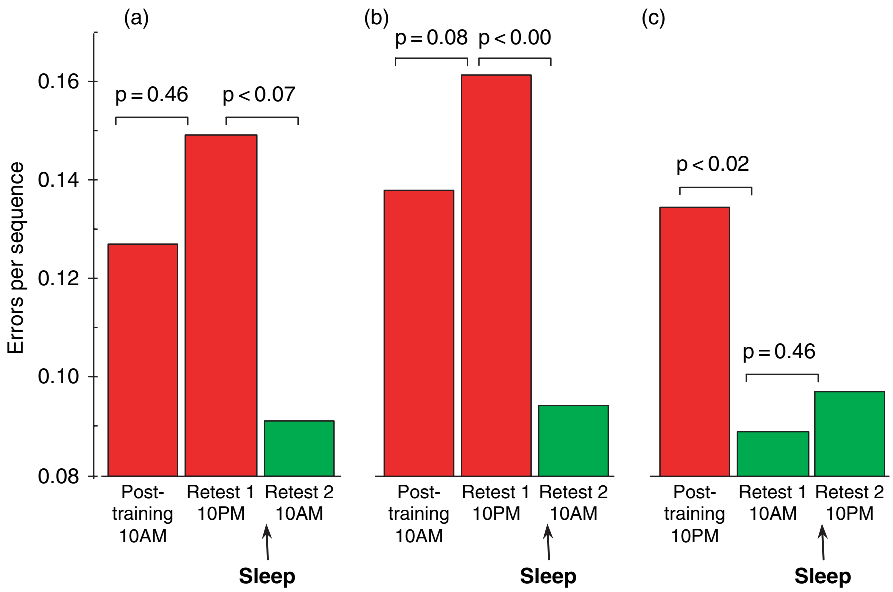

**Figure 6** Sleep-dependent motor learning. Improvement in accuracy was seen in all three groups over a night of sleep, but not over 12 h of daytime wake. From Walker MP, Brakefield T, Hobson JA, and Stickgold R (2002) Practice with sleep makes perfect: Sleep dependent motor skill learning. *Neuron* 35(1): 205–211.

that sleep following training is critical for delayed performance improvements. However, they found this improvement to be most strongly correlated with REM sleep rather than stage 2 NREM sleep (see 'Stages of sleep' above).

This discrepancy in sleep stage correlations mirrors similar discrepancies in the declarative memory section below, and remains to be resolved. Nonetheless, it is possible that the more novel finger-to-thumb task requires REM sleep, whereas the keyboard typing task, so similar to the well-learned typing most of us do regularly, is consolidated during stage 2 NREM sleep. A similarly subtle distinction has been reported by Robertson et al. (2004), who found that sleep-dependent enhancement of performance on a perceptual-motor sequence task again correlated with NREM, but only when subjects were explicitly aware of the presence of a repeating sequence, and not when knowledge of the sequence was gained only implicitly (Robertson et al., 2004).

Moving to another type of motor memory – motor adaptation – Maquet et al. (2003) showed that sleep benefits performance on a pursuit task. Participants were trained on a task in which the target trajectory was only predictable on the horizontal axis. This meant that optimal performance could only be achieved by developing an implicit model of the motion characteristics of the learned trajectory. Half of the subjects were sleep deprived on the first post-training night, while the other half were allowed to sleep normally. Three days later, after 2 full days of recovery sleep, performance was superior in the sleep group compared to the sleep-deprived group, and fMRI revealed that the superior temporal sulcus (STS) was differentially more active for the learned trajectory in subjects who slept than in sleep-deprived subjects. Moreover, increased functional connectivity was observed between the STS and the cerebellum, and between the supplementary eye field and the frontal eye field, suggestive of sleep-related plastic changes during motor skill learning in areas involved in smooth pursuit and eye movements.

Similarly, Smith and MacNeill (1994) demonstrated that selective stage 2 NREM sleep deprivation impairs memory for a pursuit rotor task and Huber et al. (2004) demonstrated improved performance on a motor reaching-adaptation task across a night of sleep, but not across an equivalent period of time spent awake. Here, daytime motor skill practice was accompanied by a subsequent increase in NREM slow-wave EEG activity over parietal cortex. This increase was proportional to the amount of delayed learning that developed overnight. Subjects who showed the greatest increase in slow-wave activity in the parietal cortex during NREM sleep showed the largest benefit in motor skill performance the following day (Huber et al., 2004).

Taken together, these findings strongly suggest that sleep is fundamentally important for the development of motor skill memory. Initial daytime learning benefits are supplemented by a night of sleep, which triggers additional learning without the need for further training. Although the role of the various sleep stages in skill memory remains unclear, overnight memory improvements tend to exhibit a strong relationship to NREM sleep, and, in some cases, to specific NREM sleep stages at specific times of the night (Walker and Stickgold, 2006).

Admittedly, visual discrimination, finger tapping, and motor adaptation are all relatively basic, low-level procedural tasks that may become automated fairly quickly. What about more complex implicit and procedural tasks? Animal work clearly demonstrates that complex tasks (e.g., instrumental conditioning, avoidance or maze learning) benefit from sleep, with rats showing increases in REM sleep that continue until the tasks are mastered (Smith et al., 1980; Smith and Wong, 1991; Hennevin et al., 1995). For instance, Smith and Wong (1991) trained rats on a complex operant bar press task, on which only some rats demonstrated increases in REM sleep after training. This split successfully predicted which rats would improve on the task and which rats would fail. Furthermore, after training rats on an avoidance task, Datta (2000) observed an increase in PGO waves (waves of neural activity that are generated in the pons and activate the forebrain during REM sleep) during the first four post-training REM sleep episodes. Changes in REM density observed during the first three of these episodes were proportional to improvement in task performance. These data suggest that the activation of pontine cells that generate PGO waves during REM sleep lead in turn to the activation of forebrain and cortical structures involved in memory consolidation and perhaps to the initiation of these consolidation processes (Datta, 2000).

Recently, Datta and colleagues examined whether the activation of PGO waves could reverse the learning impairment seen after REM sleep deprivation. Rats were trained on a two-way avoidance-learning task and either slept normally or underwent REM sleep deprivation. In addition, they either received a saline injection (placebo) or a carbachol injection in the P-wave generator. The rats that received both saline and REM sleep deprivation showed learning deficits when compared with the saline-injected rats that slept. But a carbachol-induced activation of PGO waves prevented this learning impairment in the sleep-deprived rats, suggesting that the PGO waves mediated the normal sleep-based memory consolidation (Datta et al., 2004).

Depriving rats of REM sleep after training also leads to performance deficits in complex skills, particularly if the deprivation occurs during so-called critical periods or paradoxical sleep windows (Smith et al., 1995; Smith and Rose, 1996). Two such critical periods emerged in rats attempting to learn a shuttle avoidance task when 20 trials per day were given over a 5-day period. The first occurred 9–12 h after training and the second occurred 17–20 h after training. If the rats were deprived of REM sleep during these windows, their memory for the task was significantly impaired. However, with more intensive training, the window appears earlier. When rats were given 100 training trials in a single session, the critical period appeared at 1–4 h after the end of the shuttle avoidance training (Smith and Butler, 1982).

Critical periods thus appear to vary depending on the task and the intensity of training, and hint at the complexity of sleep–memory relationships that we discuss later. Nonetheless, critical periods are thought to mirror the time after acquisition when REM sleep would typically increase over normal levels. These REM windows may not be prevalent in humans, however, who appear to be sensitive to deprivation during any REM period when trying to learn new complex skills (Smith, 1995).

REM sleep has been implicated in complex procedural learning in humans as well. In a PET (positron emission tomography) study of visuomotor skill memory using the serial reaction time task (SRTT) (Maquet et al., 2000), six spatially permanent position markers were shown on a computer screen and subjects watched for stimuli to appear below these markers. When a stimulus appeared in a particular position, subjects reacted as quickly as possible by pressing a corresponding key on the keyboard. Because the stimuli were generated in an order defined by a probabilistic finite-state grammar, improvement on the task (compared to randomly generated sequences) reflects implicitly acquired knowledge of this grammar (Maquet et al., 2000).

Neuroimaging was performed on three groups of subjects. One group was scanned while they were awake, both at rest and during performance of the task, providing information about which brain regions are typically activated by the task. A second group of subjects was trained on the task during the afternoon and then scanned the night after training, both while awake and during various sleep stages. Thus, group 2 was included to determine if similar brain regions were reactivated during sleep. A post-sleep session was also conducted to verify that learning had indeed occurred. Finally, a third group, never trained on the task, was scanned while sleeping to ensure that the pattern of activation present in natural sleep was different from the pattern of activation present after training.

Results showed that in REM sleep, as compared to resting wakefulness, several brain areas used during task performance were more active in trained than in nontrained subjects. These included occipital, parietal, anterior cingulate, motor and premotor cortices, and the cerebellum – all of which are consistent with the component processes involved in the visual and motor functioning involved in this task. Behavioral data confirmed that trained subjects improved significantly more across the night.

More recently, Peigneux et al. (2003), using the same task, showed that the level of acquisition of probabilistic rules attained prior to sleep was correlated with the increase in activation of task-related cortical areas during posttraining REM sleep. This suggests that cerebral reactivation is modulated by the strength of the memory traces developed during the learning episode, and as such, these data provide the first experimental evidence linking behavioral performance to reactivation during REM sleep (Peigneux et al., 2003). As with previously described animal studies (Datta, 2000), these findings suggest that it is not simply experiencing the task that modifies sleep physiology, but the process of memory consolidation associated with successful learning of the task.

These results support the hypothesis that implicit/procedural memory traces in humans can be reactivated during REM sleep, and that this reactivation is linked to improved consolidation. Indeed, looking a bit more closely at the literature, human REM sleep has also been linked to memory for complex logic games, foreign language acquisition, and to intensive studying (Smith, 2001). It is interesting that these more complex conceptual–procedural tasks often show REM sleep relationships, while more basic procedural tasks benefit mainly from NREM sleep. In order to understand these differences in sleep stage correlations, it is helpful to draw on a proposal by Greenberg and Pearlman (1974), who suggested that habitual reactions may be REM sleep-independent, while activities involving the assimilation of unusual or unrelated information require REM sleep for optimal consolidation. Such a distinction would support Pearlman's suggestion that simpler tasks are learned without a REM sleep dependency, while the learning of more complex tasks is dependent on posttraining REM sleep (Pearlman, 1979; Greenberg and Pearlman, 1974).

The above findings provide encouraging evidence that sleep-based processes can aid in procedural memory consolidation, not only for basic forms of sensory and motor memory in humans, but for complex procedural and conceptual knowledge as well. Moreover, it argues that the consolidation of familiar skills, or those that are similar to other well-learned skills, may be reliant on NREM sleep stages (particularly stage 2 NREM sleep), whereas REM sleep may be required for the integration of new concepts or skills with pre-existing information that is already stored in memory. This is an important question that warrants future investigation.

Although much remains to be understood about the precise relationship of specific sleep stages to different procedural memory processes, we can say with confidence that sleep generally aids in the consolidation of implicit and procedural forms of memory. Evidence in support of this relationship is now so overwhelming that strong positions to the contrary will, at minimum, have to be revised (Vertes and Eastman, 2000; Siegel, 2001).

## 2.35.6 Episodic Memory

We turn next to the relationship between sleep and the consolidation of episodic memories. Interest in this relationship can be traced back to a landmark study by Jenkins and Dallenbach (1924), which showed that a period of sleep led to better retention of nonsense syllables than an equivalent period of wakefulness. They interpreted this work to mean that sleep, being an inactive state, transiently protected memory from interference, whereas reduction of recall during wakefulness was due to interference.

> "The results of our study as a whole indicate that forgetting is not so much a matter of the decay of old impressions and associations as it is a matter of interference, inhibition, or obliterations of the old by the new" (Jenkins and Dallenbach, 1924: p. 612).

This interpretation struck a serious blow to the then dominant trace decay theory of forgetting, which posited that the simple passage of time was responsible for forgetting.

Nonetheless, the fact that memories were protected during sleep led to increased interest in the topic (particularly among interference theorists), and Jenkins and Dallenbach's (1924) finding was quickly replicated in better-controlled studies (e.g. Lovatt and Warr, 1968; Benson and Feinberg, 1977). Researchers began to wonder if sleep was actively promoting memory formation, rather than simply reducing interference. Moreover, they began to hypothesize that some types of sleep played a bigger role in episodic memory consolidation than others (The relationship between sleep and the consolidation of semantic memory has received scant attention to date, although see Stickgold et al. (1999) and Brualla et al. (1998) for evidence of semantic memory processing during sleep.).

After the discovery of REM sleep by Aserinsky and Kleitman (1953), the prevailing hypothesis – inspired by psychoanalytic theory – was that memory content would show up in REM sleep, because this was the only stage of sleep in which dreams were thought to occur. (It is now clear that dreams and other types of mental content can occur in all sleep stages, including SWS (Foulkes, 1966; see also Payne and Nadel, 2004)). It made a great deal of intuitive sense that REM sleep should be the stage involved in the reprocessing and consolidation of episodic memories, because, as noted above, the brain during REM sleep is intensely active and looks like it is engaging in some sort of cognitive processing.

This hypothesis was initially supported by several REM sleep-deprivation studies, which showed that such deprivation interfered with memory for prose passages (Empson and Clarke, 1970) and increased the time interval over which memories remained fragile and susceptible to electroconvulsive shock (Fishbein et al., 1971). However, as summarized in Smith (2001), REM deprivation studies in humans provided mixed results on the whole (Chernik, 1972) (see Johnson et al., 1974; Lewin and Glaubman, 1975), which may not be surprising given that sleep deprivation suffers from many confounds, including disrupted natural sleep, decreased levels of arousal and motivation, and increased levels of stress (Maquet, 2001). The stress hormone cortisol, for example, often impairs memory at high levels but can facilitate some aspects of memory at low to moderate levels (Payne and Nadel, 2004; Payne et al., 2004).

Seeking to avoid the confounds inherent in sleep deprivation studies, Ekstrand and colleagues developed a procedure that attempted to isolate SWS, which is prevalent early in the night, from REM sleep, which is maximal late in the night (see 'Stages of sleep' section above). These researchers were thus the first to systematically investigate the impact of different sleep stages on memory performance while controlling for the unspecific effects of REM sleep deprivation. Their findings implicated NREM, particularly stage 4 SWS, as the most beneficial sleep stage for episodic memory consolidation. Yaroush et al. (1971) required subjects to study a paired-associates list just before bedtime. Half of the subjects were awakened after 4 h of early sleep (dense in SWS) and tested for recall. The other half were allowed to sleep for 4 h prior to awakening; they then studied the list and returned to sleep for another 4 h late in the night (REM-rich sleep) before being awakened to recall the word pairs. A third group of subjects were trained during the day and returned 4 h later for the recall test. The early night group remembered more of the words than either the late night or wake groups in several tests of memory (paced and unpaced tests, matching, and relearning tests), suggesting that early sleep, rich in SWS, benefited episodic memory (Yaroush et al., 1971).

In a follow up-study, Barrett and Ekstrand (1972) replicated this effect while attempting to control for circadian differences. Here, all subjects were required to learn and recall at the same time of day; the retention interval was always between 3.00 a.m. to 7.00 a.m. One group remained awake until training at 3.00 a.m., slept for 4 h, and then were awakened at 7.00 a.m. for testing. Another group arrived in the lab at 10.00 p.m., slept for 4 h prior to training, awakened at 2.50 a.m. to train, returned to sleep for another 4 h and then awakened for testing at 6.50 a.m.. As in the Yaroush et al. (1971) study, recall of word pairs was better in the first-half sleep condition than in either the second-half sleep or wake conditions, thus replicating the early sleep effect while controlling for time of day (Barrett and Ekstrand, 1972).

Fowler et al. (1973) replicated the early sleep effect, this time in the sleep laboratory, where they showed that SWS was indeed most prevalent early in the night (first-half of sleep), while REM was maximal late in the night (second-half of sleep) in spite of the experimental awakenings. The authors pointed out that their findings were not easy to reconcile with an interference theory of forgetting. Subjects in the first and second half of night conditions slept for equivalent amounts of time during the retention interval, so simple protection against interference should have been equal in both groups. Unless one wanted to argue that dreaming is as much an interfering factor as a waking mental activity (and this remains to be determined), it seemed that early-night SWS, and perhaps particularly stage 4 sleep, was most important for episodic memory consolidation (Fowler et al., 1973).

More than 20 years later, Born and colleagues revived this procedure (Plihal and Born, 1997; Plihal and Born 1999a,b). In the first of their studies (Plihal and Born, 1997), both episodic (recall of semantically related paired associates) and procedural (performance on a mirror tracing task) memory were assessed within the same subjects. Participants were trained to criterion on both tasks and then retested after 3-h retention intervals, containing either early or late nocturnal sleep. The results showed that memory improvements were greater after sleep than after a corresponding period of wake, but more importantly, the different periods of sleep seemed to support consolidation of different types of memory. Recall of paired associates improved more after 3 h of early sleep rich in SWS than after 3 h of late sleep rich in REM, or after a 3-h period of wake. Conversely, mirror tracing improved more after 3 h of late, REM-rich sleep than after 3 h spent either in early sleep or awake.

In a related study, Plihal and Born (1999a) examined different measures of episodic and implicit memory in order to separate the effects of type of material (verbal vs. nonverbal) from type of memory (episodic vs. procedural). Thus, a nonverbal episodic memory task (spatial rotation) and a verbal implicit task (word-stem priming) were used in the same early versus late night sleep procedure, and the findings mirrored the previous results. Compared to wake, recall of spatial memory was enhanced after early retention sleep but not late retention sleep, while priming was enhanced more after late than early retention sleep.

It is important to note that this early-/late-night sleep procedure suffers not only from confounds associated with sleep deprivation, but also from an incomplete separation of REM and NREM sleep. Early sleep is an imperfect proxy for SWS, and similarly, late sleep is an imperfect proxy for REM sleep. SWS does appear in the second half of the night, and REM appears in the first half of the night, and thus one cannot exclude the possibility that REM and SWS during these periods contributed to the noted consolidation effects. Moreover, the distribution of stage 2 NREM sleep is not entirely equal in both halves of the night. Thus, one cannot examine early versus late sleep and make definitive conclusions about SWS versus REM sleep.

In addition, SWS is tested by training subjects before they go to sleep (at around 10.00 or 11.00 p.m.) and then awakening them 3 h later for memory testing. REM sleep, on the other hand, is tested by awakening subjects to train in the middle of the night. These subjects then return to sleep before being awakened 3 h later for memory testing. Training in the middle of the night may well be less effective than training that occurs before subjects have slept at all, which means that the lack of improvement seen after REM awakenings in some experiments may be confounded; what looks like a failure to consolidate may simply reflect a difference in the quality of encoding and degree of attentional resources available for the task after being awakened in the middle of the night as opposed to in the evening prior to sleep. Finally, control groups that are awake for similar periods in the night are acutely sleep deprived, limiting the validity of the comparisons. Therefore, while the value of this creative procedure is that it manipulates sleep stages experimentally, a number of problems limits the clear interpretation of these findings.

In spite of these problems, two neuroimaging investigations of episodic memory consolidation have also suggested an important role for SWS. The first of these investigated performance on a hippocampally dependent virtual maze task (Peigneux et al., 2004). Daytime learning of the task was associated with hippocampal activity. Then, during posttraining sleep, there was a reemergence of hippocampal activation, and it occurred specifically during SWS. The most compelling finding, however, is that the increase in hippocampal activation seen during posttraining SWS was proportional to the amount of improvement seen the next day (see also Peigneux et al., 2003 described above). This suggests that the re-expression of hippocampal activation during SWS reflects the off-line reprocessing of spatial episodic memory traces, which in turn leads to the plastic changes underlying the improvement in memory performance seen the next day.

The second study (Takashima et al., 2006) investigated the time course of episodic memory consolidation across 90 days. Subjects studied 360 photographs of landscapes and were then tested on subsets of the photographs either after a nap the same day, or after 2, 30, or 90 days. Prior to each test, subjects studied 80 new pictures, and then were tested on 80 of the original pictures and the 80 new ones, as well as 80 pictures they had never seen before. All memory retrieval sessions occurred during fMRI scanning.

Following the initial 90-min nap, stage 2 sleep was positively correlated with successful recall of both remote and recent items, indicating a nonspecific benefit of stage 2 NREM sleep on episodic memory. This is an intriguing finding, given that stage 2 is where sleep spindles are most prominent (see the section titled ‘Electrophysiological signatures’). Slow-wave sleep, on the other hand, was correlated only with memory for remote (but not recent) items. Because performance on remote items increased with longer SWS duration, but performance for recent items did not, the effect on memory performance for remote items cannot be explained by a general effect of SWS on memory retrieval processes. The authors also point out that this brief period of SWS may have had an even longer-lasting effect on memory, because there was a linear relationship between the amount of SWS during the nap and recognition memory performance after both 2 and 30 days, whereas there continued to be no such correlation for recent items. This finding is striking, given that this was a nap rather than a full night of sleep, and that only 15 of the 24 subjects reached SWS. Finally, longer SWS durations led to decreases in hippocampal activation when remote items were successfully retrieved (it should be noted that while this finding appears to support traditional consolidation theory (Squire and Cohen, 1984), the hippocampus remained active during successful retrieval throughout the study (up to the last test at 90 days), suggesting that episodic memories may never become completely independent of the hippocampus (Nadel and Moscovitch, 1997; Moscovitch et al., 2006). These findings strongly suggest that episodic memories can undergo initial consolidation within a rather short time frame and that this consolidation is promoted by SWS.

In another nap study, Tucker et al. (2006) found that naps containing only NREM sleep enhanced declarative memory for word pairs. Performance on episodic (paired-associates) and procedural (mirror tracing) memory tasks were tested 6 h after training, either with or without an intervening nap. While there was no difference between nap and wake subjects on the procedural memory task, the nap subjects performed significantly better on the paired associate task relative to the subjects who remained awake

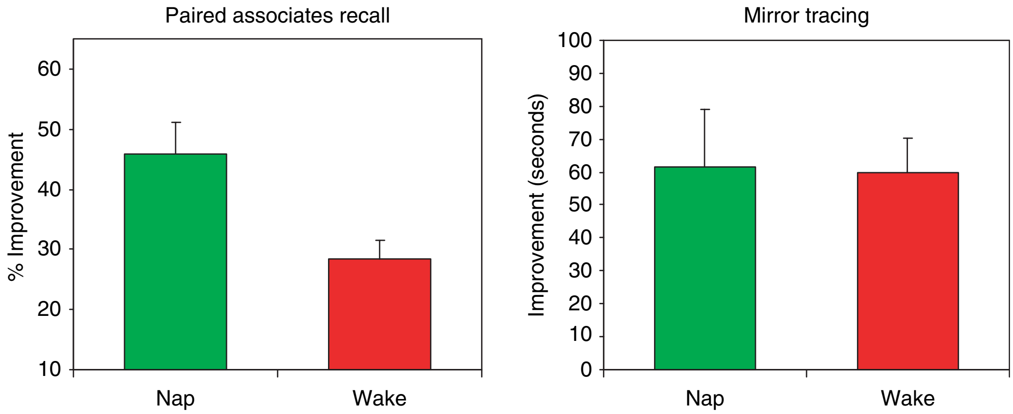

**Figure 7** A brief daytime nap benefits episodic memory. Note that the nap (which did not contain REM sleep) benefited episodic, but not procedural, memory. From Tucker MA, Hirota Y, Wamsley EJ, et al. (2006) A daytime nap containing solely non-REM sleep enhances declarative but not procedural memory. *Neurobiol. Learn. Mem.* 86(2): 241–247.

(**Figure 7**). Subjects in the nap condition also showed a weak correlation between improved recall and the amount of SWS in the nap, further supporting the relationship between episodic memory and SWS (Tucker et al., 2006). It will be interesting to see a follow-up study in which the contribution of REM sleep physiology is assessed.

These results should not be taken to mean that REM sleep mediates the consolidation of procedural memories, whereas SWS mediates the consolidation of episodic memories. Matters are clearly not so simple. Recall that improvement on a visual discrimination task depended on SWS as well as REM (Gais et al., 2000), and improvement on a motor task correlated with stage 2 NREM sleep (Smith and MacNeill, 1994). Moreover, emotionally charged episodic memories may rely on REM sleep for their consolidation (see 'Emotional episodic memory' section below).

There are two possible interpretations of these apparent contradictions. First, the sleep stage dependency of these various memory tasks may depend on aspects of the task other than simply whether they are episodic or procedural, perhaps depending more on the intensity of training, the emotional salience of the task, or even the manner in which information is encoded (e.g., deep versus shallow encoding or implicit versus explicit). The second possibility involves an inherent oversimplification in correlating performance improvements with sleep stages as they are classically defined. Indeed, mounting evidence points to several electrophysiological, neurotransmitter, and neuroendocrine mechanisms that may underlie these effects and which do not necessarily correlate with any single sleep stage (see section below), and sleep staging, as it has been defined for 40 years, may not capture all of the key elements that lead to memory consolidation enhanced by sleep.

At an even more basic level, none of the verbal episodic memory studies described above demonstrated that a full night of sleep can produce the kinds of benefits seen following a half-night of sleep or an afternoon nap. The idea of early SWS-rich sleep, but not late REM-rich sleep, being linked to improvements in episodic memory performance, for example, loses much of its interest if these early-night benefits were lost across the second half of the night, such that they would not be available the following day.

Fortunately, several very recent reports dispel this concern (e.g., Ellenbogen et al., 2006; Gais et al., 2006b). These studies demonstrate lasting benefits of a full night of sleep on episodic memory. For example, Ellenbogen et al. (2006) showed that a full night of sleep not only strengthened memory for unrelated paired associates, but also made these memories more resistant to interference than an equivalent period of time spent awake.

Using a classic AB-AC interference paradigm (Barnes and Underwood, 1959), subjects first learned a list of paired associates, $A_iB_i$. After either a 12-h period including a night with 7–8 h of sleep, or an equivalent 12-h period of wakefulness during the day, half of the subjects in each group recalled the previously learned word pairs (cued recall). The other half learned a new list of paired associates, $A_iC_i$, before being tested for recall of the original list. To control for circadian effects and to demonstrate that the effects of sleep persist, an additional group of subjects was trained at the same circadian time as the sleep group (9.00 p.m.), and tested 24 rather than 12 h later.

While sleep provided modest protection against memory deterioration even in the absence of interference training, it provided a large and dramatic protection against post-sleep interference, and this benefit was sustained throughout the subsequent waking day (**Figure 8**). Thus, memories after sleep were highly resistant to interference and remained resistant across the subsequent day, demonstrating significantly better recall after 24 h than memories encoded in the morning and tested just 12 h later, without sleep. This study suggests that sleep does more than simply protect memories from interference while asleep: sleep stabilizes memories, making them resistant to future interference during the subsequent wake period.

A study by Gais et al. (2006b) provides additional evidence that sleep does more than protect memories against interference (see Wixted, 2004 for a full review of the interference argument). Subjects learned English–German vocabulary lists in the morning (8.00 a.m.) or in the evening (8.00 p.m.) and were tested immediately via cued recall to establish a baseline memory retention score. They were then retested after 24 or 36 h, either at the same circadian time or at a different circadian time (i.e., subjects trained at 8.00 a.m. and were retested at 8.00 p.m. or vice-versa). Subjects went to sleep either soon after training and initial testing (approximately 3 h in the 8.00 p.m. training condition) or after a significant delay (approximately 15 h in the 8.00 a.m. training condition).

Subjects who slept soon after training (and were retested either 24 or 36 h later) performed better on the retest session, suggesting that a night of sleep shortly after training benefited their performance on the task. In a second experiment, subjects were similarly trained in the evening either prior to sleep or to a night of sleep deprivation. Sleep-deprived subjects were allowed to sleep the following day, where they made up much of their lost sleep. However, the deprived subjects did not sleep until 10 h after training, whereas control subjects went to sleep a mere 3 h after training. In both conditions, recall testing took place 48 h after initial learning, again in the evening, to allow for recovery sleep in the deprivation condition. Although no differences emerged in the initial test on the first evening, there was a clear deficit after a night of sleep deprivation. Subjects remembered more words when they slept the night following training than when they remained awake, thus providing further evidence that sleep benefits memory consolidation. Importantly, both the 24 h groups (a.m. and p.m.

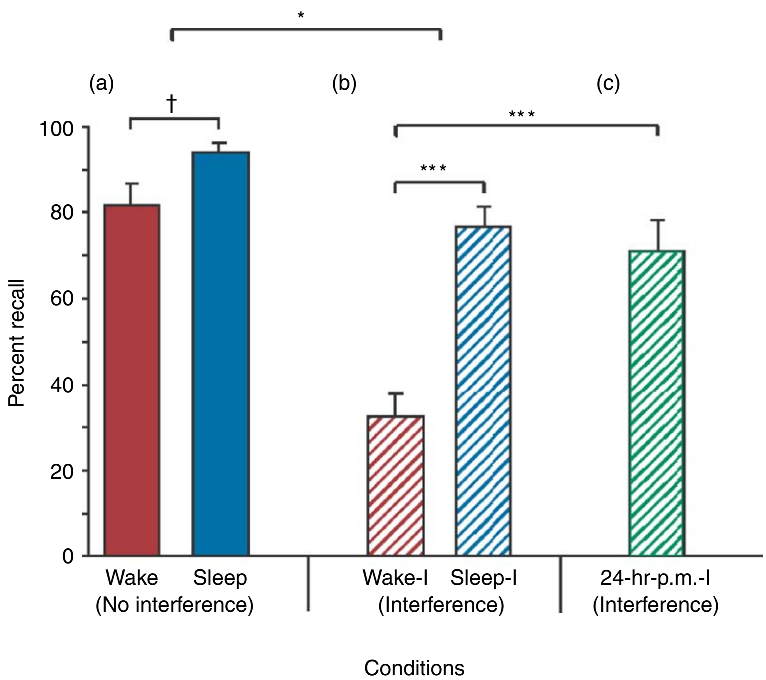

**Figure 8** Sleep makes memory resistant to interference. Note that this beneficial effect of sleep was seen after 12 nighttime hours including sleep and remained 24 hours later. From Ellenbogen JM, Hulbert JC, Stickgold R, et al. (2006a) Interfering with theories of sleep and memory: Sleep, declarative memory, and associative interference. *Current Biology* 16(13): 1290–1294.

training) underwent identical amounts of waking interference, as did the two 48-h groups (controls and sleep-deprived), which strongly suggests that the sleep benefits cannot be explained by a decrease in waking interference.

Thus, it appears quite unlikely that sleep merely offers a permissive, interference-free environment for memory consolidation. It is plausible that sleep also activates unique neurobiological processes that play an active role in consolidation (for a recent review, see Ellenbogen et al., in press). This would suggest that there are sleep-specific neural processes that contribute to memory consolidation – an argument we review in the section titled 'Electrophysiological signatures'.

### 2.35.6.1 Emotional Episodic Memory

Sleep also appears to contribute to the consolidation of emotional episodic memories. This is interesting in light of the many early studies that demonstrated slow, time-dependent improvements in emotional memory, where memory for emotionally laden events, or emotional aspects of complex events, often continued to improve over days and even weeks (Kleinsmith and Kaplan, 1963; Kleinsmith et al., 1963; Kleinsmith and Kaplan, 1964). While it is well known that memories of emotional events are encoded and subsequently persist more strongly than memories for neutral events (McGaugh, 2000; Kensinger, 2004), only recently has sleep's contribution to this apparent consolidation effect been examined (Hu et al., 2006; Wagner et al., 2001).

Hu et al. (in press) examined the impact of a full night of sleep on both axes of emotional affect – valence (positive/negative) and arousal (high/low), across both remember and know measures of memory for pictures. Results showed that a night of sleep improved memory accuracy for emotionally arousing pictures relevant to an equivalent period of daytime wakefulness, but only for know judgments. No differences were observed for remember judgments. Moreover, memory bias changed across a night of sleep relative to wake, such that subjects became more conservative when making remember judgments, especially for emotionally arousing pictures. No bias differences were observed for know judgments between sleep and wake. These findings provide further evidence that the facilitation of memory for emotionally salient information may preferentially develop during sleep. Whether these effects emerge primarily after REM-rich, late night sleep, as in Wagner et al. (2001) (discussed in the section titled 'Neurohormones and neurotransmitters'), remains to be investigated. Nonetheless, the enhancing impact of sleep on the remembrance of emotional episodic information is becoming increasingly clear.

## 2.35.7 Electrophysiological Signatures

But what is it about sleep that leads to memory consolidation? Several electrophysiological signatures of sleep, recorded in animals with cortical electrodes as well as in the human EEG, reflect synchronized oscillatory patterns of neuronal activity in the cortex that may actively promote memory consolidation. There are still relatively few studies examining these proposed neurophysiological mechanisms. However, we expect the number to increase dramatically in the near future, and so we review what is currently known here.

### 2.35.7.1 Sleep Spindles

Sleep spindles are one example of such a mechanism. Sleep spindles are bursts of coherent brain activity visible on the EEG, which are most evident during stage 2 sleep. They consist of brief 11- to 16-Hz waves lasting 0.5–1.5 s. In animals, the initiation of cortical sleep spindles tends to occur with high-frequency (~200 Hz) ripples that ride on hippocampal sharp waves in NREM sleep (Siapas and Wilson, 1998). This co-occurrence of hippocampal sharp waves and cortical spindles may underlie the integration of information between the hippocampus and neocortex as memories are consolidated during sleep (Buzsáki, 1996).

In support of this hypothesis, several human studies have shown a correlation between hippocampally dependent episodic learning and cortical sleep spindles. In one such study (Gais et al., 2002), subjects studied a long list of unrelated word pairs 1 h prior to sleep, on two separate occasions, at least a week apart. In one case, they were instructed to imagine a relationship between the two nominally unrelated words, while in the other they were simply asked to count the number of letters containing curved lines in each word pair. Such instructions lead to deep, hippocampally mediated encoding and shallow, cortically mediated encoding, respectively. During the subsequent nights of sleep, subjects showed significantly higher spindle densities on the nights following deep encoding, averaging 34% more spindles in the first 90 min of sleep. Moreover, sleep spindle density was positively correlated both with immediate recall tested in the final stage of training and with recall the next morning, after sleep. Thus, those who learned better had more spindles the following night, and those with more spindles showed better performance the next morning.

These findings mirror previous observations by Meier-Koll et al. (1999), who reported a similar increase in spindles following learning of a hippocampally dependent maze task, and by Clemens et al. (2005) who found a correlation between spindle density and overnight verbal memory retention (although not between spindle density and memory for faces). Interestingly, Smith and colleagues have reported increased spindle density after intensive training on a pursuit rotor task, and after combined training on several simple procedural motor tasks (Fogel and Smith, 2006; Fogel et al., 2007). Thus, spindles might contribute to the consolidation of both explicit and implicit memories (Meier-Koll et al., 1999; Clemens et al., 2005; Fogel and Smith, 2006).

But sleep spindles also appears to correlate strongly with IQ (Bodizs et al., 2005; Schabus et al., 2006), and it can thus be difficult to discern whether high spindle content correlates with overnight improvement in memory *per se*, or whether both reflect correlations with IQ. While this is not problematic when repeated measures or factorial designs compare nights with and without preceding memory encoding, the correlation with IQ confounds correlational studies that show more posttraining spindles in subjects who subsequently show better recall.

### 2.35.7.2 Slow Waves

Given the evidence for early night facilitation of episodic memory recall (e.g., Plihal and Born, 1997, 1999a,b), it is not surprising that neurophysiologic markers associated with slow-wave sleep (SWS) have also been implicated in memory consolidation. Slow-wave rhythms, including both classical delta activity (1–4 Hz), and the more recently characterized cortical slow oscillations (<1 Hz) increase as humans pass into SWS. Indeed, these cortical slow oscillations are now considered a hallmark of SWS (Steriade and Timofeev, 2003). Such slow oscillatory activity in neuronal networks allows distant ensembles to become synchronized in rats and has been hypothesized to facilitate the binding and consolidation of memories that are dispersed across distant brain regions (Buzsáki and Draguhn, 2004).

Cortical slow oscillations have recently been observed in humans in conjunction with increased EEG coherence. EEG coherence is a large-scale measure of the coactivation of distant brain regions. Molle et al. (2004) recently showed that increased EEG coherence, which was strong during the memorization of word pairs, reappeared with cortical slow oscillations during subsequent slow wave sleep. Interestingly, while there were only marginal increases in coherence when measured over all NREM sleep, this coherence was dramatically increased when the analysis was time-locked to the occurrence of cortical slow oscillations (Molle et al., 2004).

This finding suggests that slow oscillations are important for the reprocessing of memories during sleep, a conclusion that is based on two assumptions. First, it assumes that high coherence between EEG signals from different sites on the scalp reflect an increased interplay between the underlying neuronal networks, and second, it assumes that efficient encoding of associations in episodic memory is facilitated by the large-scale synchrony of cortical neuronal activity measured by EEG coherence. Given these assumptions, the finding suggests that cortical slow oscillations may be of particular functional significance for the reprocessing of newly acquired associative memories during human SWS.

Slow oscillations also appear to exert a grouping influence over spindle activity. Molle et al. (2002) examined the temporal dynamics between spindle activity and slow oscillations in the human EEG during NREM stage 2 and SWS. They found that during human SWS, rhythmic activity in the spindle frequency range correlated with periods of slow oscillations. They also showed that discrete spindles identified during NREM stage 2 sleep coincided with the depolarizing portion of the cortical slow oscillations and were preceded by pronounced hyperpolarizing half-waves (Molle et al., 2002). These results suggest that slow rhythmic depolarizations and hyperpolarizations in cortical neurons might alternately drive and inhibit thalamically generated spindle activity, thereby contributing indirectly to memory consolidation through their regulation of spindles.

There are two distinct mechanisms by which spindles might provide the conditions necessary to induce long-term synaptic changes. Relevant cortical neural networks may be selectively activated during spindle activity as a result of previous learning, and, in turn, this activation may induce activity in, and thus modification of, related networks within the hippocampal complex. Alternatively, hippocampal activity driven by recent learning might selectively prime relevant cortical networks, which would then be activated and modified during subsequent sleep spindles (Siapas and Wilson, 1998). Either way, the spindles themselves may induce long-term synaptic changes in the neocortex.

Sleep spindles and slow oscillations represent promising candidate mechanisms for sleep-dependent memory consolidation, but it is important to note that a causal role for these electrophysiological signatures remains to be demonstrated. Nevertheless, they provide preliminary support, in humans, for the idea that the hippocampus and neocortex cooperate to integrate new information into long-term memory during sleep (Buzsáki, 1996).

### 2.35.7.3 Hippocampal and Cortical Replay

This hippocampal–neocortical communication paradigm is important, because it is intimately intertwined with theories of memory consolidation. New memories are at least initially dependent on connections between medial temporal and neocortical regions, and increased communication between these regions after training on a memory task may reflect consolidation of these recently acquired memories. A growing literature demonstrates precisely these effects in animals, where hippocampally dependent learning leads to post-training reactivations in brain areas involved in memory processing.

In the earliest studies, Pavlides and Winson (1989) demonstrated spontaneous neuronal replay of task-specific firing patterns during posttraining sleep, with individual hippocampal place cells that discharged during spatial exploration increasing their firing rates during subsequent sleep. Recording from large ensembles of place cells in the CA1 field of the hippocampus, Wilson and McNaughton (1994) showed that pairs of cells that fired together as rats passed through specific locations in an open field also fired together during subsequent SWS. This cellular activity during sleep mimicked the firing patterns seen when the task was performed, suggesting that information acquired during wake is re-expressed during sleep and that this reactivation forms a neurophysiological substrate of sleep-dependent memory consolidation (Pavlides and Winson, 1989; Wilson and McNaughton, 1994).

Since then, numerous studies have reported neuronal replay during both SWS (Skaggs and McNaughton, 1996; Kudrimoti et al., 1999; Lee and Wilson, 2002) and REM sleep (Poe et al., 2000; Louie and Wilson, 2001). Interestingly, the replay of temporal patterns of activity during SWS occurs on a time scale 20 times faster than the previous waking pattern (Lee and Wilson, 2002), while during REM it occurs in close to real time, averaging just 40% slower than in wake (Louie and Wilson, 2001).

The finding, discussed above (Siapas and Wilson, 1998), of temporal correlations during SWS between hippocampal sharp-wave/ripples and the initiation of individual prefrontal sleep spindles, along with similar correlations between the hippocampus and somatosensory cortex (Sirota et al., 2003) provides a mechanism by which such neuronal replay could lead to consolidation in both hippocampal and cortical networks.

### 2.35.7.4 Theta Rhythm

There is evidence in both humans and animals that theta frequency (4–7 Hz) oscillations are associated with enhanced learning and memory during the waking state (Bastiaansen and Hagoort, 2003), and it has been suggested that the integration of information within hippocampal and neocortical circuits may be mediated by theta activity. Although there is little theta activity during SWS, it is at waking levels during REM sleep, when hippocampal cell discharge is modulated at the theta frequency. This theta activity may aid memory reprocessing during REM sleep by enabling information to flow from the neocortex (through the superficial layers of the entorhinal cortex) into the hippocampus, where it can reverberate within hippocampal circuitry (i.e., replay). In contrast, during the sharp-wave and ripple activity of SWS, information may flow in the opposite direction, out of the hippocampus and back to the neocortex (through deep layers of the entorhinal cortex Buzsáki, 1996; Buzsáki, 1998), thus allowing information to flow throughout the complete neocortex–hippocampal circuit. Indeed, it has been proposed that high levels of the neurotransmitter acetylcholine and the neurohormone cortisol during REM sleep, and low levels during SWS, might modulate communication between hippocampus and neocortex as memories undergo consolidation (Payne and Nadel, 2004). In this view, as in others (Giuditta et al., 1995;Ficca et al., 2000), both SWS and REM sleep are thought to contribute to the consolidation of episodic memories. In addition, for emotional memory processing, cooperative theta oscillations between hippocampal and amygdala regions during REM sleep may play an important role as well (Pare et al., 2002).

## 2.35.8 Neurohormones and Neurotransmitters

Many modulatory neurotransmitters contribute to memory formation. Acetylcholine, however, has received the most attention by the sleep community to date, most likely because it is critically involved in control of the NREM/REM cycle, and because it is present at particularly high levels during REM sleep and low levels during SWS (Hobson et al., 1998).

Acetylcholine, although mainly involved in memory encoding, appears to also play a role in the flow of information between memory systems during different stages of sleep. According to a model by Hasselmo (1999), acetylcholine inhibits feedback loops both within the hippocampus and between the hippocampus and neocortex. As a result, the high cholinergic activity seen during wakefulness minimizes consolidation and promotes encoding of new episodic memories, whereas the low cholinergic activity in SWS blocks new input and supports the replay of recently encoded information in the hippocampus. This replay may then lead to integration of this information within hippocampal and neocortical memory stores (Buzsáki, 1996; Hasselmo, 1999; Payne and Nadel, 2004).

To investigate the role of acetylcholine in the consolidation of episodic memory during sleep, Gais and Born (2004b) trained subjects on a list of paired associates, as well as a mirror tracing task, before 3 h of SWS-rich nocturnal sleep or wakefulness during which they received a placebo or an infusion of the cholinesterase inhibitor physostigmine (which increases cholinergic tone). When tested after 3 h of sleep, recall on the paired-associates task was impaired in the physostigmine group, while procedural memory performance was unaffected (Gais and Born, 2004b). This provides initial support for Hasselmo's (1999) model and suggests that the inhibition of cholinergic activity during SWS is critical for sleep-based episodic memory consolidation.

As with neurotransmitters, hormonal fluctuations across the sleep cycle may also help to explain why different sleep stages contribute differentially to the consolidation of episodic memories. Activation of the neuroendocrine hypothalamic–pituitary–adrenocortical (HPA) system, for instance, results in the release of the stress hormone cortisol from the adrenal glands. Cortisol then feeds back onto the brain, where the hippocampus and frontal cortex, arguably two of the most critical memory regions, contain the highest number of cortisol receptors in humans (Lupien and Lepage, 2001). Several studies have demonstrated cortisol-induced memory impairments with episodic memory tasks during wake (Kim and Diamond, 2002; Payne et al., 2002; Payne et al., 2006). Intriguingly, cortisol levels are at their lowest during early nocturnal sleep, while achieving a diurnal maximum during late night sleep (Plihal and Born 1999b; Born and Wagner, 2004).

Plihal and Born (1997, 1999a) have thus argued that the circadian suppression of cortisol release early in the night makes this SWS-rich sleep an ideal physiological environment for episodic memory consolidation. Naturally low cortisol levels during early sleep promote more efficient consolidation of episodic memories than is seen during late, REM-rich sleep, when cortisol levels are high. In support of this view, Plihal and Born (1999b) showed that artificially elevating cortisol levels during early sleep eradicated the normal episodic memory benefit seen during this period, suggesting that the salubrious environment provided by early sleep is a result, at least in part, of the naturally low levels of cortisol during this time.

Cortisol levels in the Plihal and Born (1999b) study were elevated to levels similar to those typically seen in response to mild to moderate stressors, that are sufficient to disrupt episodic memory function during wakefulness (Kirschbaum et al., 1996; de Quervain et al., 2003; de Quervain, 2006).

In another study suggestive of a cortisol-related influence on memory consolidation (Wagner et al., 2001), memory for emotionally laden narrative material was facilitated after late night, REM-rich sleep periods. At first blush, this result seems to contradict the evidence reviewed in the section titled 'Emotional episodic memory', which demonstrated that late night REM sleep does not support episodic memory consolidation, perhaps due to high cortisol levels. Yet studies have consistently shown that cortisol facilitates memory for emotional episodic materials, while impairing closely matched neutral materials during wakefulness (Buchanan and Lovallo, 2001; Payne et al., 2006). Given the role of cortisol in enhancing emotional episodic information, the late-night enhancement of emotional memory in this study is not surprising.

In addition to cortisol, other hormones (e.g., growth hormone) are known to impact memory function in the waking state, and also vary across sleep, suggesting that they might contribute to sleep-based memory consolidation. Although initial studies of growth hormone have failed to find such an effect (Gais et al., 2006), further investigation of the neurochemistry underlying the relationship between sleep and memory consolidation is a productive avenue for future research. Indeed, it seems especially important to forge ahead into precisely this neuromodulatory realm, where the chemical basis of the sleep/memory consolidation connection is examined.

## 2.35.9 Concluding Comments

Over the past 10 years, the field of sleep and memory has grown exponentially, with reports of sleep–memory interactions emerging from myriad disciplines, ranging form cellular and molecular studies in animals to behavioral and neuroimaging studies in humans. In our view, sleep undoubtedly mediates memory processes, but the way in which it does so remains largely unknown. This makes the future of the field truly exciting, but also challenging. Much remains to be done, from uncovering the mechanisms of brain plasticity that underlie sleep-based memory processing, to untangling the complex relationship between the various sleep stages and types of memory. In so doing, memory researchers may find a field in which some of the more recalcitrant problems of basic memory research can also be answered.

# 2.36 Infant Memory

**C. Rovee-Collier and K. Cuevas**, Rutgers University, New Brunswick, NJ, USA

## 2.36.1 Introduction

Infant memory is a burgeoning topic, difficult to comprehend and difficult to summarize, but one thing is clear: Infants from their inception have robust capacities to learn and remember. In the development of these capacities are hidden the secrets of adult learning and memory.

The infancy period extends from birth through 2 years of age. Over this period, the infant is dramatically transformed from a helpless, altricial organism who sleeps 99% of the time and depends on its parents for nourishment and protection into an active, highly social being who sleeps largely at night, locomotes independently, and exhibits unflagging curiosity (**Figure 1**). A central problem in cognition is understanding how the superior memory of adults evolves from the memory ability of infants. This is the question of how we came to be as we are. In this chapter, we review research that has shed some light on the solution to this problem. We conclude that memory processing in infants and adults is fundamentally the same.

### 2.36.1.1 Paradox of Infant Memory

Developmental scientists have long assumed that the effects of infants' early experiences gradually accrue and lay the foundation for their later cognitive development (Watson, 1930; Stevenson et al., 1967). Paradoxically, although this assumption requires

**Figure 1** From left to right, infants are 2, 3, 6, 9, 12, 15, and 18 months of age. Note the dramatic physical and behavioral differences between the youngest and oldest infant.

that infants maintain a relatively enduring record of their early experiences, most also believe that infants lack the ability to do so. They think that the infant brain is too immature to encode or retrieve memories of specific events (Nelson, 1995; Liston and Kagan, 2002; Bauer et al., 2007), that infants younger than 18 months cannot form mental representations (Piaget, 1962; Anisfeld, 2005), or that the ability "to retain a memory over a long period of time [is] not possible" before the child can converse about it with others (Nelson, 1990: p. 307).

Researchers from different laboratories using different procedures, however, have amassed compelling evidence that preverbal infants can retain memories of their experiences for periods ranging from days and weeks to months and years (for reviews, see Rovee-Collier et al., 2001; Hayne, 2004, 2007).

### 2.36.1.2 Associative Memory and Retentive Memory

Associations play a central role in accounts of learning and memory phenomena. The formation of an association between two events is determined by their temporal contiguity. If an association is formed between two events that are separated by a delay, then the individual is said to have exhibited associative memory over the delay (Revusky, 1971). The upper limit of associative memory is the maximum interval between the conditional and unconditional stimuli that leads to classical conditioning and the maximum delay between a response and reinforcement that leads to operant conditioning.

Relative to associative memory, retentive memory is long lasting (Revusky, 1971). It is implicated when an individual exhibits the effect of prior training over an interval between training and testing. Watson (1984) referred to these forms of memory as memory in learning and memory of learning, respectively. This chapter focuses primarily on retentive (long-term) memory.

### 2.36.1.3 Historical Perspectives

The systematic study of infant long-term memory can be traced to Fagan's (1970) report of visual recognition memory with 5-month-olds and Rovee and Fagen's (1976) report of delayed recognition with operantly trained 3-month-olds. Earlier reports, often anecdotal, were of single subjects who were observed over long periods. In his autobiography, for example, John Stuart Mill said that his father, James Mill, taught him formal Greek at the age of 3, which he used throughout his life (Mill, 1909). In a single-subject study of the long-term maintenance of early memory, Burtt (1932, 1937, 1941) read the same Greek passages to his infant son once daily between 15 and 36 months of age, introducing a different set of passages every 3 months. When the child was 8.5, 14, and 18 years old, Burtt measured savings during relearning of the passages. Early exposure to the passages produced the largest savings at 8.5 years (a 5-year retention interval), when the child required 30% fewer repetitions to relearn old passages than to learn new ones. Savings were smaller (8%) at 14 years and negligible at 18 years.

The classic study of Little Albert also provided evidence of long-term memory (Watson and Rayner, 1920). Here, the authors asked whether a conditioned emotional reaction (CER) could be established in an 11-month-old infant. Albert initially exhibited no aversive reactions to various novel stimuli, including a white rat. A loud noise was then sounded directly behind Albert's head on two occasions that he reached for the rat. The noise produced crying and hand withdrawal, which transferred to the rat. One week later, Albert still withdrew his hand when presented with the rat; in this session, he also received five more rat-noise pairings. Five days later, Albert generalized the CER to test objects that shared perceptually similar properties with the rat (a rabbit, dog, fur coat, Santa Claus mask, cotton) but did not generalize to perceptually different objects (wooden blocks). After an additional 10 days, Albert's CER to the rat had become muted and was freshened by another rat-noise presentation. The rabbit and dog were also explicitly paired with the noise during this session. One month later, Albert still exhibited strong CERs to the rat, dog, mask, and fur coat.

In another early study, Jones (1930) exposed a 7-month-old to repeated pairings of a tapping sound (the conditional stimulus, or CS) and an electrotactual stimulus (the unconditional stimulus, or US) for 5 days. The CR (conditional response), a galvanic skin reflex, was established in session 1. Despite receiving no additional conditioning trials in the interim, the infant still exhibited the CR 6 weeks later, and the CR had not completely disappeared after 7 weeks.

## 2.36.2 Methods of Study

The major impediment to research on the ontogeny of infant memory has always been methodological: The tasks commonly used with older infants are usually inappropriate for use with younger ones. This problem is hardly surprising when one considers the rapid physical and behavioral changes that infants undergo over the first 18 months of life (**Figure 1**). As a result, researchers used a hodgepodge of tasks with stimuli, task parameters, and task demands that varied nonsystematically with infants of different ages, making cross-age comparisons dubious at best. In addition, the use of verbal prompts biased results in favor of older, linguistically more competent infants. Within the last decade, new operant and deferred imitation tasks were developed to overcome this obstacle.

Most of what is known about infant memory has come from research with visual recognition memory, operant conditioning, and deferred imitation tasks. In visual recognition memory tasks, retention is measured indirectly, inferred from general reactions such as looking/orienting, electrophysiological and psychophysiological responses, facial expressions, and so forth. In these instances, the meaning of a response is a matter of interpretation (Lewis, 1967; Haith, 1972). In classical conditioning, operant conditioning, and deferred imitation tasks, retention is measured directly in the performance of a previously learned behavior.

### 2.36.2.1 Visual Recognition Memory

Visual recognition memory is studied using the visual paired-comparison (VPC) task (Fantz, 1956, 1964; Fagan, 1970) and the habituation task (Berlyne, 1958; Cohen and Gelber, 1975). Both exploit infants' propensity to look longer at novel than at familiar stimuli. The underlying assumption is that infants who exhibit a novelty preference must remember what they saw before. Recognition of a preexposed stimulus, therefore, is inferred from the relative extent to which infants look at a novel one.

In the VPC task, infants view two identical stimuli presented side by side (or occasionally only one) for a fixed duration. During the retention test, a novel stimulus replaces one of them (**Figure 2**).

**Figure 2** The visual paired-comparison (VPC) test with a 6-month-old infant. Immediately before the test, the infant was shown two identical pictures of the woman's face. During the test, the infant is shown the previously exposed picture (the woman's face) and a novel one (the man's face). Proportionally longer looking at the novel picture is taken as evidence that the infant recognized the preexposed one.

Recognition of the original stimulus is inferred if the percent of total time spent looking at the novel stimulus significantly exceeds chance (50%). The upper limit of retention is the longest test delay at which infants fixate the novel stimulus more.

In the habituation task, infants are repeatedly exposed to one stimulus until looking time decreases by a specified amount, at which point they are successively tested with a novel stimulus and the original one. Increased looking at the novel stimulus indicates recognition of the original one. As the interval between the final habituation trial and testing increases, infants look increasingly longer at the original stimulus. The delay after which they fixate it for as long as they had on Trial 1 indicates forgetting.

Visual recognition memory tasks that are administered in one session provide a measure of short-term memory. In this situation, the upper limit of retention approximates 5–15 s at 3–4 months, 1 min at 6 months, and 10 min at 9–12 months (Diamond, 1990; Rose et al., 2004). Long-term memory is implicated when multiple sessions are administered. Using the VPC task over multiple daily sessions, Fagan (1973) found that 4–5-month-olds looked longer at a novel black-and-white pattern after 48 h and at a novel facial photograph after 2 weeks. Face recognition, however, may be special. Following habituation to faces, infants exhibit significant recognition after 2 min at 3 days of age (Pascalis and de Schonen, 1994) and after 24 h at 3 months of age (Pascalis et al., 1998).

### 2.36.2.2 Delayed Nonmatching-to-Sample

The delayed nonmatching-to-sample (DNMS) task is analogous to the VPC task but requires substantial motor coordination. Initially a reward (cereal, toy) is hidden in a well under a sample object, and infants retrieve the reward by displacing the sample. After a delay, the sample and a novel object are presented simultaneously, but the reward is under the novel one. To retrieve the reward, infants must recognize the sample object and displace the novel one. The upper limit of associative memory is the maximum delay after the sample trial when infants retrieve the reward. Infants younger than 15–21 months fail standard DNMS tasks after 5–10 s (Overman, 1990; Diamond et al., 1994). When the reward is the opportunity to play with the novel object, however, even 6-month-olds succeed after 10 min (Diamond, 1995).

### 2.36.2.3 Classical Conditioning

In classical conditioning, infants acquire an association between two stimuli, a CS and a US, that usually occur in succession. They must remember the CS until the US occurs (associative memory). The upper limit of associative memory is the maximum interval between the CS and US (ISI, interstimulus interval) that promotes learning.

In eyeblink conditioning, the optimal ISI is three to four times longer for infants than adults (Kimble, 1947). Using a delay conditioning procedure, Little (1970) presented 2-month-olds with a tone (CS) and airpuff (US) at ISIs of 500, 1000, 1500, or 2000 ms. Only the two longest ISIs promoted conditioning. Little et al. (1984) used 500-ms and 1500-ms ISIs with 10-, 20-, and 30-day-olds. At all ages, infants exhibited associative memory after the 1500-ms ISI only, and only 20- and 30-day-olds exhibited significant retention of the association (retentive memory) on a savings measure 10 days later (**Figure 3**). The optimal ISI decreases to 650 ms at 4–5 months of age (Ivkovich et al., 1999) and 500 ms in adults (Kimble, 1947). This decrease parallels an increase in synaptic efficacy (Kandel and Hawkins, 1992) and may reflect changes in infants' ability to perceive the CS and US as distinct events.

### 2.36.2.4 Operant Conditioning

In operant conditioning, infants acquire an association between a response and reinforcement. They must remember the response until reinforcement occurs (associative memory). The upper limit of associative memory is the maximum response-reinforcement interval that promotes learning. The upper limit is 0 s (immediate reinforcement) at 3 months (Ramey and Ourth, 1971), 1–2 s from 6 to 8 months (Millar, 1990), and 9 s from 9 to 16 months (Brody, 1981).

The most extensive analysis of infants' long-term memory (retentive memory) has come from operant research with the mobile conjugate reinforcement task (Rovee and Rovee, 1969) and its upward extension, the train task (Hartshorn and Rovee-Collier, 1997; for review, see Rovee-Collier et al., 2001). The logic behind using these tasks is straightforward: Because infants lack a verbal response to say what they recognize, they are taught a motoric one (a foot kick or lever press) that they can use instead. When tested with a display that is the same as or different from the training one, infants 'say' whether or not

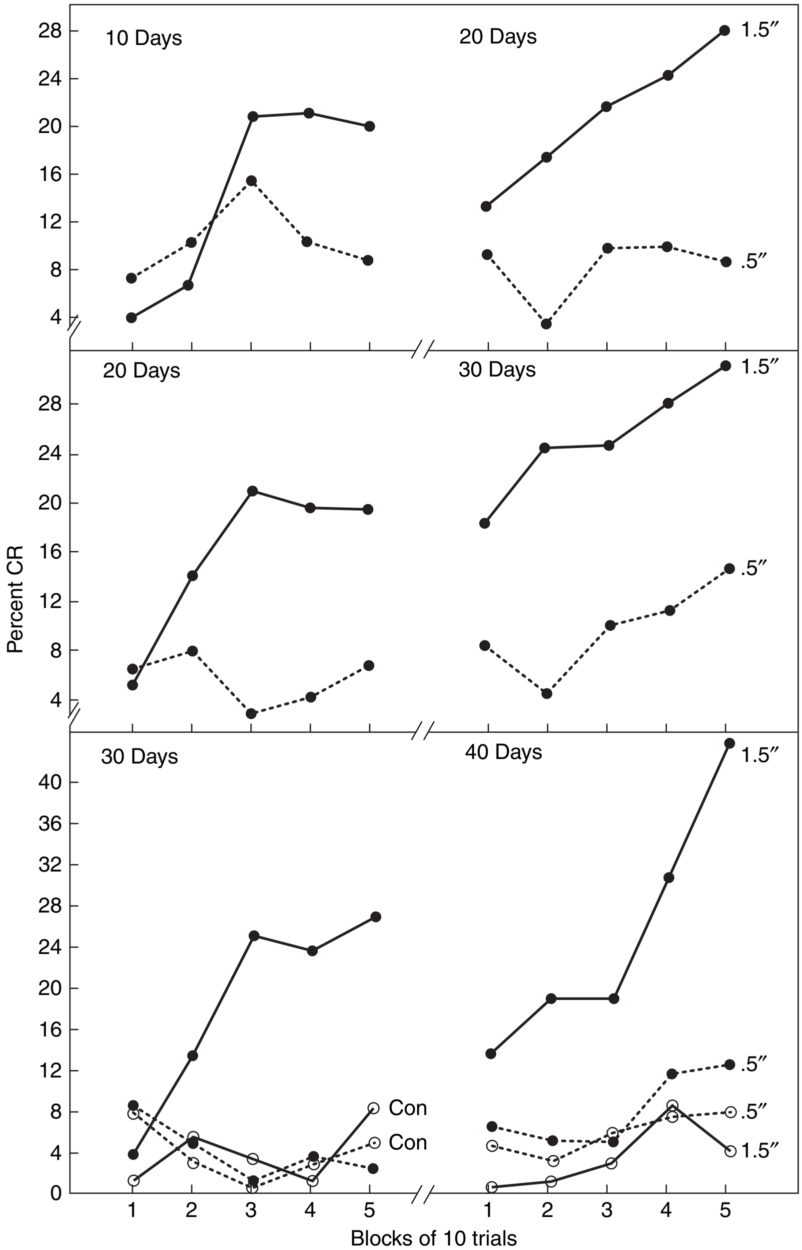

**Figure 3** Percentage of responses on conditional stimulus–unconditional stimulus (CS–US) trials by infants who were classically conditioned at 10, 20, or 30 days of age (left panels) to blink their eyes to a tone (CS) that was paired with an air puff (US) and were retrained in a second session 10 days later (right panels). The CS and US were separated by either a 1500-ms or 500-ms interstimulus interval (ISI). Reprinted with permission from Little AH, Lipsitt LP, and Rovee-Collier C (1984) Classical conditioning and retention of the infant's eyelid response: Effects of age and interstimulus interval. *J. Exp. Child Psychol.* 37: 512–524. Copyright © Academic Press, Inc.

they recognize it by whether or not they produce the learned response.

In all studies, infants are trained in their homes for two sessions 24 h apart. At 2–6 months, the mobile task is used (**Figure (4a)–(4c)**). During the 9-min acquisition periods (6 min at 6 months) in each session, kicks are conjugately reinforced by mobile movement via a ribbon that is strung from the infant's ankle to the same suspension hook as an overhead crib mobile (**Figure 4(b)**). During 3-min nonreinforcement periods (2 min at 6 months) at the beginning and end of each session, the ankle ribbon is connected

**Figure 4** The experimental arrangement used with 2- to 6-month-olds in the operant mobile task, shown here with a 3-month-old. From top to bottom, (a) Baseline: The ankle ribbon and mobile are connected to different hooks, and kicks do not move the mobile; (b) Acquisition: Kicks conjugately move the mobile via an ankle ribbon connected to the mobile hook; (c) Immediate retention test, long-term retention test: The ankle ribbon and mobile are again connected to different hooks. Infants who recognize the mobile kick to move it during the test, even though they cannot.

to an empty suspension hook, and kicks cannot move the mobile (Figures 4(a), 4(c)). The baseline kick rate (operant level) is measured during the first nonreinforcement period in session 1; the response rate that indicates the final level of learning is measured during the last nonreinforcement period in session 2 (the immediate retention test). To proceed beyond the training phase, each infant must satisfy a learning criterion (responding 1.5 times above the baseline rate).

The long-term retention test occurs days to weeks later and is another 3-min (2 min at 6 months) nonreinforcement period when the response rate is measured again. Because individual operant levels vary widely, an infant's responding during the long-term retention test is expressed as a ratio of the same infant's responding during the baseline phase (the baseline ratio) and the immediate retention test (the retention ratio). A group baseline ratio that significantly exceeds 1.00 indicates retention; if the accompanying retention ratio is significantly below 1.00 (i.e., significant forgetting), however, then the group's retention is partial. Because long-term retention is assessed during a nonreinforcement period, savings (faster relearning) are not measured.

Because the mobile task cannot be used with infants older than 6–7 months, the train task was developed as an upward extension of the mobile task for infants between 6 and 24 months (Figure 5). Instead of moving a mobile by kicking, infants move a miniature train around a circular track by lever pressing. During reinforcement periods, each discrete lever press moves the train for 1 s (2 s at 6 months); during nonreinforcement periods, the lever is deactivated. At 6 months, all retention measures in the two tasks are identical, including the rate of forgetting before and after

**Figure 5** The experimental arrangement used with 6- to 24-month-olds in the operant train task, shown here with a 6-month-old. Each lever press moves the toy train for 2 s (1 s at older ages) during acquisition; during baseline and all retention tests, the lever is deactivated, and presses do not move the train.

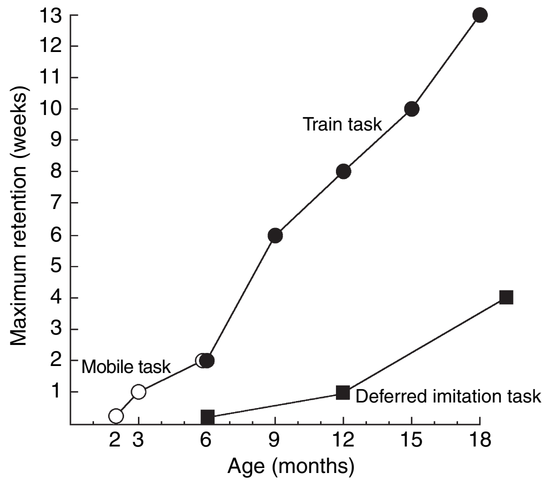

**Figure 6** Standardized reference functions for the maximum duration of retention (in weeks) of infants who were trained and tested in standardized procedures with age-calibrated parameters. The experimental paradigms were the operant mobile and train tasks and the deferred imitation (puppet) task. Differences in the slopes of the two functions are solely the result of the use of different parameters. From Hartshorn K, Rovee-Collier C, Gerhardstein P, et al. (1998b) The ontogeny of long-term memory over the first year and a half of life. *Dev. Psychobiol.* 32: 69–89.

priming (Hildreth and Rovee-Collier, 2002), the latency of responding to a memory prime (Hildreth and Rovee-Collier, 1999), responding to cue or context changes before and after priming (DeFrancisco, in press; Hartshorn et al., 1998a), the minimum duration of an effective prime (Sweeney and Rovee-Collier, 2001), and the faster forgetting rate after a minimum-duration prime (Hsu et al., 2005). This equivalence permitted the mobile and train tasks to be used in combination to study memory development systematically over the entire infancy period.

**Figure 6** shows that the maximum duration of retention increases linearly with age over the first year and a half of life. The overlapping points at 6 months show that infants' memory performance is not task specific. These data provide no hint that memory changes qualitatively at the end of the first year of life, when a late-maturing memory system is thought to emerge (Schacter and Moscovitch, 1984), or during the second year of life, when spoken language first appears (Best, 1984).

## 2.36.2.5 Deferred Imitation

In deferred imitation tasks, infants reproduce one or more target actions after a delay. Both Piaget (1962) and Meltzoff (1995) argued that true imitation prohibited performing the modeled behavior before the delayed test, so that imitation would reflect only the memory of what was seen and not what was done. Piaget claimed that infants younger than 18 months could not form mental representations and hence were incapable of true imitation. His claim was refuted by evidence that, with no opportunity to practice, 14-month-olds imitated a novel action (pulling apart a toy) 24 h later (Meltzoff, 1985), and 9-month-olds imitated three unique, single-step actions 24 h later (Meltzoff, 1988).

Barr et al. (1996) developed a task that permitted the systematic study of deferred imitation from 6 to 24 months of age. Here, infants watch an experimenter model three actions on an acrylic hand puppet wearing a same-color mitten (**Figure 7**). Modeling one sequence of actions (remove the mitten, shake it thereby ringing a jingle bell pinned inside during modeling, and replace the mitten) takes 10 s. Three repetitions (30 s) yield immediate imitation at 6 months and 24-h deferred imitation at 9–24 months; six repetitions (60 s) yield 24-h retention at 6 months. An infant's imitation score is the total number of actions copied within 90–120 s of touching the puppet. Between 6 and 24 months of age, the base rate of spontaneously producing the target actions is low (0.13–0.17). Older infants have higher imitation scores and remember progressively longer. The pattern of long-term retention in deferred imitation tasks is the same as in operant tasks except that the slope is flatter and the asymptote is lower (**Figure 6**).

**Figure 7** The experimental arrangement used with 6- to 24-month-old infants in deferred imitation studies. Shown here is the experimenter modeling the three target actions to a 6-month-old.

These differences reflect task differences in training (30–60 s in one modeling session vs. 11–30 min over two conditioning sessions 24 h apart).

Development of the puppet imitation task spawned numerous studies with 6-month-olds (for review, see Hayne, 2004, 2007). Because infants younger than 6 months are motorically limited, whether they could exhibit deferred imitation was unknown until recently, when this problem was overcome by periodically reactivating the memory of the demonstration until they could finally perform the actions (Campanella and Rovee-Collier, 2005). Three-month-olds watched three target actions modeled six times (a total of 60 s) on a puppet. Over the next 3 months, infants received a total of six 30- to 60-s exposures to the stationary puppet. At 6 months of age, they successfully imitated the actions. These infants had not seen the target actions since they were modeled 3 months earlier and obviously had not imitated them immediately. A yoked reactivation control group received the same reminders but did not see the demonstration. It responded at the base rate during the long-term test. These results clearly indicate that the memory system of very young infants is sufficiently mature to support deferred imitation.

#### 2.36.2.6 Elicited Imitation

Elicited imitation is a variant of deferred imitation in which infants imitate immediately (and sometimes during the retention interval) and experimenters provide verbal prompts. Both factors significantly affect infants' deferred imitation: Immediate practice facilitates generalization and priming (Hayne et al., 2003; Learmonth et al., 2004), and verbal cues facilitate imitation after long delays (Hayne, 2004; Hayne and Herbert, 2004).

Elicited imitation tasks have been used with infants between 9 and 32 months to assess their ability to imitate multistep actions (for review, see Bauer, 2004; Bauer et al., 2007). Researchers have consistently reported that the structure of an event influences imitation (Bauer et al., 1995). Imitation of actions that must be performed in a specific order (e.g., putting a toy bear in bed before covering it with a blanket) is superior to imitation of actions that can be performed in any order (e.g., removing the bear's coat and hat). The same result has been found with older children (Fivush et al., 1992) and adults (Ratner et al., 1986).

#### 2.36.2.7 The Ruler Matters

Retention depends on how it is measured. Adults' retention of serial lists, for example, is better when measured by recognition than by recall or relearning (Postman and Rau, 1957, cited in Crowder, 1976). For infants, visual recognition measures of retention range from 5 s at 3 months to 10 min at 12 months (for review, see Rose et al., 2004), but operant measures fix retention from 5 days to 8 weeks over the same period (Hartshorn et al., 1998b). Even under the same conditions of testing, novelty preference and operant measures yield different estimates of retention. Wilk et al. (2001) trained 3- and 6-month-olds in the mobile task and gave them a paired-comparison test with the original mobile and a novel one 1–21 days later. In multiple experiments, infants consistently exhibited long-term retention on the operant measure but not on the VPC measure, looking longer at the training mobile. They concluded that infants look at what is predictive.

Using a split within-subjects design, Gross et al. (2002) exposed 6-month-olds to a picture in a visual recognition memory task and to either a hand puppet on which actions had been modeled or a mobile that they had moved by kicking. Immediately after modeling or operant training, the infants administered a VPC test with the original stimulus and a novel one, followed by a performance test with the original puppet or mobile. On VPC tests, infants looked longer at the novel picture but not at the novel puppet or mobile, indicating a failure to recognize them. On performance tests, however, the same infants imitated the modeled actions on the original puppet and kicked significantly above baseline to the mobile. Again, infants remembered at the predictive stimulus.

### 2.36.3 Reminders

Reinstatement and reactivation reminders have been used with infants of all ages to maintain, extend, or recover memories of earlier experiences. During reinstatement, infants are returned to the original training conditions during the retention interval and given a small amount of partial practice or repetition of the original event (Campbell and Jaynes, 1966). A reactivation procedure entails exposing infants to an isolated component or fragment of the original event at the end of the retention interval, after the memory was forgotten but before the long-term test

(Spear and Parsons, 1976). For both reminders, the essential control groups are the same: a forgetting control group that receives training but no reminder(s) and a reactivation or reinstatement control group that receives reminder(s) but no training.

Most scientists regard reinstatement and reactivation reminders as equivalent (e.g., Hudson and Sheffield, 1998; Mandler, 1998). Howe et al. (1993) wrote that the distinction between them "is artificial in that both . . . have similar (if not the same) memory-preserving effects" (Howe et al., 1993: p. 855), and Richardson et al. (1993) wrote, "there are some minor procedural differences between reactivation and reinstatement. . ., [but] the underlying process is the same in both cases" (Richardson et al., 1993: p. 2). Operant research with infants, however, has revealed that the two reminders differ functionally as well as procedurally. At 3 and 6 months of age, for example, retention is two times longer after reinstatement than reactivation when both are given midway through the forgetting function (Adler et al., 2000; Galluccio and Rovee-Collier, 2006) and ten times longer when both are given after the memory is forgotten (Hildreth et al., 2003). Also, three reinstatements protract retention longer than three reactivations (Hayne, 1990; Galluccio and Rovee-Collier, 1999).

What accounts for the superiority of reinstatement is unclear. Reinstatement is a partial learning trial, but it protracts retention longer than an equivalent amount of overtraining (Adler et al., 2000). Reactivation, on the other hand, is a retrieval trial that has been likened to rehearsal in nonverbal animals (Wagner, 1976). For now, this question remains unanswered.

### 2.36.3.1 Reactivation

Reactivation procedures used with infants and priming procedures used with amnesic adults are the same. Reactivation, like priming in amnesics, is an automatic, perceptual identification process that re-activates a preexisting memory representation and brings it to mind at a time when neither the prime nor the target item can be recognized (Schacter, 1990, 1992; Rovee-Collier, 1997). Because the time required for 3-month-olds to exhibit renewed retention after reactivation is so long (24 h), whereas amnesics respond to a prime (e.g., a word fragment) instantaneously, skeptics initially doubted that that reactivation and priming were the same. Hildreth and Rovee-Collier (1999), however, found that the latency of responding to a memory prime decreased linearly over the first year of life, from 24 h at 3 months to 1 h at 6 months and 1 min at 9 months. By 12 months, infants responded to the prime instantaneously, just like adults. These results confirmed that reactivation in infants and priming in adults are the same.

For both infants and adults, effective primes are hyperspecific to the original event, an extreme instance of encoding specificity (Tulving and Thomson, 1973). Effective primes for infants between 2 and 24 months include the reinforcer (Hsu and Rovee-Collier, 2006), the distinctive training context (Rovee-Collier et al., 1985; Hayne and Findlay, 1995), the demonstration hand puppet (Hayne et al., 2003; Campanella and Rovee-Collier, 2005), the occlusion event (Shuwairi and Johnson, 2006), a pre-exposed photograph (Cornell, 1979), the modeled actions (Barr et al., 2002), a subset of structured activities (Sheffield and Hudson, 1994), photographs of partially completed activities (Deocampo and Hudson, 2003), and a video of another child performing the activities (Sheffield and Hudson, 2006).

During reactivation in the mobile task, infants are in a sling-seat (to minimize activity) under the mobile (**Figure 8**). Instead of being connected to the ankle, the ribbon is used by the experimenter to move the mobile at the same rate that each infant had kicked to move it at the end of acquisition, thus ensuring that the prime is phenomenologically identical to what infants saw before. In the train task, the response lever is deactivated, and the computer is programmed to move the train accordingly.

**Figure 8** The experimental arrangement during reactivation (priming), shown here with a 3-month-old. The ribbon was not connected to the infant's ankle but was held by the experimenter, who pulled it to move the mobile at the same rate that the infant had moved it by kicking during the last few training minutes. The infant seat minimized spontaneous kicking.

In the first reactivation study with infants, 3-month-olds were trained in the mobile task, allowed to forget it, and then were primed either 13 or 27 days later. Independent groups received a standard retention test 24 h later and after longer delays until they reforgot the task (Rovee-Collier et al., 1980). (Because kicking is also a general excitement behavior, priming occurred 24 h before the test so that any arousal it might induce would dissipate.) Priming restored responding to its original level, and infants forgot the reactivated memory at the same rate as the original one (**Figure 9**). Both results have since been obtained throughout the infancy period. The duration of retention increases linearly with age between 2 and 18 months (**Figure 10**, squares), and a reactivation reminder doubles it (**Figure 10**, diamonds; Hildreth and Rovee-Collier, 2002; Hsu et al., 2005). Thus, although reactivation does not protract retention as long as reinstatement, its consequences are nontrivial.

There is an upper limit to how long after training the memory can be primed successfully. Because retention is a monotonically increasing function of age, the absolute upper limit of reactivation increases linearly over the first year as well (**Figure 10**, triangles). The original memory can be reactivated after delays ranging from 1 month (3-month-olds) to 8 months (12-month-olds). When the upper limit of reactivation is expressed as a ratio of the maximum duration that infants typically remember at a given age, the relative upper limit is constant over ages, four times longer than the duration of original retention at a given age (Hildreth and Hill, 2003). The absolute upper limit of reactivation did not continue to increase beyond its peak at 12 months because infants trained at 15–18 months outgrew the train task by the time of testing. As a result, they could not be tested after relative delays longer than 1.5–2 times the duration of original retention (Hsu and Rovee-Collier, 2006). (The long-term retention test is an increasingly conservative test of retention as infants approach 2 years of age. Older infants often stop lever pressing when the train does not move and remark that it is broken or needs batteries.)

At 3 months of age, multiple reactivations flatten the forgetting function (Hayne, 1990), extend retention from 4 weeks with one reminder (Rovee-Collier et al., 1980) to at least 6 weeks with two reminders (Hayne, 1990), speed the memory recovery from 24 h with one reminder (Fagen and Rovee-Collier, 1983) to 1 h with two reminders (Hayne et al., 2000b), reduce the minimum duration exposure to a prime 1 week after forgetting from 2 min with one reminder (Joh et al., 2002) to 1 min with two reminders (Bearce and Rovee-Collier, 2006), and reduce the accessibility of

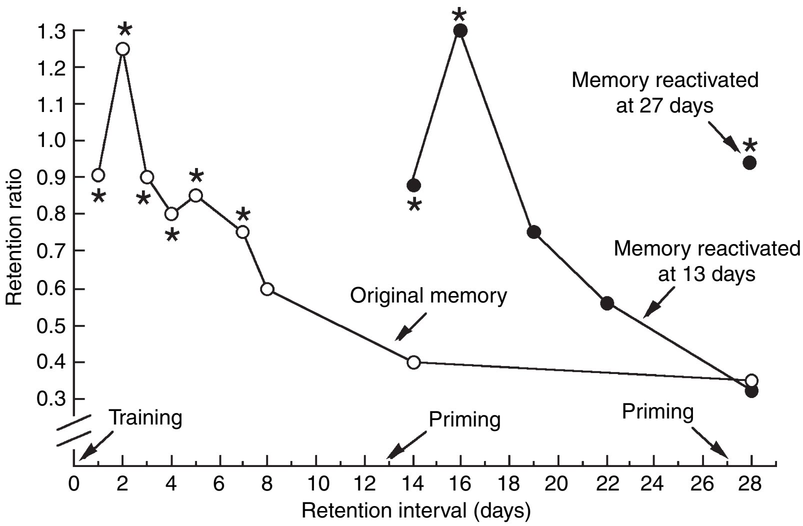

**Figure 9** The forgetting and reforgetting functions of the original memory and the reactivated memory, respectively, as a function of the number of days after training or priming when retention was tested. Priming occurred either 13 or 27 days after training was over. Irrespective of priming delay, retention was renewed at the same level that it was 24 h after training. An asterisk indicates significant retention. memory attributes representing contextual details (Hitchcock and Rovee-Collier, 1996).

Finally, Shuwairi and Johnson (2006) used an innovative application of reactivation as a precue to probe whether explicit training with an occlusion event had an enduring effect on anticipatory eye movements. For either one or four training trials, 4-month-olds watched a ball move back and forth on a constant trajectory on a video monitor (**Figure 11(a)–(d)**). On test trials, its path was partially occluded. Immediately after training, the proportion of total eye movements that anticipated the ball's reemergence from behind the occluder significantly exceeded that of a baseline control group after four 30-s trials but not after one 30-s trial (**Figure 12**). Thirty minutes after training, when the memory was forgotten, infants received a single 30-s trial (a precue) immediately before the retention test. (Recall that one 30-s trial produced no learning.) The prime reactivated the training memory and restored anticipations to the previous level (**Figure 12**). This result indicates that early and relatively brief exposures to occlusion events produce stable and relatively enduring object representations that can be maintained and potentially strengthened by repeated reminders.

### 2.36.3.2 Reinstatement

During reinstatement in the mobile and train tasks, the ankle ribbon is connected to the mobile hook and the response lever is active, so that kicks and lever presses are reinforced. In both tasks, reinstatement is timed from the first response and lasts 3 min at 2–3 months and 2 min at 6–18 months. This regimen is insufficient to produce 24-h retention of new learning during reminding.

Hartshorn (2003) tested Campbell and Jaynes's (1966) original hypothesis that reinstatement is the mechanism by which early memories are maintained over significant periods of behavioral development. Recall that 6-month-olds typically remember the train task for 2 weeks. In three progressive replications, 6-month-olds learned the train task, received a 2-min reinstatement at 7, 8, 9, and 12 months of age, and were tested at 18 months of age. Prior to

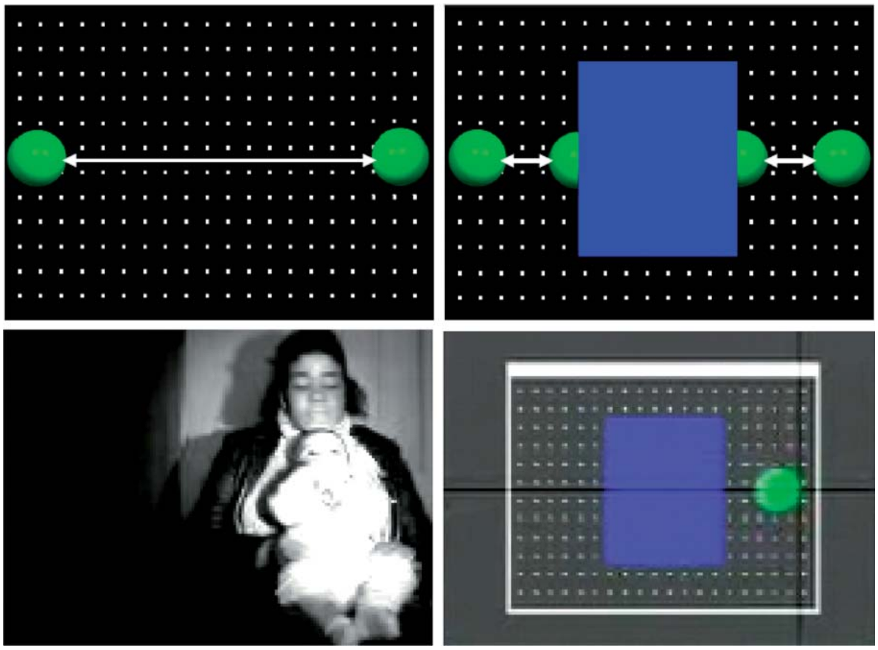

**Figure 11** The experimental arrangement and stimuli used to study anticipatory eye movements in the eye-tracking paradigm. (a) Unoccluded (training) trial: The ball moved horizontally back and forth along an unoccluded trajectory. (b) Occluded (test) trial: The ball moved horizontally back and forth along an occluded trajectory. The ball moved behind a blue box and reemerged on the opposite side. (c) The experimental arrangement with a 4-month-old infant. (d) The corneal reflection eye tracker recorded the infant's visual fixation (the black cross to the right of the ball) as the ball emerged from behind the occluded object. Figure courtesy of Sarah M. Shuwairi and Scott P. Johnson.

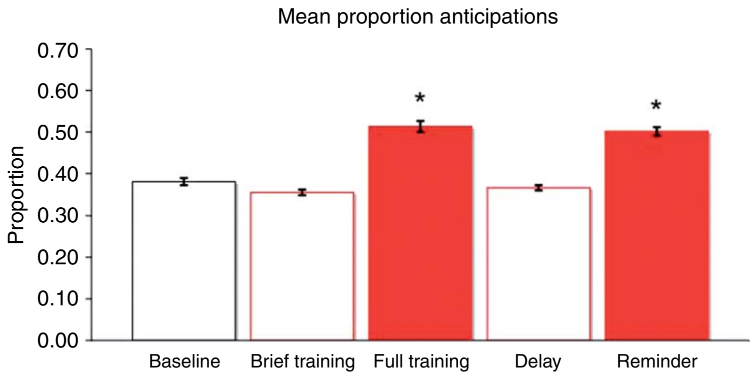

**Figure 12** Mean proportion of anticipatory eye movements of independent groups of 4-month-old infants. The experimental groups received either a brief (Brief training) or full (Full training, Delay, Reminder) training regimen and were tested either immediately after training (Brief training, Full training) or after a 30-min delay (Delay, Reminder). The reminder condition received a brief training trial immediately prior to testing. An asterisk indicates significant anticipations relative to the baseline control group. Vertical bars indicate + 1 SE. Figures courtesy of Sarah M. Shuwairi and Scott P. Johnson.

reminding at 9 and 12 months, infants received a 2-min retention test as a memory probe. All infants not only remembered the task then but also remembered it during the 18-month test, 1 year after training. In each replication, yoked reinstatement control groups that received the same reinstatements but were not originally trained exhibited no retention after any delay. Immediately after the 18-month test, Hartshorn gave infants another reinstatement and retested them 6 months later, at 24 months of age. The infants also exhibited significant retention during the 24-month test, 1.5 years after they were originally trained, despite receiving only one reinstatement in the preceding year.

In a concurrent study, Rovee-Collier et al. (1999) trained 2-month-olds in the mobile task and then administered either a reinstatement or a reactivation reminder every 3 weeks. Before each reminder, they presented a preliminary retention test as a memory probe to assess whether an infant remembered the task. Infants who did remember received a reinstatement, while those who did not received a reactivation reminder. Even though 2-month-olds typically remember the mobile task for only 1–2 days, they remembered the task for 21 weeks, through 7.25 months of age, after the periodic reminders. At that point, the experiment was discontinued because infants outgrew the task. Because periodic reminders maintained the memories of two equivalent tasks from 2 months to 2 years of age, the entire period presumably characterized by infantile amnesia, it seems likely that periodic reminders would also maintain a single memory over the same period, if not longer.

The preceding evidence casts serious doubt on popular accounts of infantile amnesia (see section 2.36.5). As long as infants periodically encounter an appropriate nonverbal reminder, their memory of an early experience will be maintained. Thus, whether or not an early experience will be remembered later is determined only by whether or not an appropriate reminder is periodically available in nature. In essence, the ultimate source of infant forgetting resides in the structure of the environment, not in the structure of the brain.

## 2.36.4 Ontogenetic Changes

### 2.36.4.1 Forgetting

Because adults of all species remember for so long, animal researchers have had to study forgetting with immature organisms. The first systematic study of the ontogeny of memory documented that forgetting by infant rats was inversely related to age (Campbell and Campbell, 1962). A parallel study with human infants, modeled after the Campbell and Campbell study, yielded the same result (Hartshorn et al., 1998b). Between 2 and 18 months, infants of all ages exhibited equivalent retention after the shortest test delay, but as the retention interval progressively increased, the younger infants forgot first (**Figure 13**).

The magnitude of the difference in retention between 2 months (1–2 days) and 18 months (13–14 weeks) has two major implications for interpretations of how different variables affect retention at different ages. First, effects on retention must be expressed in relative rather than absolute terms. Whereas 5 days is the longest interval that operantly trained 3-month-olds typically remember, for example, 5 days is a trivial retention interval for 18-month-olds. Second, age effects should not be expected after a short retention interval. Thus, claims that particular variables have no age effects must be treated skeptically unless the effects were also assessed at later points along the forgetting function.

Infants, like adults, forget and retrieve different memory attributes at different rates (Riccio et al., 1994). In operant and deferred imitation tasks, for example, infants forget object color faster than object form (Bhatt and Rovee-Collier, 1996; Hayne et al., 1997). They also forget the specific details of the training mobile before they forget its general features (Rovee-Collier and Sullivan, 1980), and after forgetting, a memory prime recovers its general features before its specific details (Rovee-Collier and Hayne, 1987). One day after priming, infants respond to both a novel test mobile and the original one; 3 days later, they discriminate the mobiles and respond only to the original one. This result is consistent with other evidence that more accessible memories are retrieved faster (see the section 2.36.4.2).

### 2.36.4.2 Accessibility

Memories that are inaccessible but available can still be retrieved; memories that are both inaccessible and unavailable cannot (Tulving, 1983). In both infants and adults, the rapidity with which a memory is retrieved is directly related to its accessibility and inversely related to both the strength or number of cues required to retrieve it and the length of time it has been forgotten. An important consequence of retrieving a memory is an increase in its accessibility (*See* Chapter 2.16). Paradoxically, after a less accessible memory is retrieved, both infants and adults subsequently remember it longer (Schmidt and Bjork, 1992).

Joh et al. (2002) found that the minimum duration of exposure to an effective prime is a linearly increasing function of how long the memory had been forgotten. At 3 months of age, when the memory had been forgotten for 1 day, the minimum duration of priming was 7.5 s; when it had been forgotten for 1

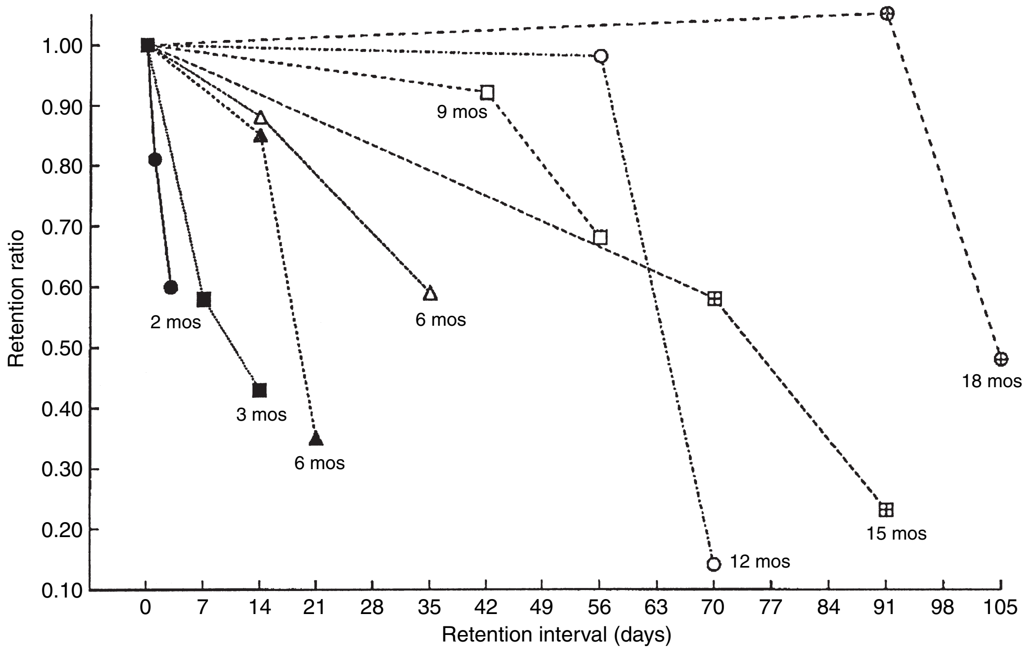

**Figure 13** Forgetting as a function of infant age and test delay. Mean retention ratios of independent groups of infants between 2 and 18 months of age who were trained for 2 consecutive days in the mobile task (2–6 months) or the train task (6–18 months) and received an immediate retention test after the conclusion of acquisition on day 2. Six-month-olds were trained and tested in both tasks. Infants of each age received a delayed recognition test after different retention intervals until, as shown in the last point on each curve, they exhibited no retention. From Hartshorn K, Rovee-Collier C, Gerhardstein P, et al. (1998b) The ontogeny of long-term memory over the first year-and-a-half of life. *Dev. Psychobiol.* 32: 69–89.

week, the minimum duration was 120 s; and when it had been forgotten for 2 weeks, the minimum duration was 180 s. The finding that a longer prime is required to reactivate a memory that has been forgotten longer is theoretically important. In the past, there was no way to measure the accessibility of a memory that was not expressed. These data indicate that the minimum duration of exposure to a prime that can reactivate a latent memory is a direct measure of its accessibility.

A research problem with important applied and theoretical implications concerns manipulations that increase the accessibility of a forgotten memory. Because the latency of response to a memory prime (the priming latency) decreases logarithmically over the first year of life (Hildreth and Rovee-Collier, 1999), it is tempting to attribute the increased accessibility to maturational changes in the nervous system. Hayne et al. (2000b), however, reported that two reactivations decreased the priming latency of 3-month-olds from 24 h to 1 h, which is the typical priming latency of 6-month-olds given one reactivation. This result indicated that priming latency is experientially rather than maturationally based. They concluded that prior priming increased the accessibility of the forgotten memory.

Because prior priming increased the accessibility of a memory by decreasing priming latency (Hayne et al., 2000b), Bearce and Rovee-Collier (2006) hypothesized that prior priming would also increase its accessibility by reducing the minimum duration of exposure to the second prime. It did. The forgotten memory could be reactivated by a briefer prime after it had been primed before.

For infants initially trained between 3 and 18 months of age, the minimum duration of exposure to an effective prime presented 1 week after forgetting decreases logarithmically from 2 min at 3 months of age to 1.5 s at 18 months (**Figure 10**, circles; Hsu et al., 2005). In priming studies with adults, Schacter et al. (1991) reported that a 1-s exposure was not long enough to produce a priming effect, but a 5-s exposure was. Taken together, these findings indicate that successful priming of a preexisting memory representation requires attention that is longer than a mere glance, which takes 1 s. Even though exposure durations decreased by six log steps between 3 and 18 months, infants of all ages forgot twice as fast after a minimum-duration prime as after a full-length one. Nonetheless, the total period over which infants given a minimum-duration prime could remember the training memory was still quite considerable, exceeding 5.5 months at the oldest age (**Figure 10**, circles).

These findings reveal that the minimum duration of exposure to an effective prime is the currency by which the accessibility of memories can be psychophysically scaled. That is, all latent memories that can be activated by primes of the same minimum duration are equally accessible. This principle applies to all memories irrespective of subject age, time since forgetting, memory content, speed of processing, number of prior retrievals, spacing of successive retrievals, and so forth.

### 2.36.4.3 Context

The incidental context refers to relatively invariant aspects of the setting in which an event occurs that do not affect the characteristics or demands of the task. Studies with animals and human adults have found that the context provides additional retrieval cues for the target memory (Riccio et al., 1984). Relatively little attention has been paid to the role of context in infant memory. This neglect has reflected the widespread assumption that infants' brains are too immature to store information about the place where learning occurs (e.g., Nelson, 1995). This assumption, however, is incorrect. Even 3-month-olds encode numerous aspects of the incidental training context, including location (room in home, laboratory), the immediate visual surroundings (a colored-and-patterned cloth covering the sides of the crib), the experimenter (social context), an ambient odor (Rubin et al., 1998), and background music (Fagen et al., 1997).

In order to assess contextual specificity at the same relative points along the forgetting functions of differently aged infants, Hartshorn et al. (1998a) compared retention at the first, middle, and last points on the forgetting functions of 3-, 6-, 9-, and 12-month-olds (see section 2.36.4.1). They found that a change in the testing context impaired retention only after delays near the end of the forgetting function at all ages except 6 months, when it impaired recognition only after relatively short delays. The latter result was attributed to infants' heightened sensitivity to context preceding independent locomotion (Borovsky and Rovee-Collier, 1990). Apparently, the context disambiguates infants' memory of the training cue when it becomes fuzzy and facilitates its recognition (Bouton and Bolles, 1985). The deleterious effect of a context change on recognition is overridden at 3 and 6 months of age by training infants in a different context each day (Amabile and Rovee-Collier, 1991; Rovee-Collier and DuFault, 1991).

After delays so long that the memory has been forgotten, if the memory has been reactivated in the original context, then infants can recognize the training cue in a different test context 24 h later by 9 months of age. By 12 months of age, the memory can also be reactivated in a different context (DeFrancisco, in press). Thereafter, reactivated memories become increasingly less context dependent with age. Thus, infants can transfer what they learn from one place (e.g., nursery school) to another (e.g., home) if asked to do so before too much time has elapsed.

Deferred imitation also increasingly generalizes across physically different contexts with age. Six-month-olds exhibit 24-h deferred imitation when either the test room or the mat they sit on during testing is different from the room or mat present during modeling but exhibit no deferred imitation when both differ (Learmonth et al., 2004). By 9 months, infants generalize when both the floor mat and the room differ. Also, a global context change (e.g., laboratory vs. home) impairs 24-h deferred imitation at 6 months but not at 12 and 18 months after test delays up to 28 days (Hanna and Meltzoff, 1993; Hayne et al., 2000a). Learmonth et al. (2005) found that a novel tester (the social context) disrupted 24-h retention of deferred imitation from 6 to 18 months of age, but preexposure to the novel tester in their home 2 days earlier allowed infants of all ages to generalize imitation. This finding parallels findings from operant studies with infants that novelty inhibits responding. These findings reveal that the similarity between the conditions of encoding and retrieval – not whether the task is deferred imitation or operant conditioning – determines whether young infants generalize.

Recent research on the renewal effect provides evidence that 3-month-olds can also associate the context with experimental contingencies (Cuevas et al., 2005). The renewal effect was originally described by Bouton and Bolles (1979) as the recovery (renewal) of acquisition performance when the contextual cues that were present during extinction are removed. Infants learned to kick to move the mobile in the presence of a distinctive context

(context A) and received an extinction manipulation (kicks did not move the mobile) with the original mobile in a different context (context B). Twenty-four hours later, infants tested with the original mobile in either the acquisition context (context A) or a neutral context (context C) exhibited retention, but infants tested in the extinction context (context B) exhibited none. Thus, the reduction of learned behavior via an extinction procedure in infants, as in adults, is context specific: In contexts other than the extinction context, infants will resume the behavior that was previously reinforced.

## 2.36.5 Latent Learning

Infants learn an enormous amount of information by merely observing their surroundings, but what they learn remains latent until they have a response and an opportunity to express it. Brogden (1939) introduced the sensory preconditioning (SPC) paradigm to study the latent learning of associations between neutral stimuli. The SPC paradigm has three phases. In phase 1, two stimuli (A, B) are repeatedly exposed in close temporal or spatial contiguity; in phase 2, a distinctive response is trained to one of the stimuli (A→R1); and in phase 3, the subject is tested with the other stimulus (B). The transfer of responding to the untrained stimulus (B→R1) but not to an equally familiar but unpaired stimulus is taken as evidence that an association was formed between A and B during the phase 1. Because the association that individuals form during phase 1 remains latent until it is expressed in phase 3, SPC is a form of behaviorally silent learning.

In the first infant study of SPC, Boller (1997) found that simultaneously preexposing 6-month-olds to two cloth panels (contexts) for 1 h daily for 7 days (phase 1) enabled them to associate the contexts. Twenty-four hours after phase 1, she operantly trained infants in one of the contexts (phase 2) and tested them in the other context 24 h later (phase 3). These infants transferred conditioned responding to the other context, but infants who were exposed to the contexts unpaired in phase 1 did not. Using a deferred imitation task, Barr et al. (2003) repeated Boller's procedure and preexposed 6-month-olds to puppets A and B either paired or unpaired for 1 h daily for 7 consecutive days (phase 1), modeled the target actions on puppet A 24 h later (phase 2), and tested infants with puppet B 24 h after that (phase 3). During the deferred imitation test, only the paired preexposure group imitated the target actions on puppet B. The same result was obtained when phase 1 lasted 2 days instead of 7.

Cuevas et al. (2006b) demonstrated that 6-month-olds could form an association between two objects that were neither physically present nor had ever occurred together. The association was formed when the memory representations of those objects were simultaneously activated by associated cues that the infants noticed. In phase 1, infants were exposed simultaneously to hand puppets A and B to establish an association between them. In phase 2, infants were trained to kick to move a crib mobile in a distinctive context to establish a mobile-context association. In phase 3, infants were exposed to puppet A in the distinctive context to establish a puppet B–mobile association. Presumably, puppet A would retrieve its associated memory of puppet B, and the distinctive context would retrieve its associated memory of the mobile. When the memory representations of puppet B and the mobile were simultaneously activated, then infants formed a new association, even though neither object was physically present.

Cuevas et al. subsequently demonstrated three target actions on puppet B to provide infants with an overt, measurable behavior that they could use to express the association. Typically, 6-month-olds remember the deferred imitation task for 1 day but not 3 days (Barr et al., 1996, 2001; **Figure 14**, solid circles), and they remember the mobile task for 14 days (Hill et al., 1988; **Figure 14**, triangles). If 6-month-olds had associated puppet B and the mobile *in absentia*, however, then they would be expected to imitate the actions on puppet B after the same test delays that they remember the mobile task. In fact, independent groups of infants successfully imitated the target actions on puppet B after delays up to 2 weeks, the same duration for which they remember the mobile (**Figure 14**, open circles). Two association control groups failed to imitate on puppet B even 1 week later (**Figure 14**, squares). These findings reveal that young infants form specific and enduring associations between the memory representations of stimuli that are simultaneously activated.

Townsend (2006) found that 6-month-olds are able to associate two puppets that they have never seen together. In phase 1, infants were preexposed to either two or three different pairs of puppets on 2 or 3 consecutive days (A–B, B–C or A–B, B–C, C–D; respectively). One day following their last exposure,

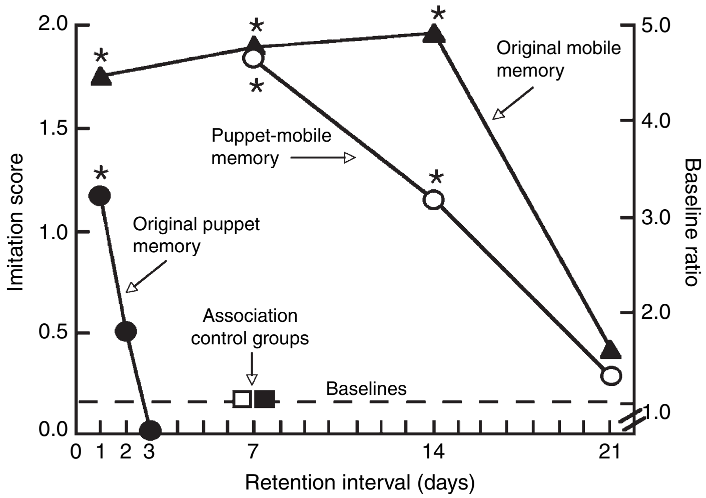

**Figure 14** Mean imitation-test score (left *y*-axis) and mean baseline ratio, the index of operant retention (right *y*-axis), as a function of the retention interval. The deferred imitation function for the three experimental groups that associated the memory representations of puppet B and the mobile is presented along with the original deferred imitation function and the forgetting function for the operant mobile task. Also shown is the test performance of two association control groups. The dotted line indicates the mean base rate (baseline control group) for spontaneous production of the target actions in the deferred imitation task and the theoretical baseline for the mobile task. Asterisks indicate that test performance significantly exceeded the base rate or the theoretical baseline. Note that the form of the retention function of experimental groups in the deferred imitation task mirrors the form of the retention function of infants in the mobile task. Reprinted with permission from Cuevas K, Rovee-Collier C, and Learmonth AE (2006b) Infants form associations between memory representations of stimuli that are absent. *Psychol. Sci.* 17: 543–549. Copyright © 2006 by the Association for Psychological Science.

the target actions were modeled on the final puppet (C or D; phase 2). When tested with puppet A 24 h later (phase 3), infants in both groups imitated the modeled actions, whereas those tested with a novel puppet (puppet E) did not. Thus, 6-month-olds had apparently associated two puppets (A and C or D) that were never presented together. Infants who were preexposed to puppets A and B unpaired or to puppet B alone after the puppet A–B association was formed (an extinction procedure) did not imitate the modeled actions on puppet A, confirming that the A–B link was necessary for imitation.

Simultaneously preexposing two stimuli in phase 1 of SPC results in their association between 3 and 9 months of age (Barr et al., 2003; Campanella and Rovee-Collier, 2005; Bullman et al., 2006), but at 15 months, the same preexposure regimen is less successful (Bullman et al., 2006). Cuevas et al. (2006a) found that the extent of temporal contiguity required for two stimuli to be associated decreased with age from only simultaneous preexposure at 6 months to only sequential preexposure at 15 months. This result resembles age-related increases in associative memory in delay-of-reinforcement studies with infants.

Subsequent research has examined how long infants can remember an association before they finally express it. After one preexposure session at 6–9 months, infants remember the association between two puppets for only 2–3 days. After two preexposure sessions, infants remember the association for 1 week at 6 months and 2 weeks at 9 months (Bullman et al., 2006). The basis for the retention benefit afforded by the additional session results from the additional retrieval at the outset of session 2 and not from the longer exposure time afforded by two sessions. When the total duration of the two sessions was the same as that of one session, infants still remembered longer. These findings reveal that new learning acquired via mere observation can remain latent for a substantial period before it is finally used.

In the preceding studies, infants learned an association (correlation) between two different objects when they repeatedly saw those objects together, irrespective of the experimental paradigm within which they exhibited that knowledge. In all instances, however, the association that infants had picked up by merely looking remained latent until they were subsequently given an opportunity to demonstrate that knowledge through their direct actions.

## 2.36.6 Interference and Memory Updating

Retroactive interference is rare or nonexistent in studies of infant visual recognition memory (for review, see Rose et al., 2007) but common in conditioning studies of infant long-term memory (Rossi-George and Rovee-Collier, 1999; for review, see Rovee-Collier and Boller, 1995). Three-month-olds who were exposed to a novel mobile immediately after training, for example, recognized it but not the original one 24 h later. With the passage of time, the retroactive interference dissipated, and infants again recognized only the original mobile 48 h later (Gulya et al., 2002). In serial learning studies with adults, a recency effect after short test delays and a primacy effect after longer ones is also common.

Because we have never observed an instance of modification or updating that was not also accompanied by response suppression to the original cue, we conclude that retroactive interference is functionally adaptive, enabling memory updating. When responding to the original cue is suppressed and organisms respond to the more recently encountered one, if that recent cue is also predictive, then the original memory is modified or updated. If response suppression is necessary for subjects to respond to a recently encountered stimulus, then the opportunity for memory updating may be over when responding to the original stimulus resumes. Because retroactive interference dissipates if a new cue is not encountered, however, the time window within which updating can occur also decreases until the details of the original cue are forgotten (Rovee-Collier et al., 1994) or the memory is reactivated later (Galluccio and Rovee-Collier, 2005).

Suppressing response to the original stimulus is evidence of retroactive interference, which is temporary. Responding to a recently exposed stimulus instead of the original one, however, is evidence that the memory was permanently modified. Retroactive interference is common at the beginning of the retention interval, when the details of the original stimulus are highly memorable, whereas modification occurs readily at the end of the retention interval, when the details of the original stimulus have been forgotten. Reactivated memories are resistant to modification shortly after forgetting (Boller and Rovee-Collier, 1994; Galluccio, 2005) but are more readily modified when reactivation approaches its upper limit. At 3 months, forgetting is complete in 6 days. One week after training, exposure to a novel mobile immediately after reactivation did not affect infants' recognition of the original mobile; 2 weeks afterward, it interfered with recognition of the original one; and 4 weeks afterward (the upper limit of reactivation at 3 months), it both interfered with recognition of the original mobile and modified the reactivated memory, replacing the memory attributes of the original mobile with those of the novel one (Galluccio and Rovee-Collier, 2005). Findings that both original and reactivated memories are initially resistant to modification but become more malleable when they are older suggest that the same basic mechanism underlies the malleability of original and reactivated memories.

## 2.36.7 Spacing Effects

A general rule in the memory literature is that greater spacing between successive items during training (associative memory) produces memories that are more enduring (Cohen, 1985). The classic retention advantage of distributed over massed training (Crowder, 1976; Glenberg, 1979; Schmidt and Bjork, 1992) has also been obtained with infants. Using a visual recognition memory task. Cornell (1980) showed 5- to 6-month-olds a pair of identical photos of people of one sex for four trials and then tested them after delays of 5 s, 1 min, 5 min, or 1 h with a previously exposed photo paired with a photo of a person of the opposite sex. He found that greater spacing between successive items prolonged infants' retention. When intertrial intervals were 3 s (massed condition), infants recognized the familiar photo only after the 5-s delay; when intertrial intervals were 1 min (distributed condition), they recognized it after all test delays. Using the operant mobile task, Vander Linde et al. (1985) trained 2-month-olds for three 6-min sessions (distributed condition) or one 18-min session (massed condition). Infants given massed training remembered for 1 day, but infants given distributed training remembered for 2 weeks.

Recent research on spacing effects has focused on the interval between successive events (retentive memory) after the first event has been acquired. This research has been conducted within the conceptual framework of the time window construct, which specifies the conditions in which two successive events are integrated (Rovee-Collier, 1995). A time window is a limited period that begins with the onset of an event and ends when the event is forgotten. It specifies when a second event can be integrated with the memory of the first one and when it cannot. New information encountered while the time window is open can be integrated with the initial event; information encountered after it has closed will be treated as unique. The integration is accomplished when the new event retrieves the representation of the initial event into primary or active memory. The time window construct specifies that each retrieval of a memory expands the time window (i.e., increases the period within which it can be retrieved again). Finally, the effects of retrieving the memory of the initial event at different points within the time window are nonuniform; retrieving it near the end of the time window expands the width of the time window more than retrieving it closer to when the time window opens.

In the first time-window study, Rovee-Collier et al. (1995) trained 3-month-olds in the mobile task for two sessions spaced by 1, 2, 3, or 4 days and tested them 8 days after session 1. The control group received session 1 only and the test. Groups exhibited significant retention when sessions were separated by 1–3 days. The group whose two sessions were separated by 4 days and the one-session control group exhibited no retention. Thus, the time window for integrating successive training sessions closed after 3 days. When the second session occurred after the time window closed, it was treated like a first-time event. In a follow-up study, groups received session 2 either inside the time window (2 days after session 1) or outside the time window (4 days after session 1) and a reactivation reminder 2 weeks later. Because memory reactivation requires two training sessions to be successful (Boller and Rovee-Collier, 1992; Richardson et al., 1993; Hayne et al., 2003), infants were expected to exhibit renewed retention after priming only if sessions 1 and 2 had been integrated. In fact, infants who received session 2 inside the time window exhibited retention, but infants who received session 2 outside the time window exhibited none. These results provide convergent evidence that successive events are integrated only if the second event occurs within the time window.

Hsu (2007) used the operant train task to study time window effects in infants between 6 and 18 months of age. The duration for which infants remembered a single training session defined the width of the time window at each age. Despite vast differences in the absolute durations of retention across ages, the pattern of results was remarkably uniform (**Figure 15**). Infants given session 2 just inside the time window remembered longer than infants given only one session, but infants given session 2 just outside the time window behaved as if they received only one session. Additionally, infants whose second session occurred at the end of the time window remembered longer than infants whose second session occurred at the beginning of the time window, 1 day after session 1.

The time window construct also predicts that retrieving the memory of the first event progressively later in its time window will produce an increasingly greater retention benefit. Using a reinstatement procedure, Galluccio and Rovee-Collier (2006) tested this prediction with 3-month-olds. Because 3-month-olds remember the mobile task for 5 days, they gave infants a single 3-min reinstatement 0, 3, or 5 days after mobile training. At the beginning of the time window (day 0), reinstatement afforded only a small retention benefit, 1 additional day. In the middle of the time window (day 3), reinstatement yielded a retention benefit of 5 additional days, or twice the duration of original retention. At the end of the time window (day 5), reinstatement yielded a retention benefit of 16 additional days, a duration of retention more than four times longer than 3-month-olds otherwise remember (**Figure 16**). The exponential increase in the retention benefit as a result of the timing of the reinstatement within the time window was particularly remarkable considering that the reinstatement lasted only 3 min, it was the same for all reinstatement groups, and the timing difference between the final reinstatement groups was only 2 days.

Because young infants' memories are so short-lived relative to the memories of older individuals, the consequences of the timing of a reinstatement within the time window are particularly dramatic. However, the differential retention benefit of presenting a reinstatement late in the time window is not unique to either the operant mobile task or 3-month-olds. A similar effect was obtained in a deferred imitation study with 6-month-olds. At 6 months, infants who imitated the actions immediately after the demonstration, when the time window opened, could defer imitation for 1 but not 2 days (Barr et al., 2001). In contrast, infants who first imitated the actions 1 day later, at the end of the time window, deferred imitation for 10 days after the demonstration (Barr et al., 2005).

Actively imitating the actions was not why infants' retention increased tenfold; infants who merely witnessed an adult model the actions again for 30 s 1 day later also deferred imitation after 10 days. Because

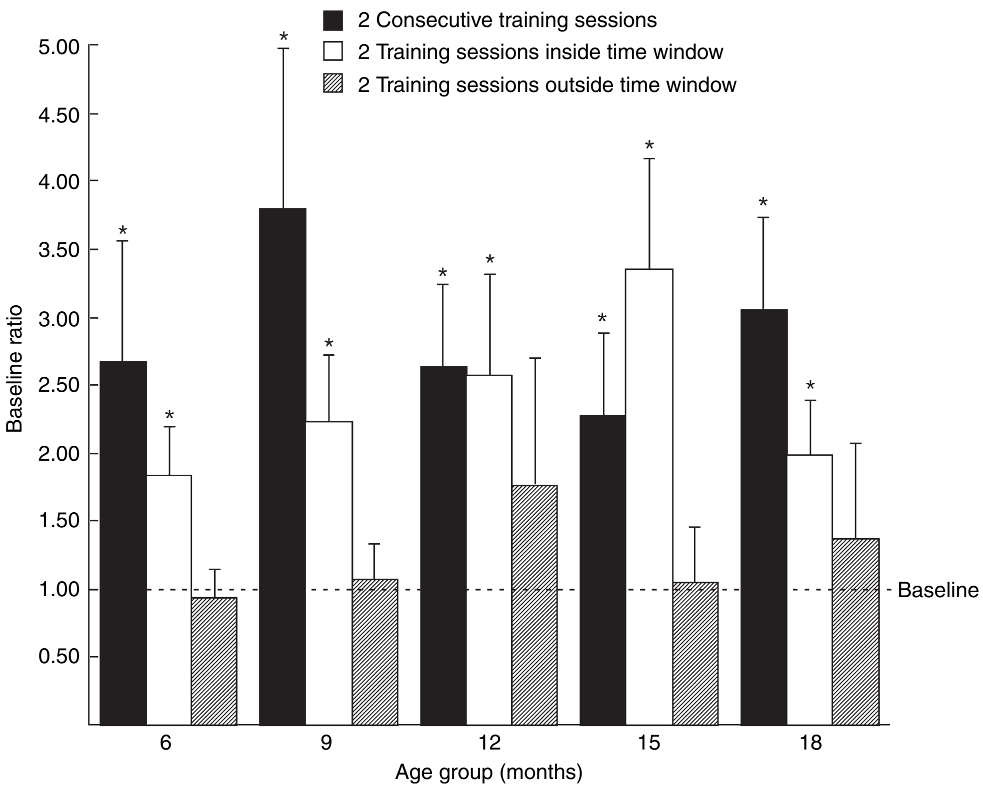

**Figure 15** Mean baseline ratios of independent groups of 6-, 9-, 12-, 15-, and 18-month-olds who received a second training session either inside (black bars, white bars) or outside (gray bars) the time window (i.e., before or just after infants forgot the first training session). Infants given session 2 just inside the time window (white bars) remembered longer than infants who were given only one session, but infants given session 2 just outside the time window did not. The dotted line indicates the theoretical baseline ratio of 1.00 (i.e., no retention). An asterisk indicates significant retention. Vertical bars indicate + 1 SE. From Hsu VC (2007) *Time Window Effects on Retention over the First Year-and-a-Half of Life.* PhD Thesis, Rutgers University, New Brunswick, NJ.

6-month-olds who observe the original demonstration for 30 s cannot defer imitation 1 day later (Barr et al., 1996), merely retrieving the memory at the end of the time window prolonged its retention. In a follow-up experiment, 6-month-olds who repeatedly retrieved the memory at or near the end of the expanding time window on days 1, 10, 30, and 70 still exhibited significant deferred imitation after 10 weeks. Whether they might have done so after a longer delay was not determined. Given that infants otherwise exhibit deferred imitation of the same modeled actions for 1 day, this finding is compelling evidence of the effects of repeated retrievals near the end of the time window.

In a recent study, 6-month-olds' memory of the demonstration was associated with the 'retrieved' memory of the operant train task (Rovee-Collier and Barr, 2006). Six-month-olds first learned to move the train by lever pressing, and 7 days (the midpoint of the time window for the train task) or 14 days (the end of its time window) later, the target actions were modeled on a puppet in the presence of the stationary train. After both delays, the sight of the train cued retrieval of the memory of the train task, and the demonstration was then associated with the updated status of its memory representation. When the demonstration was associated with the retrieved memory 7 days after operant training, infants remembered the train task for 4 weeks instead of 2 weeks, and they also deferred imitation on the puppet for 4 weeks instead of 1 day. When the demonstration was associated with the retrieved memory 14 days after operant training, infants remembered the train task for 8 weeks instead of 2 weeks and deferred imitation on the puppet for 6 weeks instead of 1 day. A no-association control group that saw the demonstration and the stationary train unpaired 7 days after operant training failed to defer imitation 1 week later but continued to remember the train task for 14 days.

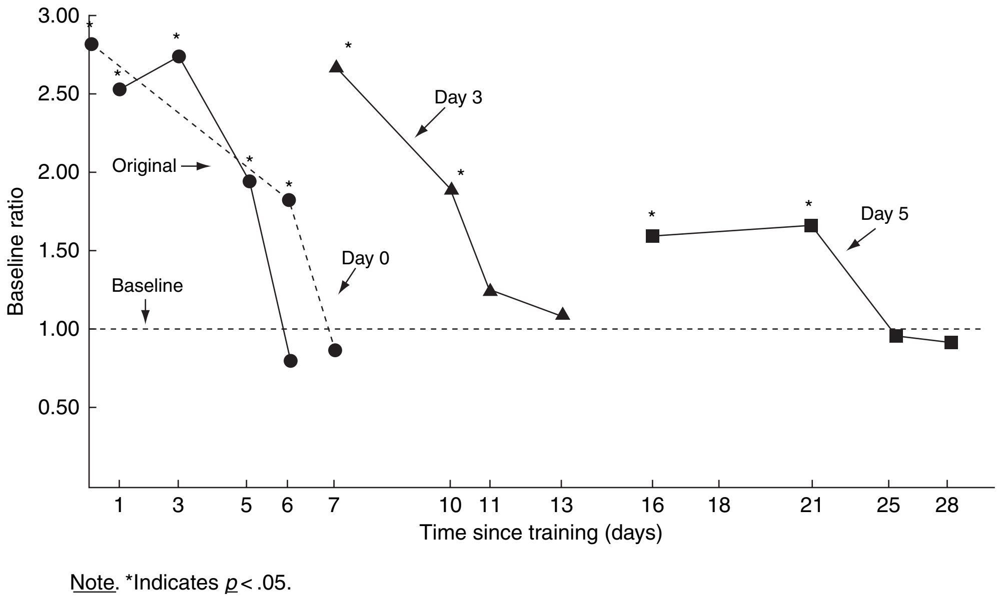

**Figure 16** Mean baseline ratios of independent groups of 3-month-olds whose retention was tested after increasing delays since training (the simple forgetting function: circles, solid lines) and after receiving a reinstatement on day 0 (circles/dashed lines), day 3 (triangles/solid lines), and day 5 (squares/solid lines). The first point on the day-0 function is the retention of group 0/6 at the end of training, immediately before the reinstatement was administered. An asterisk indicates that a group exhibited significant retention. From Galluccio L and Rovee-Collier C (2006) Nonuniform effects of reinstatement within the time window. *Learn. Motiv.* 37: 1–17. Copyright © 2006 by Elsevier Inc.

What does all of this mean? Clearly, memory retrieval – particularly later in the time window – has a huge effect on the memory of what was retrieved as well as on the memory of what is associated with it, and the effects of multiple retrievals are even greater. Because most memory retrievals in real-world settings are probably latent, as are most of the associations into which retrieved (activated) memories enter, the extent of their contribution to the growth of the early knowledge base can never be known.

Time window effects have also been reported in infant studies of categorization, eyewitness testimony, postevent information, memory modification, and language acquisition (for review, see Rovee-Collier, 1995; Hsu, 2007). Although the applicability of the time window construct is not constrained by age or stage of development, its impact on the retention of very young infants, whose retention is initially so brief, may be most obvious.

## 2.36.8 Implicit and Explicit Memory

Many psychologists believe that adults possess two functionally independent and anatomically different memory systems that mature hierarchically (e.g., Schacter and Moscovitch, 1984; Bauer et al., 2007). By this account, infants possess only the primitive memory system (implicit memory) until late in their first year, when the higher-level system (explicit memory) matures. Proponents of dichotomous memory systems interpret functional dissociations as evidence for different memory systems (e.g., Tulving, 1983; Squire, 1987). A functional dissociation is seen when the same experimental manipulation that produces impaired performance by brain-damaged amnesic adults on recall or recognition tests does not affect their performance on priming tests. Recall and recognition tests are thought to tap the explicit memory system, which presumably processes information about a specific past experience; in contrast, priming tests are thought to tap the implicit memory system, which presumably processes information only about skills and procedures that can become habitual or automatized and general facts. A large literature has now amassed, however, documenting that even 3-month-olds exhibit all of the same functional dissociations on recognition and priming (reactivation) tests as adults (for review, see Rovee-Collier et al., 2001).

For proponents of dichotomous memory systems, however, the defining characteristic of explicit memory is the conscious awareness of previously experiencing the event (Tulving, 1985), and they use conscious awareness to distinguish explicit from implicit memory. On a priming test, for example, amnesics (who presumably possess only an implicit memory system) respond with a word from a list they had just studied while being unaware that they had studied it. Amnesics also fail deferred imitation tests that healthy adults use conscious recollection to perform. As a result, proponents of dichotomous memory systems assume that infants who exhibit deferred imitation must also use conscious recollection to do so. Based on this assumption, they use deferred imitation as a benchmark that the explicit memory system is functionally mature (McDonough et al., 1995; Bauer, 1996; Bauer et al., 2007). If successful deferred imitation constitutes evidence that the explicit memory system has matured, however, then it must be mature by 3 months of age. Recall that infants who saw target actions modeled on a hand puppet at 3 months of age successfully imitated them once they were motorically capable of performing them (Campanella and Rovee-Collier, 2005).

Evidence that 3-month-olds exhibit both functional dissociations and deferred imitation disputes the notion that implicit and explicit memory develop hierarchically during the infancy period. If there are two memory systems, then they must develop in parallel from early in infancy. We note, however, that because scientists can neither define consciousness nor state what the function of consciousness in memory might be, it is not yet clear how memories that have it might be different from memories that do not (Willingham and Preuss, 1995).

## 2.36.9 Infantile Amnesia

Infantile amnesia refers to the fact that most people cannot remember events that occurred before the age of 3 or 4 (but see Fivush and Hamond, 1990; Usher and Neisser, 1993). There has been little agreement about the basis or even the ubiquity of this phenomenon (Mandler, 1990). Common explanations of infantile amnesia include the classical psychoanalytic account of repressed infantile memories, the immaturity of the infant's brain that prevents the encoding, storage, and retrieval of memories over the long term, young infants' exclusive reliance on a primitive memory system, and rapid forgetting within the infancy period. Most of these explanations were discounted by evidence reported earlier in this chapter.

Additionally, verbal cues are usually presented as retrieval cues in studies of infantile amnesia. The common conclusion is that "virtually no early memories slip through the barrier" (Nelson, 1990: p. 306). Simcock and Hayne (2002 see also Simcock and Hayne, 2003) questioned whether the development of language actually blocked early memories. To answer this, they developed a memory task using the Magic Shrinking Machine (**Figure 17**), in which 27-, 33-, and 39-month-olds participated in a highly unique, multistep event in their homes. Children learned a sequence of five target actions: Pull a lever to activate an array of lights and turn the machine on, pick a toy from the toy case (ball, teddy bear), drop the toy in a chute on top of the machine, turn the handle on the side of the machine (which produced noise and music from inside the box), and retrieve a smaller version of the toy from the front of the machine. Either 6 or 12 months later, infants' memory of the event was assessed with both verbal and nonverbal measures. Children of all ages exhibited retention on both measures after both test delays, but their memory performance on nonverbal measures was consistently superior. Importantly, children's verbal reports during the long-term test reflected their verbal skills at the time of encoding, even though the words that could be used to verbally recall the event were in their vocabularies at the time of testing. Thus, children with language could remember the prior event that had been encoded preverbally, but they could not translate what they had encoded into words.

Because the fundamental principles of memory processing in human infants and adults are the same, we conclude that the phenomenal experience of infantile amnesia can be understood within the existing framework of normal memory process. First, the encoding specificity principle (Tulving and Thomson, 1973) states that a match between the encoding and retrieval contexts is critical for retrieval. In infancy, this is especially true after long delays (Hartshorn et al., 1998a). As a result, the shift from nonverbal to verbal retrieval cues dramatically lessens the probability that a memory encoded in infancy would be retrieved later in life. From this perspective, words are retrieval cues whose status is no different than that of other potential retrieval cues.

Second, even if an appropriate retrieval cue were to recover an early memory later in life, a person

**Figure 17** A child participating in the memory task with the Magic Shrinking Machine. The child places a large toy in a chute on top of the machine, turns the handle on the side of the box (presumably to shrink the toy), opens a side bin (where the shrunken toy has presumably dropped), and retrieves a miniature version of the toy. Photos courtesy of Harlene Hayne and Julien Gross.

would be unlikely to identify it as such. Because reactivated memories that are older are readily updated, for example, they may be impossible to identify as having originated early on (Galluccio and Rovee-Collier, 2005).

Third, as memories of healthy individuals become increasingly remote, they appear to become increasingly disconnected from their original temporal context and more semantic and fact-like (Bayley et al., 2003). Even in infants, specific contextual information is quite fragile and disappears from memories that are older or were previously reactivated (Hitchcock and Rovee-Collier, 1996; Galluccio and Rovee-Collier, 2005). As a result, people might actually remember many early-life events without knowing where or when they occurred. Alternatively, if an early memory was modified after a long delay, then it might differ substantially from the original one (Galluccio and Rovee-Collier, 2005). Even if an early memory were neither updated nor repeatedly retrieved, its recovery is ultimately constrained by the upper limit of reactivation (Hildreth and Hill, 2003; Hsu and Rovee-Collier, 2006).

## 2.36.10 Conclusions

Although the neurological mechanisms (the hardware) that underlie learning and memory change over development, the operating principles (the software) that describe how individuals learn and remember do not. While the same variables and manipulations affect memory processing in the same ways in infants and adults, the temporal parameters of memory processing change dramatically but in an orderly fashion over the infancy period: (1) the duration of retention after original training increases, (2) the duration of retention after reminding increases, (3) the speed of responding to a memory prime increases, (4) the upper limit of reactivation increases, and (5) the minimum duration of exposure to a memory prime decreases. Most if not all of these changes can be produced at younger ages by retrieval experience. While later developments such as verbal and conversational skills, strategies for remembering, and the development of the self-concept may facilitate the efficiency of memory processing, they do not alter the fundamental mechanisms that underlie it.

Recent research with very young infants has expanded our knowledge of infant memory far beyond what was ever imagined possible, with equally dramatic implications for the infant's rapidly burgeoning knowledge base. The findings show that very young infants rapidly form new and relatively enduring associations between stimuli that are physically present in their visual surroundings and even between the activated memory representations of stimuli and events that are not. These new associations become linked with each other and with other members of a complex and rapidly growing associative network. When one member of an association is activated, the activation spreads to other members in the network and indirectly activates them as well. As a result, infants as young as 6 months of age exhibit bidirectional priming (Barr et al., 2002) and transitivity (Townsend, 2006) on deferred imitation tests and use correlated attributes to categorize novel stimuli on delayed recognition tests (Bhatt et al., 2004). The same processes may also be responsible for false memories and behavior that appears insightful in children and adults.

These findings necessitate a major revision in how we think about infant memory. Although some aspects of infant memory processing are age invariant, such as the effects of priming on various independent variables, other aspects of infant memory processing change with experience. Importantly, the fact that these changes are logarithmic and subject to Weber's Law indicates that memory processing is perceptually based. That said, the content of what is retrieved apparently results from activation that spreads nonlinearly through a growing web of associations, most of which will always remain latent. In short, infant memory is like other things in life: nothing is as simple as it once seemed.

**C. A. Haden**, Loyola University Chicago, Chicago, IL, USA

**P. San Souci**, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

## 2.37.1 The Development of Skilled Remembering in Children

A number of the intellectual giants of the nineteenth and early twentieth centuries thought seriously about the mnemonic abilities of young children. Initial considerations of children's remembering can be seen in Darwin's (1877) and Preyer's (1882/1889) diary case studies of their own children's memory skills, in Binet's (e.g., Binet and Henri, 1894a, Binet and Henri, 1894b) early experiments on children's memory for words and ideas, and in Freud's (1901) initial psychoanalytic writings about infantile amnesia. Sustained interest in children's memory was reflected in Hunter's (1913) basic studies of memory capacity and retention and in Stern and Stern's (1909) applied investigations of memory, suggestibility, and eyewitness testimony. Moreover, assessments of memory figured prominently in initial measures of intellectual capacity (e.g., Terman, 1916; Terman and

Merrill, 1937; Wechsler, 1939) – as they do today – but even this important early work did not prompt widespread interest in the development of memory. Indeed, reflecting to some extent the dominance of the behaviorist perspective in both experimental and developmental psychology, it would take more than 50 years for systematic research on children's memory to start to appear in the developmental literature. The first signs of renewed interest in the development of memory can be seen in Flavell's seminal explorations of children's use of strategies for remembering (e.g., Flavell, 1970; Flavell et al., 1996), and in a few years, there was sufficient critical mass in the area to justify a symposium on children's memory at the 1971 meeting of the Society for Research in Child Development. Flavell organized this now-celebrated symposium – "What is memory development the development of?" – to characterize what was then known about children's memory.

The last 35 years have witnessed a dramatic increase in research on children' abilities to remember (Kail and Hagen, 1977; Schneider and Pressley, 1997; Ornstein et al., 1998; Courage and Cowan, in press), but in many ways the research literature bears the imprint of the question posed at the 1971 symposium. Admittedly, the answers to this question have changed dramatically over the years as a function of changes in research paradigms, theoretical frameworks, and even the ages of the children being studied, but there has nonetheless been a consistent emphasis on characterizing that 'something' (e.g., strategies, underlying knowledge, basic capacity) thought to be changing with age (Ornstein and Haden, 2001; Ornstein et al., 2004). The net result is that a great deal is now known about the contrasting memory skills of children of different ages, as is documented in this chapter. However, in contrast to the progress that has been made in response to the 'what develops' question, relatively little is known about the process of development. For example, how do early manifestations of a skill (e.g., a naming strategy) give way to later and more sophisticated examples of that skill (e.g., a more complex rehearsal strategy), and what can be said about the rate of change that is observed? Most importantly, what factors are responsible for bringing about this developmental change? To a certain extent, researchers have focused remarkably well on issues of memory development but not very much on the development of memory (Ornstein and Haden, 2001; Ornstein et al., 2004).

In addition to this important distinction between memory development and the development of memory, the stage for this chapter is set by two pervasive themes in the now-voluminous research literature on children's remembering. First, a substantial corpus of work now documents the remarkable mnemonic competence of infants (e.g., Meltzoff, 1995; Rovee-Collier, 1995, Bauer et al., 2000; Bauer, 2006; *See* Chapter 2.36) and preschoolers (Baker-Ward et al., 1984; Goodman et al., 1990). Second, an equally impressive literature confirms the presence of substantial age differences in aspects of memory performance that include the degree of detail reflected in children's reports (e.g., Fivush and Hamond, 1990; Roebers and Schneider, 2001), the amount of forgetting observed (Brainerd et al., 1990; Howe and Courage, 1997), and the deployment and effectiveness of deliberate strategies for remembering (Ornstein et al., 1988; Bjorklund, 1990; Schlagmüller and Schneider, 2002). These two themes – the surprising competence of young children's memory on the one hand and clear age-related differences in performance on the other hand – represent a distillation of evidence stemming from research paradigms that range from elicited and deferred imitation (Meltzoff, 1995; Bauer et al., 2000, Bauer, 2006) and conditioning (Rovee-Collier and Shyi, 1992; Rovee-Collier, 1997) to those involving the production of narrative accounts of previous experiences (Fivush, 1991; McCabe and Peterson, 1991; Reese et al., 1993) and verbal measures of both strategy use and remembering (Baker-Ward et al., 1993; Folds et al., 1990; Schlagmüller and Schneider, 2002).

The aim of this chapter is to provide an overview of children's memory, focusing on age-related differences in the underlying processes of encoding, storage, retrieval, and reporting. With respect to the flow of information within the developing memory system, the emphasis is on early mnemonic competence and age-related changes in a range of memory skills, characterizing children's abilities at different points in time and exploring factors that serve to bring about change. However, reflecting the relative dearth of information in the literature on the development of memory, the bulk of the work reviewed here deals with memory development. To some extent, this state of affairs reflects the predominance of cross-sectional research designs, in which the performance of children of different ages is contrasted, and the infrequent use of longitudinal designs in which the same children are tracked over time. There are, of course, many reasons why cross-sectional designs have been favored, but longitudinal research is certainly necessary for an account of developmental change within individuals, especially given the evidence to date that cross-sectional findings are not always replicated within a longitudinal framework. For example, although the cross-sectional literature would suggest a smooth age-related progression in the skill with which an organizational strategy is deployed, inspection of individual developmental trajectories available from the Munich Longitudinal Study reveals a markedly different pattern: Children's strategic deployment seems to be characterized by inconsistency and abrupt change across measurement points (Sodian and Schneider, 1999). As such, longitudinal designs are essential if the aim is to address issues concerning the development of memory, but these designs must be chosen so as to provide information concerning factors – within the child and within the environment – that may serve as mediators of the developmental change that is observed.

The bulk of the chapter is devoted to characterizing age differences in various aspects of children's memory performance, making extensive use of the cross-sectional literature. To the degree possible, longitudinal data are utilized to supplement this characterization of children's abilities in an attempt to move the discussion to (1) a description of the course of developmental change and (2) a treatment of potential mediators of this change. However, because longitudinal research designs are inherently correlational in nature, the treatment of longitudinal studies is combined, where possible, with parallel experimental investigations in which hypothesized mediators of change (e.g., mother–child communicative interactions) are brought under experimental control. These experimental interventions (e.g., Carr et al., 1989; Boland et al., 2003) are necessary if the aim is to make causal statements about factors that serve to bring about developmental change. In addition, the findings of these cross-sectional, longitudinal, and intervention studies are supplemented by a discussion of the few extant microgenetic studies of children's memory. In microgenetic studies (see Siegler and Crowley, 1991; Siegler, 2006), frequent observations are made of children's performance during periods in which their skills are thought to undergo rapid change and development (e.g., Schlagmüller and Schneider, 2002).

The sections that follow are devoted to a discussion of two basic literatures that are not often treated together: Children's memory for specific events that are typically experienced without intent to remember, as well as their deliberate memory for materials that are encoded with the expectation of a subsequent memory assessment. These different aspects of mnemonic competence are discussed together because the underlying processes of encoding, storage, retrieval, and reporting seem to operate in a similar manner in each of these domains (Baker-Ward et al., 1997; Ornstein et al., 2006b). Moreover, it seems likely that elemental skills in talking about past experiences set the stage for later accomplishments within the domain of deliberate remembering (Haden et al., 2001). After a consideration of research on the nonverbal memory skills of infants and young toddlers, the discussion turns to children's verbally based memory for events and autobiographical experiences, and then to a treatment of their strategic efforts in tasks that require deliberate remembering.

## 2.37.2 Nonverbal Memory

Given its developmental focus, the emphasis in this chapter is on the emergence and growth of children's verbal mnemonic skills. Nonetheless, it is important to appreciate the fact that the verbal skills that are described here are built upon a nonverbal foundation and that considerable attention has focused on characterizing this foundation (see, e.g., Barr and Hayne, 2000; Rovee-Collier et al., 2001; Bauer, 2006; Oakes and Bauer, 2007; Courage and Cowan, in press), with researchers using a wide variety of behavioral measures to piece together a picture of what infants can remember over varying delay intervals. Two caveats are in order, however, as we begin this brief treatment of early memory. First, the conclusions that one can reach about young children's memory seem to vary as a function of the measures used to assess remembering, and little is known about the extent to which the different measures converge to characterize children's skill at any one point in development. Second, little is also known about the ways in which children's nonverbal memory performance leads to (or predicts) subsequent performance on tasks that require verbal reports.

### 2.37.2.1 Estimates of Long-Term Retention

It is clear that infants evidence remarkable skills in being able to retain information over delays that increase dramatically over the first year and a half of life. Early retention has been demonstrated in paradigms ranging from visual paired comparison and habituation to conditioning and imitation, with estimates of retention in neonates that range from a few minutes to weeks on visual habituation tasks (e.g., Slater et al., 1984; Pascalis et al., 1998), to months by the end of the first year on elicited imitation tasks (e.g., Carver and Bauer, 2001). But what can be said about the age-related changes in the nature and complexity of the information that is being retained? To illustrate current understanding related to this important question concerning early memory, we focus on studies of children's performance in the context of two tasks: operant conditioning (*See* Chapter 2.36) and elicited/deferred imitation procedures. (Meltzoff, 1985, 1995; Bauer, 2007). Systematic research with these behavioral tasks has enabled researchers to document infants' quite dramatic mnemonic skills and has also sparked a lively debate concerning the nature of early memory (e.g. Nelson, 1995; Bauer, 1996; Rovee-Collier, 1997).

#### 2.37.2.1.1 Conjugate reinforcement paradigms

In the conjugate reinforcement paradigm, an infant – typically between 3 and 6 months of age – is placed on her back with a mobile overhead. After an operant period in which the infant's base level of kicking is measured, her leg is connected via a ribbon to the mobile. With this arrangement, each kick is followed by the reinforcement of observing the mobile move, and stable responding in its presence can easily be established. With the operant response acquired, remembering after varying intervals can readily be assessed under conditions of extinction in which the ribbon is disconnected from the mobile, so that no contingencies are in effect. Memory is then inferred if the rate of kicking observed in these test periods is greater than that seen in the baseline period, and under these conditions two fundamental patterns of age differences in performance in the first 6 months of life have been reported: Both speed of learning and length of retention increase with age. Thus, older infants acquire the kicking response more rapidly than younger children, and when trained to the same criterion of performance, they retain it longer than their younger peers (e.g., Hill et al., 1988).

Programmatic research with the mobile conjugate reinforcement task has also revealed two other important features of early memory. First, under some conditions, memories that would seem to be forgotten can be cued and recovered. Indeed, by using reinstatement, partial reminders of a previous experience (Campbell and Jaynes, 1966), and reactivation (Spear and Parsons, 1976) procedures in which a component of the original event is presented at the end of the delay interval, retention of the kicking response can be extended considerably (e.g., Sweeney and Rovee-Collier, 2001). Typically, exposure to the mobile or the context (e.g., the crib lining) can serve to maintain memory over an extended delay, but the timing of the reminder is of critical importance, with maximal facilitation occurring if it is administered shortly before the assessment of long-term memory, as long as the response has not yet been forgotten (Sullivan, 1982; Rovee-Collier et al., 1987; Rovee-Collier and Hayne, 1987). Second, Rovee-Collier and her colleagues have shown that the kicking response can be remarkably sensitive to changes in aspects of the mobile and/or the context, with maintenance of responding being dependent upon a complete overlap in the cues present during learning and subsequent testing. Even a change in a single element of the mobile or the decoration on the crib liner can lead to dramatic disruptions in performance (Hayne et al., 1986; Borovsky and Rovee-Collier, 1990; Rovee-Collier et al., 1992). These findings provide useful information about the precision of early memory and the specificity of the underlying representations in memory that have been established (*See* Chapter 2.36).

#### 2.37.2.1.2 Imitation-based paradigms

In the elicited and deferred imitation paradigms, memory is demonstrated when an infant is able to use props to reproduce an action sequence that had previously been modeled by an examiner. Consider, for example, the acts involved in constructing a gong: putting a crossbar atop two posts, hanging a metal plate on the crossbar, and then hitting the plate with a plastic mallet. After a baseline period in which a young child interacts freely with these materials, an experimenter demonstrates the sequence that will lead to the construction of the gong one or two times while, under some conditions, providing simple labels for each of the actions. Typically, in the elicited but not the deferred imitation procedure, the modeling of these actions is accompanied by a verbal description of the target actions and the goal of the event sequence. Moreover, in the elicited imitation paradigm, an immediate assessment of memory is typically obtained, with the child being invited to imitate the modeled sequence of actions: for example, "Now you show me how to make a gong." Memory is usually also assessed after a delay, with and without the verbal cue. In contrast, in the deferred paradigm, imitation is assessed, but without much verbal prompting, and only following a delay. As such, in the deferred imitation procedure, there is no immediate indication of remembering – and hence of initial encoding, or even of whether the child has the motor ability to reproduce the sequence – although control groups have been used to approximate children's ability to imitate the sequences following presentation (see Meltzoff, 1985; Barr et al., 1996). In tests of elicited imitation, children act as their own controls, such that memory is indexed by their better performance with previously modeled versus novel event sequences. It is worth noting that the procedural differences between the deferred imitation and elicited imitation tasks can make a difference in memory performance (e.g., Hayne et al., 2003), with exposure to language cues and the opportunity to imitate the action sequences immediately after modeling facilitating long-term retention.

As previously mentioned, converging evidence from the elicited and deferred imitation paradigms shows that the age-related changes that begin in infancy, to the extent to which information can be held in memory, continue during toddlerhood. For example, 6-month-olds are able to produce parts of a three-step sequence 1 day – but not 2 days – after it is modeled (Barr et al., 1996). Importantly, two features of this demonstration of early recall provide a foundation from which improvement in mnemonic skill can be observed across the first 2 years of life. First, recall at 24 h is dependent upon the amount of experience that the infants have with the modeled action sequence: Approximately two-thirds of the children who had seen the three-step sequence six times produced at least one of the actions 1 day later, whereas the children who had observed the sequence only three times did not differ from control participants who had not witnessed the modeling. Second, there is essentially no evidence that the children can produce the components of the sequence in order, either immediately or after the 24-h delay. In contrast, by 9 months of age, infants are able to recall individual components of novel two-step sequences after 5 weeks (Carver and Bauer, 2001). Approximately half of the 9-month-olds are able to produce the sequences in correct temporal order after a delay of 5 weeks (e.g., Bauer et al., 2003) but not after 3 months. To be sure, this is a period in which skills for remembering change in a dramatic fashion, as illustrated by the fact that by 10 months, children evidence ordered recall at delays of both 1 and 3 months (Carver and Bauer, 2001).

Although this improvement in performance is certainly impressive, it should nonetheless be emphasized that the temporally ordered recall of 9- and 10-month-olds is still rather limited. First, the children's recall is dependent upon multiple exposures to each modeled event sequence. Indeed, as Bauer (2006) indicates, ordered recall at these ages is observed if the infants observe the target sequence on two (and sometimes three) occasions before the onset of the delay. Under these conditions, approximately 45% of the infants evidence ordered recall after 1 month; however, if children view a to-be-remembered sequence at only one session, then these figures drop considerably, with only 7% providing ordered recall (Bauer et al., 2001; Bauer, 2006). Second, the size of the event sequences that are to be remembered is rather small, with 9- and 10-month-olds typically being able to remember two-step events, and third, the length of time over which information can be remembered is quite short.

Each of these limitations is overcome to a considerable extent over the course of the second year of life. For example, by 13 months of age, children no longer need multiple exposures to an event in order to remember it over a delay of several months (Bauer et al., 1995), and yet remembering is clearly enhanced by the opportunity to experience an event sequence several times. In addition, with increases in age, children are better able to remember longer sequences for greater periods of time. To illustrate, in contrast to the two-step events that are remembered by 9- and 10-month-olds, children at 24 months of age can produce sequences of five steps in length (Bauer and Travis, 1993). Finally, the length of time across which ordered recall can be observed increases dramatically during this time period; indeed, 100% of children at 20 months of age are able to recall in an ordered fashion after 1 month, with more than half evidencing memory for portions of the to-be-remembered sequences after delays as long as 1 year (Bauer et al., 2000). For additional information concerning imitation-based approaches to the exploration of young children's memory, see Bauer's recent reviews (2006, 2007).

### 2.37.2.2 Exploring the Underlying Representation

Research on young children's memory with the conjugate reinforcement and imitation-type paradigms provides information about age-related differences in the conditions under which representations in memory can be established and maintained over time. But what can children's behavior in these two types of situations tell us about the structure and contents of these representations? The conjugate reinforcement procedure is a recognition (as opposed to recall)-based assessment, in which the index of remembering is based on kicking in the presence of a previously experienced stimulus. The specificity of children's responding in these studies – with the response rate dropping off markedly as a function of changes in the mobile or crib context – would suggest that the representation is both detailed and specific. However, even though variation in kicking patterns provides a sensitive indicator of whether or not elements of the mobile or context have changed, the procedure is not informative about the ways in which component features may be organized sequentially in the underlying representation. Yet this type of information is available in the imitation paradigms because responding involves recall, albeit action-based – not verbally based – recall, as opposed to recognition. Admittedly, infants cannot generate long strings of actions, but those that they do produce include the elements of events that are being remembered. Moreover, with increases in age, children's productions become more and more sequentially organized, thus reflecting the structure of the events and the underlying organization of the representation (Bauer et al., 2000). Finally, 1- to 2-year-olds readily apply their prior knowledge to the task of remembering action sequences, as can be seen in their enhanced recall of enabling as opposed to arbitrary sequences (Bauer et al., 2000). With enabling sequences, each action must be performed in a temporally invariant pattern in order to reach the end state (e.g., making a rattle with a ball and a nesting cup by first placing the ball in one-half of the cup and then covering it with the other half before it is shaken); in contrast, in arbitrarily ordered sequences, there are no inherent constraints on the temporal position of the actions (e.g., in making a party hat, it does not matter if a pompom is put on top before a sticker is placed on the front).

### 2.37.2.3 Bridges to Verbally Based Remembering

Researchers using conjugate reinforcement and imitation-based tasks have provided alternative perspectives on the mnemonic skills of infants, but it is nonetheless clear that these views are complementary and indicate that an impressive memory system is in place before language is available for the encoding and reporting of information. Given these demonstrations of a mnemonic foundation, what can be said about linkages between early nonverbal memory and later verbally based skills for remembering information? At one level, statements about the extent to which young children's early (and rapidly changing) abilities are related to their later verbally based mnemonic skills are quite limited. These statements must be based on longitudinal studies in which children are assessed initially on nonverbal memory tasks and then later on verbally based procedures, and the necessary data have not yet been reported in the literature. At another level, however, questions about linkages between early nonverbal and later verbal memory can be addressed in terms of the types of memory systems that are in place at the two points in time, and from this systems perspective, there may indeed be evidence for developmental continuity. More specifically, a strong claim can be made that the imitation-based tasks tap explicit (as opposed to implicit) memory, and thus line up well with the explicit memory tasks that are employed in assessments of children's abilities to talk about past experiences and prepare for deliberate assessments of memory (Bauer, 1996, 2006).

In order to evaluate this claim, it is necessary to review the distinction between explicit and implicit memory. There certainly are many ways of characterizing memory, but a distinction between explicit (or declarative) and implicit (or nondeclarative) memory is widely accepted (Schacter, 1987; Squire, 1987; Moscovitch, 2000). These two types of memory are thought to differ on many dimensions. For example, in the type of information that is being remembered, in the speed with which it is acquired and lost over time, and in the degree to which remembering involves conscious recollection. To illustrate (and greatly simplify), consider the way in which an experience of visiting a friend may be processed by the explicit memory system. The features of this visit (e.g., names, facts, locations) are rapidly encoded, but specific information can also be lost over time (and/or replaced in a constructive manner with related information). Yet, in any event, the telling of the tale certainly involves conscious recollection. Now, by way of contrast, consider the way in which a perceptual motor skill – such as driving a car or riding a bicycle – is acquired and represented in implicit memory. These skills require a great deal of practice and are literally honed over longer periods of time; but once mastered, there is little forgetting, and production does not entail conscious recollection. In addition, recent research suggests that in the latter half of the first year, it is possible to differentiate explicit and implicit memory systems structurally, with explicit memory relying on the hippocampus (in particular, the dentate gyrus and other supportive cortical structures), and implicit memory depending on the neostriatum and cerebellum (Eichenbaum, 2003).

From this vantage point, the types of memory that are the focus of this chapter – e.g., a child's report of a recently experienced event or recall of a list of words – would certainly be seen as involving the explicit memory system, but what can be said of the demonstrations of children's nonverbal memory prowess discussed above? To the extent to which any one of the nonverbal tasks used to assess memory in infancy can be viewed as tapping into the explicit memory system, there would be continuity across the nonverbal/verbal divide in terms of memory systems that are in place. In this regard, Bauer (2006, 2007) has argued convincingly that the imitation-based techniques capture the essence of explicit memory. She points out that the infants who are assessed with imitation-based procedures rapidly encode and learn the modeled event sequences, without extensive practice, but also that their memories are fallible, with considerable forgetting over time being observed. Moreover, the memory that is assessed with imitation procedures is clearly rather flexible in that it is preserved (or generalized) across variations in materials contexts. Admittedly, these tasks do not involve verbal reports, and it is impossible to know whether the infants whose performance is assessed experience a sense of conscious recollection, but one other source of evidence is relevant to the argument: Adult humans with amnesia that impairs their performance on explicit memory tasks have been shown to have deficits on the elicited imitation task (McDonough et al., 1995).

In contrast to these procedures, conjugate reinforcement has typically been viewed as reflecting implicit memory (Mandler, 1990, 1998; Schneider and Bjorklund, 1998; but see Rovee-Collier, 1997, and Chapter 2.36, for a contrasting perspective). As indicated in Section 2.37.2.1.1, these tasks are based on operant conditioning procedures, and both operant and classical conditioning have been taken – along with perceptual-motor skills and priming – to be indicators of implicit, as opposed to explicit, memory. Moreover, the contrast between conjugate mobile and imitation tasks can be seen in the basic features of performance: Learning in the conjugate reinforcement task takes a considerable amount of practice before stable levels of kicking are reached, and once the response is acquired, the memory seems to exhibit very high levels of specificity. Indeed, as suggested earlier, even minor changes in the mobile or the context are sufficient to disrupt performance considerably.

Given this view that deferred and elicited imitation tasks involve the same explicit memory system that is activated in verbally based tasks, we would expect that longitudinal analyses would reveal linkages between children's performance on the different procedures. Another reason for this expectation is that the imitation tasks seem to have greater face validity than does conjugate reinforcement, especially in terms of potential links both to language and to event memory as is reflected in assessments of older children's mnemonic skills. For example, although the evidence is admittedly mixed (Bauer et al., 2000; Bauer, 2006), under some conditions young children's elicited imitation is influenced positively by their language skills, and it is known that verbal ability plays a significant role in later events and autobiographical memory (Bauer and Wewerka, 1995; Welch-Ross, 1997; Boland et al., 2003). In addition, the task demands of the elicited imitation procedure seem similar in certain critical respects to those of tasks that are used to explore 2- and 3-year-olds' reports of their previous experiences. More specifically, the conversations between young children and their parents about recently experienced events that will be discussed below involve remembering and subsequently reporting the details of these experiences. As such, both elicited imitation and mother–child reminiscing procedures involve event recall, even though remembering is expressed motorically in one procedure and verbally in the other. Moreover, given that both procedures yield information about children's recollections about the component details of previously experienced events, they, in principle, provide insight into the underlying memory representations.

Given this discussion of conceptual linkages between the elicited imitation and verbally based assessments of children's memory, we turn now to a treatment of children's verbal reports of personally experienced events. In the section that follows, we provide an overview of children's memory for routine and unique experiences and discuss factors that impact developmental changes in remembering.

## 2.37.3 Learning to Remember

### 2.37.3.1 Remembering Previously Experienced Events

Starting with the work of Nelson and her colleagues (e.g., Nelson and Gruendel, 1979; see Nelson, 1986, for an overview) on children's memories for familiar and recurring events, the corpus of research on preschool-aged children's abilities to remember their personal experiences has expanded in an impressive fashion. Indeed, in addition to what we now know about children's abilities to produce scripts or generalized event representations for routine experiences such as going grocery shopping or dining at a restaurant, there is now a voluminous literature concerning their abilities to recall the details of specific, distinctive events that they have experienced. In providing a selective treatment of this work, we first discuss research on children's scripts, then review evidence concerning their memory for salient target events, and finally move to a description of studies that have emphasized event memories expressed in parent–child conversations about the past. We do so with a focus on the establishment, maintenance, and modification of event memories, emphasizing the role that knowledge plays in affecting the flow of information through the developing memory system.

#### *2.37.3.1.1 Children's scripts*

In their initial studies, Nelson and Gruendel (1981) conducted semistructured interviews with children as young as 3 years of age about what happens during familiar and routine events, such as eating at McDonald's, making cookies, and attending a birthday party. The results of these and later studies (Nelson, 1978; Nelson and Gruendel, 1979; Nelson et al., 1983; Fivush, 1984; Fivush and Slackman, 1986) demonstrate that preschoolers are able to give both veridical and consistent reports of what typically occurs during such events, although certainly older children's scripts are more detailed than those of younger children. Moreover, these script reports reflect the ways in which the events being described are structured in the world, just as the elicited imitation performance of infants studied by Bauer reflected the organization of the action sequences being remembered. To illustrate, in both settings some events are ordered in an enabling fashion, such that each component activity sets the stage for the next activity, whereas other components are arbitrary and variable in their temporal order. For example, in going to McDonald's, one must order food before one can eat it, whereas during a birthday celebration, one must open presents, but this does not have to happen at any particular time during the event. Children as young as 3 years of age are sensitive to these distinctions, recounting activities connected by enabling relations in their experienced order, whereas arbitrary activities are recalled in variable order (see, e.g., Fivush et al., 1992). Equally intriguing, children recount more information about events that are linked by enabling relations than those that are arbitrarily ordered, with some suggestion that this may be true even after the very first experience with the events (Slackman and Nelson, 1984; Ratner et al., 1990; Fivush et al., 1992; Murachver et al., 1996). The linkages between Bauer's elicited imitation studies and this research on verbal scripts lead to the basic conclusion that as early as 12 months of age, children are sensitive to the structure of events in the world, and that their memory reports of those events reflect this structure.

#### *2.37.3.1.2 Memory for salient events*

Supplementing research on children's generic representations of recurring events is a considerable body of work on young children's memory for unique personally experienced events. In some studies, children have been exposed to a range of specially crafted stimulus events, such as visiting a pirate (Murachver et al., 1996) or a pretend zoo (McGuigan and Salmon, 2004), whereas in others, the focus has been on naturally occurring routine visits to the doctor and other less familiar and more stressful medical experiences (Merritt et al., 1994; Peterson and Bell, 1996; Goodman et al., 1997; Ornstein et al., 1997a; Burgwyn-Bailes et al., 2001). This literature indicates the presence of substantial age differences in various aspects of memory performance. To illustrate, with increases in age, children demonstrate higher levels of overall recall of these experiences, recount more information in response to open-ended questions, and thus show less dependence on yes/no questions to elicit memory (e.g., Fivush and Hammond, 1990; Baker-Ward et al., 1993; Ornstein et al., 1997). Moreover, older children evidence less forgetting over time (Brainerd et al., 1985, 1990; Ornstein, 1995) and are less susceptible to suggestive questions (Ceci and Bruck, 1995; Ornstein et al., 1997). Existing evidence also indicates that with age and increased experience in talking about the past, children's reports become more richly detailed and complex and less dependent on information being provided by adult conversational partners (e.g., Fivush et al., 1995; Haden et al., 1997).

In one illustration of this work, Baker-Ward et al. (1993) assessed 3-, 5-, and 7-year-olds' memory for details of a routine pediatric examination. Most children were interviewed two times, first immediately after the check-up and then after a delay of 1, 3, or 6 weeks. The interviews were structured in such a way that they began with open-ended questions (e.g., "Tell me about what happened during your check-up."), followed by more specific questions (e.g., "Did the doctor check any parts of your face?"), and, finally, yes/no probes (e.g., "Did she (he) check your eyes?"). The children were asked yes/no questions both about features that had not been volunteered in response to the open-ended probes as well as regarding activities that had not been included in the check-ups. As illustrated in the top panel (A) in **Figure 1**, even the 3-year-olds were able to report most (approximately 75%) of the features of the event. However, as illustrated in the lower panel (C) in **Figure 1**, there were clear age-related improvements in performance, such that the 7-year-olds reported the greatest number of features (approximately 90%). Moreover, even though the performance of the 3-year-olds was impressive, they nonetheless produced less information than the older children in response to open-ended probes – as shown in the black portion of the bars in the figure – and thus required more specific questions to provide information about the experience. A comparison of the bars across the three panels at each delay reveals that the younger children evidenced more forgetting than the older children over the 6 weeks of the study.

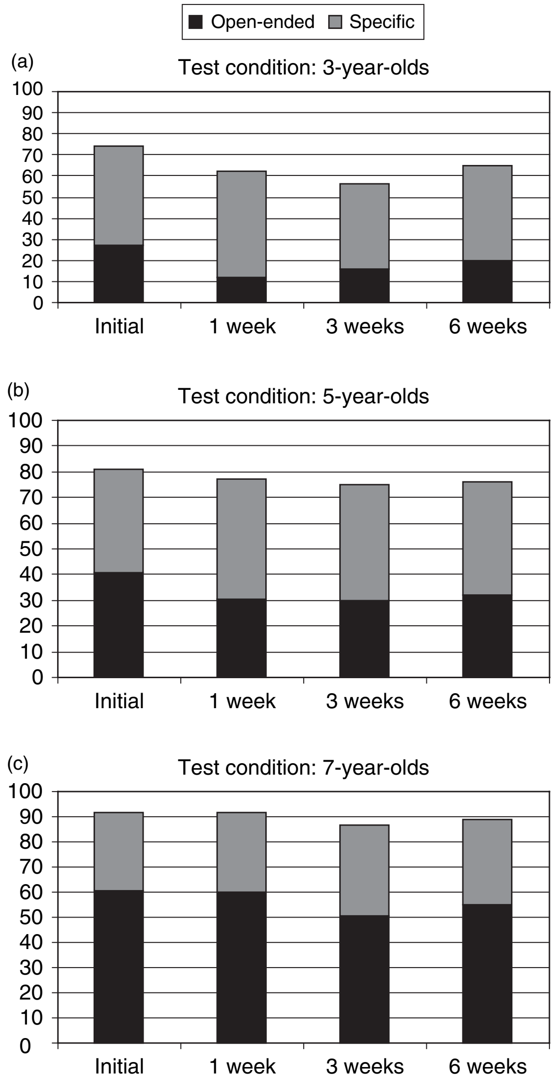

**Figure 1** Percent of features correctly reported in response to open-ended and specific probes by test condition at ages 3 (panel A), 5 (panel B), and 7 (panel C) years. Note that the data presented for the initial test are averaged across the three delay groups. ## 2.37.3.2 The Role of Knowledge

The event memory literature has both challenged earlier views of young children's recall as being quite limited (e.g., Myers and Perlmutter, 1978) and raised important questions about how we are to understand the dramatic age-related changes in remembering in terms of the factors that contribute to the encoding, storage, retrieval, and reporting of information. Children's understanding of the events being experienced is one such factor, as age differences in knowledge can seriously affect the processing and retention of information in memory.

#### 2.37.3.2.1 Prior knowledge

It is well known that prior knowledge enables people to create initial expectations that serve to focus their attention and make inferences that facilitate comprehension, so as to influence what gets into memory (Bjorklund, 1985; Chi and Ceci, 1987; Ornstein et al., 1997). In general, events about which children have significant prior knowledge are more readily encoded and subsequently retrieved than are those about which they have less knowledge. For example, studies that focus on the development of expertise in specific domains (e.g., chess, soccer) have demonstrated repeatedly that the highly organized and accessible knowledge of experts enables them to encode and remember domain-relevant information more effectively than novices (e.g., Chi, 1978; Schneider et al., 1989). In a similar manner, children's scripts (Nelson, 1986) that reflect their understanding of frequently occurring events can markedly affect their later memory of specific instances of these experiences (e.g., Farrar and Goodman, 1990).

An illustration of the impact of prior knowledge on memory can be seen in a reanalysis of the 5-year-olds' recall data from the Baker-Ward et al. (1993) study that was discussed in section 2.37.3.1.2. Clubb et al. (1993) rescored the protocols from the Baker-Ward et al. study to create memory scores representing the proportion of children who recalled each component of the check-up (e.g., blood pressure, eye check, urine specimen) in response to open-ended questions. These memory scores for each component of the office visit at each recall assessment were compared to knowledge scores that were constructed on the basis of interviews with a separate sample of 5-year-olds who responded to questions about what generally happens when they go to the doctor (e.g., "What does the doctor (nurse) do to check you?"). The knowledge scores were therefore based on the proportion of children in the Clubb et al. (1993) sample who nominated each component of the check-up in response to the interviewers' general knowledge probes. Given comparable memory and knowledge scores for individual features of the pediatric check-up, it was possible to determine the degree to which the recall of the 5-year-olds in the Baker-Ward et al. (1993) study could be predicted on the basis of Clubb et al.'s (1993) normative knowledge data.

Inspection of the data plotted in **Figure 2** indicates that there was considerable variability in the memorability of the components of the physical

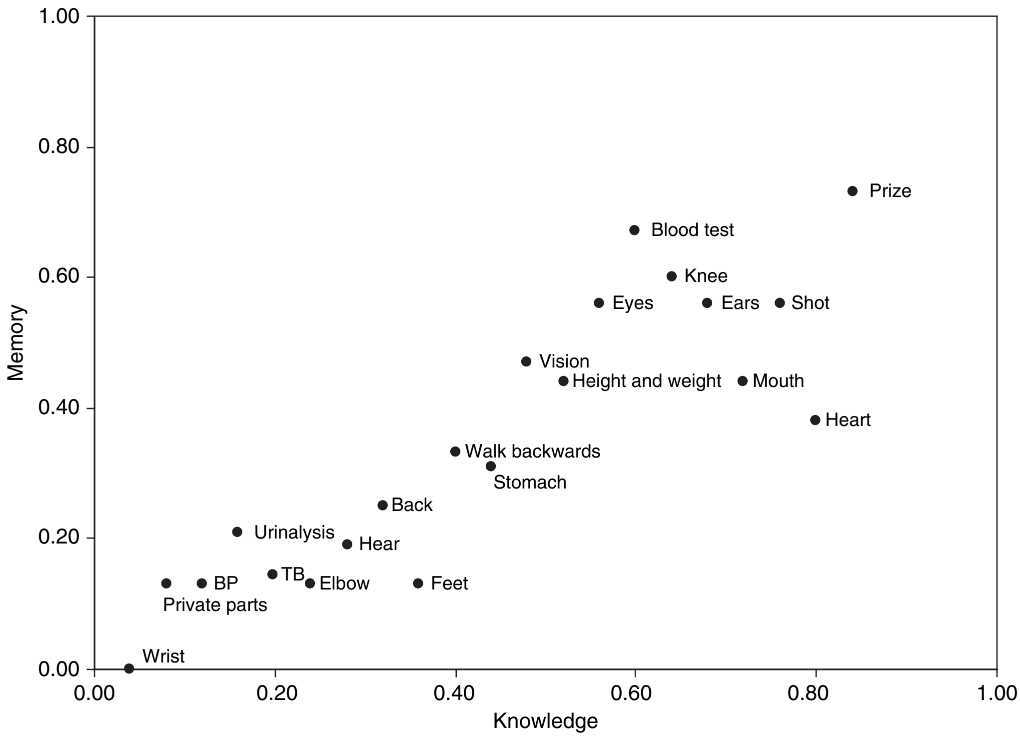

**Figure 2** Scatterplot of knowledge and memory scores at 6 weeks for 5-year-olds. Reprinted with permission from Clubb PA, Nida RE, Merritt K, and Ornstein PA (1993) Visiting the doctor: Children's knowledge and memory. *Cogn. Dev.* 8: 361–372. 

examination. There was also variability in the children's knowledge of the individual features, but most interestingly, the knowledge and memory scores were highly correlated, indicating that increases in knowledge were associated with corresponding increases in remembering; indeed, the correlations were 0.68, 0.63, 0.64, and 0.74 for the initial, 1-, 3-, and 6-week (shown in **Figure 2**) interviews. These data (see also Ornstein et al., 1997b) and other findings with the subject as opposed to the feature as the unit of analysis (Ornstein et al., 2006a) strongly suggest that what a child knows about an event can seriously affect the extent to which information about the experience is coded and placed in memory.

Although prior knowledge certainly impacts children's memory performance positively, it is important to note that it also can have negative effects. To illustrate, in an effort to explore the extent to which an individual's general knowledge can, over time, lead to alterations in memory for a specific event, Ornstein et al. (1998) studied 4- and 6-year-olds' long-term memory for the details of a specifically constructed physical examination that was both consistent and inconsistent with knowledge-driven expectations. In this experiment, the stimulus event was a mock physical examination carried out by a licensed pediatrician that included some typical medical features (e.g., listening to the heart with a stethoscope) but omitted others that, on the basis of prior knowledge, would have been expected to occur (e.g., checking the mouth). These omitted features, moreover, were replaced by unexpected and quite atypical medical procedures (e.g., measuring head circumference). The findings indicated that prior knowledge had both positive and negative effects on performance. Expected features of the procedures were better remembered than atypical features at all assessments. Most interestingly, 12 weeks after their check-ups, the children made spontaneous errors of commission (i.e., they claimed that they experienced certain medical procedures that had not been administered) and evidenced high rates of false alarms to yes/no questions about medical features that had not been included in their check-ups. The spontaneous intrusions of omitted-but-expected features and the low rates of correct denials to explicit questions about these features that were observed by Ornstein and his colleagues are consistent with the view that the representations of the children's check-ups changed over the 12-week delay interval. More specifically, it would seem that as the children's memory for the check-ups faded over the course of the interval, aspects of their generic event representations for visits to the doctor were incorporated into their specific event representations.

#### *2.37.3.2.2 Knowledge that is acquired during an event*

When previously acquired knowledge is lacking, as in a situation in which a child experiences a novel event, facilitative effects can be observed when knowledge is gained while the experience is taking place. For example, Principe et al. (1996) used data from a study of 3- to 7-year-olds' memory for an invasive and novel radiological procedure (a voiding cystourethrogram, or VCUG; Merritt et al. 1994), to look at how the provision of information to children during the event about the stressful and unfamiliar medical procedure affected their subsequent remembering of the experience. Interestingly, the radiological technicians involved in the procedure naturally varied in the extent to which they provided medically relevant information to the children about the experience as it was ongoing. Therefore, whereas some children were provided with a verbal description of the catheter and its insertion, some mention of the contrast fluid going through the catheter, and information about the filling of the child's bladder with this fluid, other children did not receive this procedural narrative. Underscoring the dramatic impact of new knowledge on comprehension and memory, children in the procedural narrative group remembered more details immediately after the exam, as well as 6 weeks later, than children who were not given such a description. These differences could not be attributed to differences among the children in their age or their levels of stress during the procedure and suggest that information that is gained during an unfamiliar and stressful event enhances remembering.

#### *2.37.3.2.3 Changes in knowledge*

Once in the memory system, the status of information about an experience can be substantially altered during the period between the event and the later report of it. Indeed, a number of variables can contribute to changes in the representation, including the passage of time (Ornstein et al., 2006a) and intervening experiences (Principe et al., 2000), and these influences may vary as a function of age. Moreover, because knowledge does not remain constant over time, it is important to ask what happens when knowledge itself changes. Ross (1989) has argued cogently that as memory for the details of an experience fades over time, one tends to 'fill in' on the basis of current understanding and knowledge. One demonstration of the ways in which changes in knowledge over time can lead to alterations in remembering was reported by Greenhoot (2000), who used a series of stories as stimulus material to lead children to develop certain assumptions about the protagonists. Over the course of several sessions, the 5- and 6-year-olds who participated in her study built up a knowledge base about the main story characters and their relationships, and hence the underlying motivation for certain acts that were depicted in the stories. Then, at later sessions, the children were given additional information that prompted some of them to reassess the relationships among the characters (and the motivation for various behaviors) that had been operative. Importantly, Greenhoot showed that the children's memory for prior episodes was distorted in the direction of the new information.

#### *2.37.3.2.4 Recall in conversations about past events*

Although much has been learned about children's memory for salient events, a great deal needs to be done to understand how a variety of factors come to together to influence the establishment, maintenance, and modification of representations in memory. In this regard, it is clear that adults have a great role to play in facilitating children's understanding and remembering. Indeed, social–communicative interactions between parents and children provide opportunities for focusing children's attention on salient aspects of an event and thus increasing their understanding and memory, as well as facilitating the acquisition of generalized skills for remembering.

#### *2.37.3.2.5 Parental reminiscing styles*

Children begin to talk about past events almost as soon as they produce their first words, and the skills for recalling past experiences in parent–child conversations develop rapidly between 2 and 4 years of age. Nevertheless, as illustrated in this example of a mother and her 18-month-old, when children first begin to reminisce, it is the adult partner who provides most of the content and structure.

> Mother: What else happened [at Taylor's house]?
> Child: (no response)
> Mother: We had dinner. What did you eat?
> Child: (goes off task).
> Mother: What did you do with Taylor?
> Child: Barney.
> Mother: Yeah, you watched a Barney video. What else did you do with Taylor? Did you guys fight about something?
> Child: (shakes head no).
> Mother: No? When you were watching Barney?
> Child: (nods head yes).
> Mother: Yeah. You guys got hungry and tired. Then what happened?
> Child: Uh oh.
> Mother: Yeah. What happened? Did you bite Taylor's finger?

A central focus in the literature on parent–child reminiscing has been on the marked individual differences in the reminiscing styles parents use to structure conversations about the past with their young children (see Fivush et al., 2006, for a review). In contrast to parents who use a low elaborative style, those who employ a high elaborative style – such as the mother in the example above – ask many questions, follow-in on their children's efforts to contribute to the conversation, and continue to add new information even when children do not. It is clear that these reminiscing styles generalize across different types of past event discussions (e.g., excursions and holidays, zoo or museum trips, entertainment outings) and tend to be consistent over several years with the same children (Reese et al., 1993) and across different-aged children in the same family (Haden, 1998). Most important, longitudinal data indicate that differences in maternal reminiscing styles are associated with later differences in children's abilities to recall personally experienced events. For example, as illustrated by the lagged correlations in **Figure 3**, Reese et al. (1993) demonstrated that mothers' elaborations during conversations with their 40-month-old children are associated positively with children's contributions of memory information in conversations with their mothers at 58 and 70 months of age. Moreover, the direction of the effect was more from mother to child over time than from child to mother. Although children did influence their mothers to a limited extent, as illustrated in the lower portion of the figure, the correlations for memory responses across age indicate that the children's own earlier skills for verbally recalling events were not directly related to their later abilities.

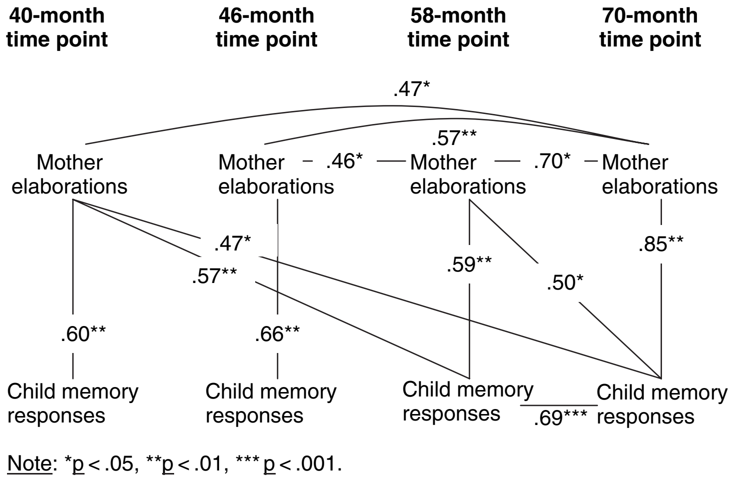

**Figure 3** Cross-lagged correlations between maternal elaborations and children's memory responses. Reprinted with permission from Reese E, Haden CA, and Fivush R (1993) Mother-child conversations about the past: Relationships of style and memory over time. *Cogn. Dev.* 8: 403–430. Copyright © 1993, Elsevier.

The finding that the more mothers engaged in highly elaborative talk about the past, the better their children's event memory skills even years later, has been widely replicated both in the United States and cross-nationally (e.g., Hudson, 1990; Flannagan et al., 1995; Welch-Ross, 1997; Haden, 1998; Harley and Reese, 1999; Peterson et al., 1999; Farrant and Reese, 2000; Leichtman et al., 2000; Low and Durkin, 2001; Welch-Ross, 2001; Fivush and Vasudeva, 2002; Bauer and Burch, 2004), such that it seems clear that mothers who are highly elaborative early in development facilitate their children's abilities to report on their past experiences in a detailed manner. Moreover, Peterson et al. (1999) were successful in manipulating mothers' conversational style when talking with their children about previously experienced events, finding that children of mothers who received their intervention produced longer memory reports that contained more details about past events than children of mothers who had not received reminiscing training.

Findings concerning the impact of maternal reminiscing styles on remembering have led to speculation about how early conversations about the past may change the way children organize and represent experiences (Fivush and Haden, 1997; Fivush et al., 2006). Interestingly, it has been suggested that children of mothers who use a highly elaborative reminiscing style may actually come to encode experiences in more richly detailed ways than children of less elaborative mothers, although presently no study has addressed this particular issue. Nevertheless, just as memories may be maintained, elaborated, or even modified through subsequent reminiscing, a growing body of evidence supports the idea that language-based interactions during events can be of critical importance in guiding initial encoding and the establishment of a representation in memory (Tessler and Nelson, 1994; Haden et al., 2001; Boland et al., 2003; McGuigan and Salmon, 2004; Ornstein et al., 2004; Hedrick, 2006). It is to this work that we now turn.

#### *2.37.3.2.6 Conversation during events*

The few studies to date that have examined mother–child talk during an event suggest that preschoolers produce longer and more detailed reports of these experiences if their mothers use elaborative Wh-questions and follow-in on and positively evaluate their children's verbal and nonverbal behaviors as events unfold (Haden et al., 2001; Boland et al., 2003; Ornstein et al., 2004). Moreover, joint linguistic interactions between parents and children during events are more strongly related to children's later memory than are interactions characterized as primarily involving mother-only talk, child-only talk, or no-talk (Tessler and Nelson, 1994; Haden et al., 2001). To illustrate, Haden et al. (2001) conducted a longitudinal investigation in which young children took part in three specially constructed activities with their mothers: At 30 months, a camping trip; at 36 months, a bird-watching adventure; at 42 months, the opening of an ice-cream shop. Within the confines of each family's living room, mother–child interactions during the events were videotaped, providing a precise record of how each dyad interacted – both nonverbally and verbally – with each component feature of the event (e.g., in the camping event, hot dogs, marshmallows, backpack, sleeping bag) as it unfolded.

Given that the majority of features that were interacted with during the events were jointly handled (and thus jointly attended to), Haden et al. (2001) asked whether recall of these components varied as a function of the type of talk (e.g., joint verbal, mother-only verbal, child-only verbal, no verbal) that had been directed toward them during the activities. The children's recall of these experiences after delays of 1 day (upper panel) and 3 weeks (lower panel) is summarized in **Figure 4**. Inspection of the figure indicates the striking effect of joint talk as the events unfolded on the information the children provided in response to the open-ended questions of the interviewers. As can be seen, at both interviews and for each of the activities, the features that were handled and discussed by both the mother and the child jointly (solid bars) were better recalled than those that were jointly handled but talked about only by the mother (gray bars), which, in turn, were better recalled than those not discussed (white bars). Additional analyses indicated further that the features of the event (e.g., a spatula in the camping event) about which questions had been asked by the mothers during the activity that had been responded to by the children (e.g., the mother asks, "What is the spatula used for?" and the child responds "For flipping.") were better recalled than features about which mothers' questions did not result in the children's response (Ornstein et al., 2004). Thus, findings from this longitudinal study – as well as the work by Tessler and Nelson (1994) involving a sample of 4-year-olds – suggest that the nature of mother–child interaction as an event unfolds influences encoding and subsequent remembering.

Experimental work also supports this conclusion. For example, Boland et al. (2003) trained some mothers to use four specific conversational techniques to enhance their children's understanding of unfolding events: (1) Wh- questions to elicit their child's linguistic participation in the activity, (2) associations to relate that which was being experienced to what their child already knew, (3) follow-ins that

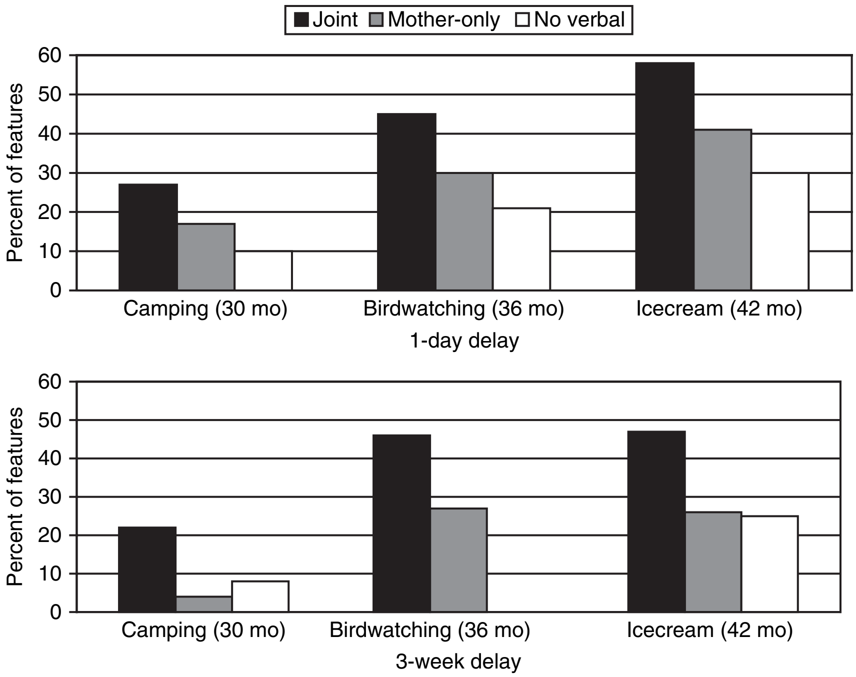

**Figure 4** Proportion of features of the camping, bird-watching, and ice-cream-store events remembered in response to open-ended questions at the 1-day and 3-week interviews, as a function of the type of talk directed toward jointly handled features. Adapted from Haden CA, Ornstein PA, Eckerman CO, and Didow SM (2001) Mother-child conversational interactions as events unfold: Linkages to subsequent remembering. *Child Dev.* 72: 1016–1031. encouraged discussion of aspects of the event in which the child was showing interest, and (4) positive evaluations to praise their child's verbal and nonverbal contributions to the interaction. After this instruction, when observed engaging with their 4-year-old children in the context of the camping event, trained mothers produced significantly more of all four of the targeted conversational techniques than did untrained mothers. Moreover, the effects of the training did not vary as a function of the children's language skills and did not impact the mothers' use of untrained techniques (i.e., repetitions, yes-no questions, and statements). Of even greater interest, the children's recall of information about the camping event was affected by the training that their mothers received. For example, the children of trained mothers exceeded those whose mothers had not received training in the production of details of the event.

Given these demonstrations of the importance of adult–child talk for children's memory performance, interesting questions concerning the potentially additive effects of conversations about the present and the past on remembering are currently being explored (McGuigan and Salmon, 2004, 2005; Conroy, 2006; Hedrick, 2006). Moreover, relatively few studies have considered how talk prior to an event may set the stage for the development of children's representations (Hudson, 2002) and the linkages between children's performance in these event memory tasks and their subsequent use of deliberate techniques for remembering (Haden et al. 2001; Lange and Carroll, 2003). We turn now to a treatment of children's developing skill in the use of these mnemonic strategies.

## 2.37.4 Learning to Be Strategic

As young children develop expertise in talking about their past experiences, they also evidence increasing skill in the use of strategies for remembering information. To a considerable extent, their growing competency in discussing the past reflects age-related improvements in the incidental encoding of information – which in turn stem from children's greater understanding of the situations that they encounter – as well as improvements in retrieving and reporting information from memory. In contrast, however, the deployment of a specific strategy for remembering – such as naming or grouping – represents intentional preparation in the service of an expected assessment of memory (Ornstein et al., 1988; Wellman, 1988; Folds et al., 1990). Given this distinction between incidental and deliberate remembering, it is interesting that even young preschoolers can demonstrate "strategic" behavior under certain circumstances. For example, when asked to remember the location of a familiar stuffed animal that was hidden in a room, 18-month-olds utilized a number of rudimentary strategies (pointing, peeking, and naming) so that the toy could be retrieved after a delay (DeLoache et al., 1985). Although the deployment of these strategic behaviors was not unambiguously related to the memory performance, these responses to a memory request do indeed suggest that children enter the preschool years with a basic understanding that remembering requires action of some sort. Nonetheless, interpretation of this finding is complicated by the fact that similar behaviors are also exhibited – but to a lesser extent – in a variation of the hide-and-seek game in which remembering is not required (DeLoache et al., 1985, Experiment 3). Consistent with Wellman's (1988) treatment of intentionality, these early mnemonic skills can be viewed as protostrategies that emerge during enjoyable activities in highly salient and meaningful situations and may not necessarily be related to later strategy acquisition (see also Ornstein et al., 1988; Folds et al., 1990).

Older preschoolers may have a firmer understanding of the need to do something in order to prepare for an assessment of memory, but the effectiveness of their efforts is analogous to that of the 18-month-olds studied by DeLoache et al. (1985). Consider, for example, a study by Baker-Ward et al. (1984) in which 4-, 5-, and 6-year-olds made use of a set of similar techniques in a memorization task with common objects. These children were directed to interact with a set of objects and toys for a 2-min period and were placed in one of three conditions: Target Remember, Target Play, and Free Play. The children in the Target Remember condition were told that they could play with all of the objects but that they should try especially to remember a subset of the items (i.e., the target objects). In contrast, the participants in the Target Play group were given instructions that did not mention remembering but rather stressed playing with a subset of the target objects, whereas those in the Free Play condition were given general play instructions.

The use of an observational coding scheme during the activity period revealed that even at age 4, the children who were told to remember behaved differently from those in the play conditions. For example, as can be seen in Figure 5, spontaneous labeling or naming occurred almost exclusively among the children in the target remember condition who were instructed to remember a subset of the objects, and it was found that these children also played less than the children in the free play and target play conditions. Moreover, as can be seen in Figure 6, the children who received instructions to remember also engaged in more visual inspection and evidenced more unfilled time than the children in the two play conditions. Unfilled time was coded when a child was not paying direct attention to the items but nonetheless did not seem to be off-task; informally, it seemed to involve reflection and self-testing. The memory instructions thus engendered a studious approach to the task among the 4-, 5-, and 6-year-olds alike, but it is important to note that only among the 6-year-olds were the strategic behaviors associated with higher levels of recall.

The literature now contains many demonstrations of what Miller (1990; see also Bjorklund and Coyle, 1995; Bjorklund et al., 1997) has termed utilization deficiencies in young children who are just beginning

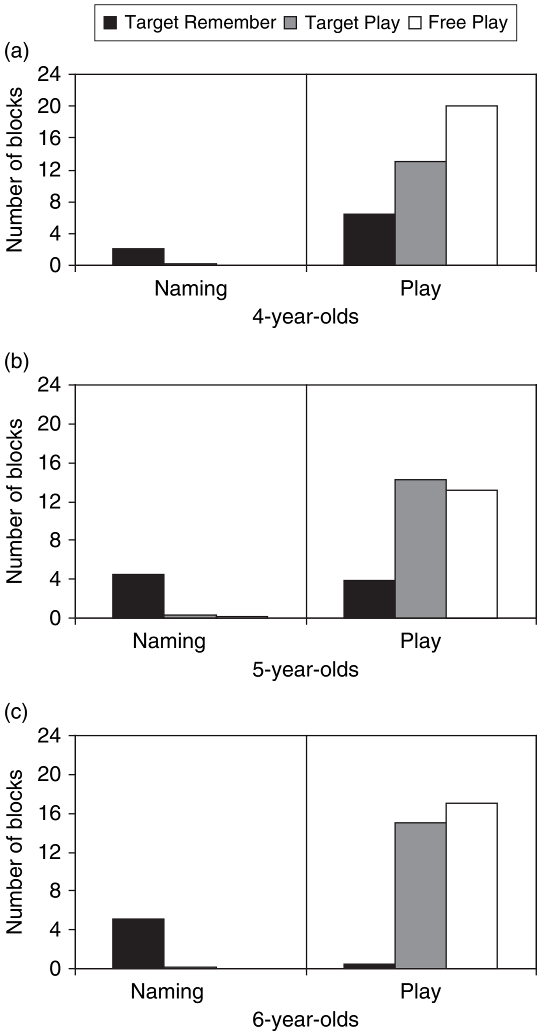

**Figure 5** Mean number of 5-s blocks of the activity period in which each naming and play occurred for the 4-year-olds (panel A), 5-year-olds (panel B), and 6-year-olds (panel C) in each instructional condition. to generate strategies in response to memory goals. As in the Baker-Ward et al. (1984) study, strategies are produced spontaneously, but they do not seem to initially correspond to improvements in the amount recalled. Why should this be the case? If Baker-Ward et al.'s 4-, 5-, and 6-year-olds were engaging in the same strategic behaviors, why did only the efforts of the 6-year-olds have a positive effect on their recall? Moreover, why should similar strategic activities differ in their mnemonic effectiveness? Of course, it is possible that even though the observable behaviors (e.g., naming, visual inspection) of the 4-, 5-, and 6-year-olds were similar, they may have been the external manifestation of quite different underlying strategies. As such, the similarity across age in strategic efforts may be illusory, with, for example, the children of different ages combining the observable behaviors into qualitatively different strategies. That this may have been the case is suggested by Baker-Ward et al.'s observation that the younger children seemed to combine verbal naming or labeling and manipulation, whereas the older children put naming together with visual examination. It thus seems worthwhile to develop higher-order coding schemes to capture these age-related changes adequately in the coordination of different mnemonic behaviors. Efforts of this kind may well result in more precise definitions of effective mnemonic techniques, but it is also possible that such fine-grained analyses will still leave open questions about the conditions under which the application of strategies may and may not impact remembering. As discussed here, there may be other factors – for example, age related changes in underlying knowledge (Bjorklund, 1985), speed of processing (Kail, 1991), and the effort requirements of strategy usage (Guttentag, 1984; Case, 1985) – that may influence whether or not a given strategy influences remembering.

At the very least, this brief treatment of early strategies that do not work serves to highlight the fact that intentionality is only one aspect of strategic behavior and that two others – consistency and effectiveness – must be considered in any account of the development of memory. This is especially the case when it is recognized that the developmental course of children's mastery of mnemonic skills extends through the end of the elementary school years. In terms of consistency, skilled strategy users have command over a broad repertoire of mnemonic techniques (e.g., rehearsal, organization, elaboration) and are able to apply them skillfully across a broad set of situations that call for remembering (Brown et al., 1983; Ornstein et al., 1988; Pressley et al., 1989). In contrast, novice strategy users not only have a limited set of techniques at their disposal, but the very application of any given procedure is often quite context-specific and not consistent across settings. Indeed, when young children are able to demonstrate sophisticated strategy use, it typically is only in highly supportive and salient settings (Ornstein et al., 1988; Ornstein and Myers, 1996). Moreover, in terms of effectiveness, work on utilization deficiencies, discussed above, indicates that the strategic efforts of young children often do not facilitate remembering. In addition, however, even when the application of strategies does influence recall, younger children may derive less benefit than do older children (Ornstein et al., 1988; Wellman, 1988; Folds et al., 1990).

Given these complexities, longitudinal data are necessary to track on a within-individual basis developmental progress in the acquisition and deployment of strategies for remembering. Ideally, young children's increasing sophistication in the use of these techniques would be charted over time with multiple indicators of strategic competence, under conditions that vary in terms of their effort and attentional demands. Data from microgenetic research designs (Siegler and Crowley, 1991; Schlagmüller and Schneider, 2002) in which children are followed intensively for limited periods of time are also very useful for developmental analyses of mnemonic skill. Unfortunately, longitudinal and microgenetic research designs are still quite rare in the area of memory development, and our understanding of age-related changes in strategy usage stems largely from the (admittedly rich) cross-sectional literature. To illustrate strategy development, we focus here on cross-sectional studies in which an age-related progression from passive to active memorization styles has been demonstrated (Ornstein and Naus, 1985; Ornstein et al., 1988).

### 2.37.4.1 Rehearsal and Organizational Strategies in the Elementary School Years

A comparison of children's performance on tasks that assess memory for personally experienced events and those that require deliberate remembering reveals substantial differences in the levels of demonstrated sophistication. Indeed, by 8 or 9 years of age, children are very adept at providing rich reports about their experiences, but at the same time their skills appear to be quite limited in situations that call for the deployment of complex deliberate mnemonic strategies.

To illustrate the relatively late emergence of these deliberate memory skills, consider the substantially different ways in which 9- and 14-year-olds behave when given a list of words to remember and are prompted to talk aloud as the items are presented. In this type of overt rehearsal task, 9-year-olds tend to rehearse each to-be-remembered item alone as it is displayed, whereas older children (and adults) rehearse each one with several previously presented stimuli (Ornstein et al., 1975; Ornstein and Naus, 1978). To illustrate, if the first three items on a to-be-remembered list are table, car, and flower, a typical third grader would rehearse table, table, table, when the first word is shown; car, car, car, when car is presented; and flower, flower, flower, when the third word is shown. In contrast, the average 14-year-old is likely to rehearse table, table, table, when table is presented; table, car, table, car, when car is presented; and table, car, flower, when flower is displayed. These children thus differ considerably in the extent to which rehearsal is limited (or passive) versus more cumulative (or active), and these differences in rehearsal style are related to substantial differences in recall. Indeed, with increases in age, not only does rehearsal become more active – with several different items being intermixed – but recall improves dramatically, especially that of the early list items. That is, children's increasingly active rehearsal styles are associated with improved recall of the primary section of the serial position curve (Ornstein et al., 1975).

These changes in the use of rehearsal are paralleled by comparable developments in the deployment of organizational strategies for remembering. Consider, for example, the performance of third and fourth graders on a sort-recall task in which they are given a set of low-associated words (or pictures) and asked to "form groups that will help you remember." Under these conditions, in which the items are sorted prior to each recall trial, children as old as 9 years of age tend not to form groups on the basis of semantic relations among the to-be-remembered materials but, rather, establish what seem to be randomly arranged groupings that vary considerably over trials (Liberty and Ornstein, 1973; Bjorklund et al., 1977). In dramatic contrast, children aged 12 and older routinely establish groups that are semantically constrained, even though the memory instructions do not prompt sorting on the basis of meaning. These older individuals seem to have the metacognitive understanding that sorting on the basis of meaning will facilitate recall, readily translating a remembering instruction into one that involves a search for a meaning-based organization (Ornstein et al., 1974). Moreover, consistent with the rehearsal literature, these age differences in the extent to which sorting is driven by the semantic organization of the materials are associated with corresponding differences in recall. However, it should be emphasized that younger children's failure to use a meaning-based grouping strategy does not imply that they lack understanding of the semantic linkages among the items, as they can readily sort even low-associated items on the basis of meaning when instructed to do so (Bjorklund et al., 1977; Corsale and Ornstein, 1980). As such, the age differences in performance would seem to reflect age differences in understanding how underlying knowledge can be applied strategically in the service of a memory goal.

### 2.37.4.2 Context Specificity in Strategy Development

These age-related differences in rehearsal and sorting represent a sampling from a now-extensive literature on children's developing skills in the use of a variety of strategies for remembering (Schneider and Pressley, 1997; Schneider and Bjorklund, 1998; Bjorklund et al., in press). Although the bulk of this literature is composed of cross-sectional studies, it is nonetheless clear that with increases in age there are corresponding increases in rehearsal, organization, elaboration, and other techniques that influence the encoding, storage, retrieval, and reporting of information. Further, demonstrations of the ways in which older and young children differ in the deployment of mnemonic strategies have been supplemented by training studies so as to document causal linkages between strategy use and remembering. To illustrate, the provision of minimal instructions to rehearse several items together is sufficient to increase the recall of younger children, and prompts to rehearse each item on a list alone or in relative isolation can reduce the recall of older children (Ornstein et al. 1977; Ornstein and Naus, 1978). Similarly, when young children are required by a yoking procedure to follow the more semantically constrained sorting pattern of older children or adults, their recall is facilitated, and when adults are yoked to these sorts of young children, their recall is reduced (Liberty and Ornstein, 1973; Bjorklund et al., 1977). Children's sorting of low-associated materials can also be manipulated – with corresponding effects on their remembering – by simply instructing them to sort on the basis of meaning (Bjorklund et al., 1977; Corsale and Ornstein, 1980) or by exposing them to materials that are highly organized (Best and Ornstein, 1986).

It is thus clear that there are causal linkages between children's strategic efforts and their recall performance. However, it is also the case that there are limits to the success of these experimental interventions that shed light on other factors that contribute to effective strategy production. For example, although third graders can follow instructions to rehearse several items together, their use of such an active rehearsal strategy does not increase their recall to the level of sixth graders (Ornstein et al., 1977). This failure to eliminate age differences in remembering most likely stems from the fact that the use of an active rehearsal strategy requires that young children expend more of their attentional resources than is necessary for older children (Guttentag, 1984). Consistent with Guttentag's observation that the attentional demands of an active rehearsal strategy may vary at different points in development, it certainly is easier for young children to rehearse several items together when the effort demands of the task are reduced. Thus, for example, when instructions to rehearse actively are combined with a procedure in which children have continued visual access to each to-be-remembered item after its initial presentation, striking improvements in strategy use and subsequent recall are noted (Ornstein et al., 1985). Although effort demands are also important in the context of organizational strategies (see Bjorklund and Harnishfeger, 1987), when children of different ages have comparable understanding of the to-be-remembered items and are led by instructions to use this knowledge as a basis for their sorting, recall differences are generally eliminated (Corsale and Ornstein, 1980).

Although context can certainly affect the outcome of training manipulations, it can also influence the degree to which children will engage spontaneously in strategic activities, as well as the sophistication of their efforts. To illustrate, the manipulation mentioned above to reduce the effort demands of an instructed active rehearsal strategy – permitting children to view all previously presented items – has been shown to increase the likelihood of spontaneously making use of a cumulative rehearsal strategy. Indeed, Guttentag et al. (1987) observed that some third graders who typically rehearsed passively when the to-be-remembered items were presented in the typical fashion changed to a multi-item rehearsal strategy without prompting when given an opportunity to continue to see all items. In addition, consistent with the finding discussed above that prior knowledge can impact children's reports of previously experienced events, knowledge and understanding of the materials can dramatically influence children's use of mnemonic strategies when acting in the service of a memory goal (Bjorklund, 1985; Ornstein and Naus, 1985). Indeed, increases with age in the contents of the knowledge base and the ease with which stored information may be accessed have serious implications for the deployment of strategies. What a child knows about the items to be remembered can certainly determine just what can – and cannot – be done strategically with those materials. At one extreme, a child may not be able execute a grouping strategy at all if he or she does not know the category structure of the to-be-remembered materials, but even when children are familiar with the meaning of the materials, they may nonetheless appear to be strategic when given some items to remember and nonstrategic with others (Ornstein and Naus, 1985; Ornstein et al., 1988).

These demonstrations of the impact of the materials on remembering have led to the suggestion that the children's first expressions of deliberate memorization will be observed when they are presented with highly meaningful materials in very salient contexts (Ornstein et al., 1988). This was illustrated above in the discussion of Baker-Ward et al.'s (1984) study in which 4-, 5-, and 6-year-olds could interact with a set of toys and objects under remember- or play-based instructions. With these very salient materials, the 4-year-olds engaged in strategic behaviors when told to remember, even though their efforts did not facilitate remembering. In addition, although it is known that third graders do not sort low-associated items in terms of their underlying meaning when told to "form groups that will help you remember" (Bjorklund et al., 1977), as discussed earlier, when given more salient, categorically related items, they will readily group on the basis of meaning when given the typical memory-based instruction (Corsale, 1978). It seems likely that the saliency of the category structure is so powerful that it is difficult not to sort in an organized manner. Similar effects of the dependence of memory strategies on the stimulus properties of to-be-remembered materials can be seen in Tarkin's (1981; see also Ornstein et al., 1988) exploration of third graders' use of rehearsal strategies. Further, it is likely that the increasing articulation of the knowledge system with age and experience may facilitate information retrieval and thus reduce the amount of attentional effort required to implement various subcomponents of memory strategies (Ornstein et al., 1988).

### 2.37.4.3 The Development of Effective Strategy Use

With increases in age, the context specificity that characterizes early strategy use is reduced, as children extend the range of settings in which they behave in a strategic fashion (Ornstein et al., 1988). In parallel with this generalization of strategy use, their strategic efforts become increasingly effective in facilitating remembering. Two features of this change in the efficacy of children's strategic efforts are discussed briefly, followed by a treatment of some of the factors that may underlie these age-related changes.

First, as already indicated, there are substantial age-related changes in what children actually do when confronted with a memory goal. Younger children, for example, are more likely than older children to select strategies that are inappropriate for a task, as, for example, when preschoolers implement deliberate strategies that do not facilitate performance in any way (see Wellman, 1988, for a treatment of faulty strategies). Moreover, when children of elementary school age are asked to remember verbal materials, there is a general progression from more passive, rote-type mnemonic techniques to more active strategies that seem to involve deliberate efforts at integrating the material being remembered with existing knowledge. Further, with increases in age, children have increased numbers of strategies at their disposal and are better able to make flexible use of this mnemonic repertoire (Folds et al., 1990; Schneider and Bjorklund, 1998). Second, even when the same strategy appears to be employed by children of different ages, the technique typically has a more facilitative effect on the memory of older as opposed to younger children. As indicated above, Baker-Ward et al. (1984) showed that 4-, 5-, and 6-year-olds all utilized strategies when trying to remember a set of objects, but these techniques only facilitated the memory performance of the oldest group of children. These data – and other demonstrations of utilization deficiencies (Miller 1990; Bjorklund and Coyle 1995) – again show that even very young children may be aware of the importance of implementing a strategy in the service of remembering, but that the strategies that they nominate may be largely ineffective.

### 2.37.4.4 Factors Underlying Developmental Changes in Strategic Memory

In an effort to understand changes in strategy deployment and effectiveness, we turn now to a brief treatment of several factors that may impact children's use of strategies and serve as mediators of the observed age-related progression: (1) Changes in the underlying knowledge base in memory, (2) reductions in the effort requirements of strategy implementation, (3) increases in metamnemonic understanding, and (4) experiences in formal schooling.

#### *2.37.4.4.1 Prior knowledge*

As discussed earlier in our treatment of knowledge and event memory, changes with age in both the content and structure of children's underlying knowledge in permanent memory can influence dramatically the flow of information within the memory system and thus affect overall performance (Chi, 1978; Bjorklund, 1985; Ornstein and Naus, 1985). Moreover, in recent years there has been a consensus among memory researchers that both knowledge and strategy use contribute in important ways to the development of children's deliberate memory skills (Ornstein et al., 1988; Muir-Broaddus and Bjorklund, 1990) and recognition that under some conditions, the impact of the knowledge base may be mediated by its effects on strategy implementation (Ornstein and Naus, 1985; Rabinowitz and McAuley, 1990). This emerging perspective emphasizes the impact that the current state of a child's knowledge system may have on both strategy selection and execution (Ornstein et al., 1988; Folds et al., 1990). Indeed, as illustrated previously in our treatment of context specificity, young children may appear to be quite strategic in supportive settings when presented with highly salient and meaningful sets of materials, but they may seem to be much more tentative, and even astrategic, when presented with less structured items.

How should these demonstrations of context specificity in strategy use be interpreted? As mentioned previously, one explanation for the sometimes dramatic differences in the performance of young children under contrasting task demands is that they may not have sufficient knowledge about the materials to carry out appropriate strategies. Indeed, knowing the meaning and categorical structure of a set of words is a necessary, albeit not sufficient, prerequisite for implementing a semantically based clustering strategy. A second explanation focuses on the beneficial effects of knowledge on the efficiency of mnemonic processing. With increases in age and experience, the knowledge system becomes increasingly articulated, with rich interconnections among items, thereby contributing to the ease of access that is needed for the skillful execution of strategies such as active rehearsal and meaning-based sorting (Bjorklund, 1987; Ornstein et al., 1988; Bjorklund et al., 1990). Interestingly, these developments in the underlying knowledge base – with the increased likelihood of the automatic activation of strong associative links – may thus make young children's strategic efforts not entirely deliberate (Lange, 1978; Bjorklund, 1985). At the same time, however, these associative links may increase the efficiency and effectiveness of the strategy use of older children. Finally, these developments in the knowledge system may contribute to age-related increases in the likelihood that children will spontaneously use their underlying knowledge strategically when confronted with memory goals (Corsale and Ornstein, 1980).

#### 2.37.4.4.2 Effort requirements of strategy use

Age-related changes in the effectiveness of children's strategies may also reflect corresponding differences in the attentional resources that are needed for the execution of mnemonic techniques. If one assumes a type of tradeoff between the processing and storage operations that are involved in carrying out any given cognitive task (Case, 1985), then in the early stages of acquiring a skill such as cumulative rehearsal, strategy execution may so tax the limited capacity system that little remains to be allocated to encoding and storage processes (Bjorklund and Harnishfeger, 1987). Consistent with this perspective, a child may be able to deploy a given memory strategy under some conditions, but the effort required to do so may be so great that the strategy does not actually facilitate performance. Indeed, as indicated earlier, Guttentag (1984) demonstrated that second graders may be capable of producing an active rehearsal strategy when so instructed, but that their deployment of this technique is more demanding of their limited capacity than is the case for older children or adults (see also Bjorklund and Harnishfeger, 1987; Kee and Davies, 1988). As suggested above, evidence consistent with this finding was reported by Guttentag et al. (1987), who found that some children who typically rehearsed passively were able to change to active rehearsal when the resource demands of this more complex strategy were reduced.

If we assume that young children may expend more of their cognitive resources on the processing component of strategy execution than older children, what factors underlie improvements with age in processing efficiency? Three possibilities can be mentioned. First, speed of information processing (e.g., Kail, 1991) increases markedly across the elementary school years, a change that is largely the result of maturation. Second, as indicated earlier, the development of the knowledge base – in terms of the greater coherence of the semantic network and increased ease of accessibility – may also contribute to increases in efficiency of strategy execution (Bjorklund, 1987). Third, the functional capacity of the system may increase with age because specific aspects of a task may come to require fewer resources, reflecting the increased automatization of skill that is associated with experience and practice (Case, 1985; Ornstein et al., 1988; Siegler, 1996).

#### 2.37.4.4.3 Metamemory

It is well documented that with increases in age, there also are changes in children's metamemory, that is, in their understanding of the demands of various memory tasks and of the operation of the memory system (Flavell and Wellman, 1977; Cavanaugh and Perlmutter, 1982; Schneider, 1985). It must be indicated, however, that even though metamemory figures prominently in accounts of mnemonic growth (e.g., Cavanaugh and Borkowski, 1980; Schneider, 1985), the results of correlational studies in which both memory and metamemory have been assessed have been quite mixed. Examples of some of the difficulties encountered in providing evidence for the proposed linkage between metamnemonic understanding and strategic deployment and effectiveness include cases in which children can articulate awareness of a memory strategy but nonetheless fail to actually use it in practice (Sodian et al., 1986), and in contrast, situations in which children use what might be viewed as a deliberate strategy but are unable to demonstrate any corresponding metamnemonic knowledge (Bjorklund and Zeman, 1982). On the other hand, both early training studies in which strategy instruction was supplemented by the provision of metamnemonic information (e.g., Paris et al., 1982), and more recent studies involving improved methods of assessing young children's understanding (e.g., Schneider et al., 1998; Schlagmüller and Schneider, 2002), provide convincing empirical evidence for the linkage between metamemory and memory development. For example, in a short-term longitudinal study, Schlagmüller and Schneider (2002) reported that children who acquired an organizational strategy over the course of the project actually showed increases in declarative metamemory well ahead of actually exhibiting the strategy.

#### *2.37.4.4.4 Schooling*

A number of lines of evidence lead to the inference that formal schooling may contribute to the development of children's increasing skill in the use of memory strategies. Consider, for example, comparative cultural investigations in which the performance of children who were matched in chronological age but who differed in terms of whether they had or had not participated in Western-style schooling have been contrasted. In studies carried out in Liberia (e.g., Scribner and Cole, 1978), Mexico (e.g., Rogoff, 1981), and Morocco (e.g., Wagner, 1978), children who attended school demonstrated superiority in the types of mnemonic skills that have typically been studied by Western psychologists and anthropologists. To illustrate, Rogoff (1981) reported that nonschooled children generally do not make use of organizational techniques for remembering unrelated items and that school seemed necessary for the acquisition of these skills. These findings, of course, do not in any way imply that schooled children outperform their unschooled peers on everyday memory tasks that are embedded in activities central to their culture. Nonetheless, they do suggest that something in the formal school context most likely is related to the emergence of skills that are important for success on tasks that involve deliberate memorization.

With comparative-cultural research indicating that something about formal schooling encourages the development of strategic behavior, the next question might be, When during a child's experience in school does this growth occur? First grade seems to be a strong possibility, as Morrison et al. (1995) showed that this grade is very important in terms of the development of memory skills. Morrison and his colleagues studied children who just made the mandated date for entry into first grade (a young first-grade group) and those who just missed the date (an old kindergarten group). As such, the children were basically matched in terms of age but nonetheless differed in their school experience, thus allowing for a comparison between a first-grade school experience and a kindergarten experience. To assess memory, Morrison et al. (1995) used a task (adapted from Baker-Ward, 1985) in which the children were asked to study a set of pictures of common objects. Taking performance at the start of the school year as a baseline, the young first graders evidenced substantial improvement in their memory skills. In contrast, the performance of the older kindergartners did not change over the year, although improvement was noted the next year, following their experience in the first grade. These findings imply that there is something in the first-grade context that is supportive of the development of children's memory skills. The potential importance of the first-grade experience is also suggested by Baker-Ward et al.'s (1984) finding, discussed above, that the strategic efforts of 4-, 5-, and 6-year-olds only facilitated the memory performance of the older children.

Given that the evidence points to formal schooling as a mediator of children's strategy development, Ornstein et al. (in press) have carried out a series of studies to characterize memory-relevant behaviors that teachers use that may support children's deliberate memory skills. Some of their findings are consistent with Moely et al.'s (1992) important report that it is quite rare to find explicit instruction in mnemonic techniques by teachers throughout the elementary school grades. However, even though mnemonic strategies are not generally taught by teachers in an explicit fashion, Ornstein and his colleagues find that first-grade teachers engage in a variety of memory-relevant behaviors in the course of whole-class instruction, including indirect requests for deliberate remembering, strategy suggestion, and metacognitive questioning. Moreover, children in first-grade classes taught by teachers who use more of this sort of memory-related language show a greater ability to take advantage of strategy training (meaning-based sorting and clustering in recall according to semantic categories) than those children with low-mnemonically oriented teachers (Coffman et al., 2003; see Moely et al., 1992, for similar results). In addition, teachers' mnemonic style in the first grade is linked to the organized sorting patterns on a sort-recall task with low-associated items that was administered to the children 3 years later, such that fourth graders who had been taught by high-mnemonic first-grade teachers sorted more semantically than did their peers who had been taught by low-mnemonic first-grade teachers. As such, this work suggests that just as 'parent talk' about events can impact preschoolers' developing abilities to remember (e.g., McCabe and Peterson, 1991; Reese et al., 1993; Haden et al., 2001; Boland et al., 2003), 'teacher talk' may also be relevant for the emergence and refinement of mnemonic skills.

#### 2.37.4.5 Determinants of Performance and Development

The research on children's strategy development reviewed here suggests that knowledge, effort, metamemory, and schooling can be viewed as mediators of the performance of children at any given age. These determinants of memory performance may also underlie developmental changes in strategic deployment and effectiveness. Changes with age in children's knowledge of the materials being remembered, the cognitive effort they need to execute tasks that involve remembering, and their understanding of the operation of the memory system all can contribute to age-related increases in strategic effectiveness. However, we attach special status to schooling as a potential mediator of change because the available evidence suggests that school represents a critical context for the emergence and consolidation of children's mnemonic efforts. Further, as suggested in our discussion of schooling, it seems likely that teacher–child conversation in the classroom is of great relevance for the development of a repertoire of strategies.

### 2.37.5 Exploring the Development of Memory

The research literature reviewed here provides a picture of the quite remarkable mnemonic competence of young children, as well as clear age-related differences in many aspects of memory performance. Much is thus known about memory development, that is, the memory skills of children of different ages, but much less is known about the development of memory in the sense of understanding the ways in which early instantiations of skill give way to later competencies, and the factors that serve to explain these changes. It also must be admitted that even understanding of memory development, while substantial, is nonetheless limited and that much remains to be learned about children's skills at various ages.

Why are there substantial gaps in what we know about memory and its development? To a considerable extent, the problem stems from the methodological choices typically made by researchers. Consider first the paradigm-driven nature of work on children's memory. Most studies of memory deal with remembering in the context of one or another task (many of which have been discussed here), and as a result, relatively little is known about linkages across tasks that vary in terms of their processing demands and other important characteristics. Yet this is exactly the type of information that is necessary to characterize adequately children's skills at any given age and to identify just what is changing with age and experience. For example, just as Bauer (2006) compared infants' abilities to imitate enabling versus arbitrary action sequences, thus providing useful diagnostic information, within-subjects contrasts in strategy use under different conditions could yield valuable insights into the memory skills of elementary school children and their development. As an example, Guttentag et al.'s (1987) description of children's rehearsal under typical (i.e., each item removed after being presented) and scaffolded (i.e., each item remained visible after being presented) conditions provides important information about skills that are in transition.

A second methodological preference of researchers also seriously hinders our understanding of developmental change. As suggested earlier, because the bulk of the literature is based on cross-sectional experiments, little can be said about the course of developmental change within individual children. Cross-sectional studies present useful accounts of the average level of competence on specified tasks at particular age levels, and the impression one derives is that of a smooth developmental pattern. However, there is nothing in a cross-sectional study that enables inferences about the course of development of an individual child or contrasting patterns of change for different groups of children. Moreover, putting both methodological concerns together, the rich cross-sectional literature can say nothing about how early skill in, say, elicited imitation relates to later ability in talking about the past, and still later competence in settings in which deliberate memorization is required. For information of this sort, it is necessary to make use of longitudinal research designs in which the development of skill is traced over time, with children being assessed on a range of contrasting tasks. Microgenetic studies (Siegler, 2006) in which children are tested repeatedly over relatively restricted periods of time during which skills are undergoing change can also be invaluable in informing our understanding of development.

The challenge, then, is for a commitment to research designs that truly can facilitate our understanding of the development of memory. Such a commitment requires a willingness to move across the sometimes cherished conceptual boundaries of different subgroups of researchers, for example, those of the information processing and the social constructivist traditions. It may be useful to think about the encoding, storage, and retrieval of information in information processing terms, and it may be equally productive to think about the forces that propel development from the perspective of social constructivism. This is especially the case when, as suggested above, children's developing memory skills may be fostered by social interaction with parents and teachers. By integrating these methods – and by including multiple assessments of children on tasks that are selected because of their contrasting information processing demands – it is possible to provide more precise cognitive diagnoses of children's changing skills as well as some insight into the social forces that drive development.

To illustrate the importance of longitudinal research for an understanding of development, consider first two longitudinal studies, one dealing with children's event recall in the context of the mother–child reminiscing work discussed above (Reese et al., 1993), and the other concerned with the development of active rehearsal strategies in deliberate memory tasks, also mentioned earlier (Guttentag et al., 1987). Admittedly, each of these studies is somewhat limited by a focus on only a single indicator of mnemonic competence and by the age range examined, but they nonetheless can serve to illustrate some of the benefits of this research strategy. For example, Reese et al. reported that the children of high-elaborative mothers showed higher levels of recall of the events under discussion (as assessed by their production of memory elaborations) than the children of low-elaborative mothers. However, what is unique about this study is the finding that, in the context of these mother–child interactions, the children acquired some generalized skills for remembering that had implications for their performance several years later. Thus, for example, levels of maternal elaboration early in development (at 40 months of age) are positively correlated with the children's skills in making independent contributions to these conversations at later points in time (e.g., at 58 and 70 months).

Guttentag et al.'s (1987) exploration of changes in verbal rehearsal from the third to the fourth grade complements Reese et al.'s (1993) event memory study. As suggested above, Guttentag and his colleagues were concerned with the effort requirements of active, cumulative rehearsal and reported that the rehearsal style of some third graders varied as a function of mode of presentation. In particular, some of the children who rehearsed in a passive fashion under the typical mode of presentation changed to a more active rehearsal pattern spontaneously when they were permitted visual access to the previously presented items. Turning this study into a short-term longitudinal investigation, Guttentag et al. assessed the children again after 1 year, when they were in the fourth grade. Interestingly, the researchers reported that the fourth graders' use of an active rehearsal technique under typical item-by-item presentation conditions was better predicted by what they could do as third graders in the scaffolded than the standard version of the task. They suggested that it was possible to view the children who evidenced active rehearsal as third graders when given visual access to the materials as being in a transitional stage of competence.

Other important insights into development are derived from two separate longitudinal studies of children's developing memory strategies that have been carried out by Schneider and his colleagues. In the first investigation (the Munich Longitudinal Study on the Genesis of Individual Competencies; Sodian and Schneider, 1999), children were tracked between 4 and 18 years of age, whereas in the second study (the Würzburg Longitudinal Memory Study; Schneider et al., 2004), a separate sample of children was observed multiple times between 6 and 9 years of age. Although the studies varied in a number of respects, a consistent pattern that emerges is that strategy development is not as gradual as the cross-sectional data discussed here would lead one to believe. In particular, in both investigations, the improvements that children showed in strategy use reflect a picture of dramatic leaps in performance and not gradual increases in sophistication over time.

Related to longitudinal investigations are microgenetic studies that feature frequent and intense observations of the same child across repeated sessions over relatively short intervals. Several unique insights have been gained from these types of investigation that provide new information concerning the emergence and consolidation of children's strategic efforts. First, Siegler's (2006) exploration of a variety of cognitive strategies suggests that children often use less effective techniques in tandem with more sophisticated and efficient strategies that have been recently acquired. In an important treatment of these patterns, Siegler (1996) describes strategy development in terms of an overlapping waves theory with elementary school children having mastery of a mix of strategies at any point in time, and development being viewed in terms of changes in the composition of this strategy mix. Consistent with this position, in their longitudinal study of developmental changes in rehearsal, Lehman and Hasselhorn (2007) observed that more than half of the children utilized two or more strategies within each measurement point, suggesting that they are making use of multiple strategies (e.g. naming, cumulative rehearsal) for remembering. Second, consistent with the Munich and Würzburg investigations, the results of microgenetic analyses confirm the fact that children do not always transition from rudimentary to complex strategies in a gradual fashion over time (Kuhn, 1995). Consider, for example, Schlagmüller and Schneider's (2002) microgenetic study of the development of a categorization strategy in the context of a sort–recall task. Fourth- and fifth-grade children, who had been identified as nonstrategy users in the context of the Würzburg longitudinal study of memory development, were given nine sort–recall tasks over the course of an 11-week period. Importantly, those children who adopted the organizational strategy did so in an all-or-none fashion at different times, with some children never categorizing during the task. However, once children came to organize the materials, immediate improvements in recall were observed and were linked to metamnemonic insights immediately prior to strategy acquisition.

## 2.37.6 Closing Thoughts

It is clear that longitudinal and microgenetic analyses of children's memory can extend the cross-sectional database in critical ways by providing a truly developmental account of the acquisition of skill. Although cross-sectional studies can generate valuable information about the abilities of children of different ages, thus suggesting age-related trends, statements about development within individuals can only be made when researchers employ designs in which the changing abilities of the same children are tracked over time. However, to be truly informative, longitudinal studies must be designed so as to identify potential mediators – such as adult–child conversations – of developmental change. Nonetheless, these important features of longitudinal investigations notwithstanding, it must be emphasized, as well, that they are not without their limitations. Indeed, most explorations of cognitive development that incorporate repeated assessments of children are correlational in nature, and as such, it is difficult to make statements about causation. It is thus essential to supplement these within-subjects approaches with experimental interventions in which variables of theoretical importance – such as the nature of the conversation to which children are exposed – are brought under experimental control. In fact, in the ideal research world, we envision an integrated methodological approach in which longitudinal studies that enable us to track children's skills and identify potential determinants of development are paired with training studies in which these mediators are explored experimentally. In this way, it should be possible to study both memory development and the development of memory.

# 2.38 Developmental Disorders of Learning*

**E. L. Grigorenko**, Yale University, New Haven, CT, USA

## 2.38.1 Developmental Disorders of Learning: What Do They Actually Mean?

Phenomenologically, the category of developmental disorders of learning refers to children who, for one reason or another, differ from their peers in acquisition of developmentally appropriate skills (e.g., speaking, counting, reading).

Conceptually, the category of developmental disorders of learning refers to deviations from typical development (1) that are substantial enough to qualify as disorders and (2) that affect learning. However, there is no single nosological category that brings these disorders together, and the two most established diagnostic manuals, the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV, published by the American Psychiatric Association, 1994) and the *International Classification of Diseases and Related Health Problems* (IDC-10, published by the World Health Organization, 2005), present only a partial overlap in how these disorders are classified.

The diversity of the disorders commonly viewed as developmental disorders of learning is captured in the following paragraphs. This list is presented here not to overwhelm the reader (and the information is quite daunting!), but rather to demonstrate a lack of agreement of what disorders of learning actually are.

Specifically, DSM-IV distinguishes a large category of Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence. This category includes, among other subcategories, the disorders that directly involve and affect learning, specifically, Mental Retardation; Learning Disorders (Reading Disorder, Mathematics Disorder, Disorder of Written Expression, and Learning Disorder Not Otherwise Specified, NOS); Motor Skills Disorders; Communication Disorders (Expressive Language Disorder, Mixed Receptive-Expressive Language Disorder, Phonological Disorder, Stuttering, and Communication Disorder NOS); Pervasive Developmental Disorders (Autistic Disorder, Rett's Disorder, Childhood Disintegrative Disorder, Asperger's Disorder, and Pervasive Developmental Disorder NOS); and Attention-Deficit and Disruptive Behavior Disorders (Attention-Deficit/Hyperactivity Disorder (ADHD), Conduct Disorder, Oppositional Defiant Disorder, and Disorders in Both Categories NOS).

ICD-10's Chapter V presents Mental and Behavioural Disorders with subcategories referred to as (1) Disorders of Psychological Development and (2) Mental and Behavioural Disorders. The former category is subdivided into Specific Developmental

* With permission from the publishers, the content of this chapter partially overlaps with Grigorenko EL (2007) Learning disabilities. In: Martin A and Volkmar F (eds.) *Lewis's Child and Adolescent Psychiatry: A Comprehensive Textbook,* 4th edn. Baltimore, MD: Lippincott Williams and Wilkins; and Grigorenko EL (2007) Triangulating developmental dyslexia: Behavior, brain, and genes. In: Coch D, Dawson G, and Fischer K (eds.) *Human Behavior and the Developing Brain.* New York: Guilford Press.

Disorder of Speech and Language (Specific Speech Articulation Disorder, Expressive Language Disorder, Receptive Language Disorder, Acquired Aphasia with Epilepsy, Other Developmental Disorders of Speech and Language, and Developmental Disorder of Speech and Language, Unspecified); Specific Developmental Disorders of Scholastic Skills (Specific Reading Disorder, Specific Spelling Disorder, Specific Disorder of Arithmetic Skills, Mixed Disorder of Scholastic Skills, Other Developmental Disorder of Scholastic Skills, Developmental Disorder of Scholastic Skills, Unspecified); Specific Developmental Disorder of Motor Function; Mixed Specific Developmental Disorders; Pervasive Developmental Disorders (Pervasive Developmental Disorders, Childhood Autism, Atypical Autism, Rett's Syndrome, Other Childhood Disintegrative Disorder, Overactive Disorder Associated with Mental Retardation and Stereotyped Movements, Asperger's Syndrome, Other Pervasive Developmental Disorders, Pervasive Developmental Disorder, Unspecified), among other disorders. The latter category includes a cluster of disorders associated with hyperactivity and conduct problems (e.g., Hyperkinetic Disorder and Conduct Disorder), separating attention problems from problems of hyperactivity (with attention problems listed in the first category as a psychological problem) and including stuttering in this category, rather than as a disorder of speech and language.

To restate, there is no uniformly accepted approach in how developmental disorders of learning should be referred to or classified. Correspondingly, in staging the discussion that unfolds in this chapter, it is important to comment on the following three issues. First, it is clear that no single nosological category captures all developmental disorders of learning. There are many developmental disorders where learning is disrupted. Second, many of these developmental disorders are comorbid, that is, co-occur in the same individual. Thus, which disorder is diagnosed as primary and what other disorders are codiagnosed is variable. Third, although there are many disorders in which learning is disrupted, the 'label' that typically denotes challenged learning is Learning Disability (LD). As mentioned earlier, this category is not used as a diagnostic category. Yet, there is a mountain (or rather a mountain chain) of literature on this category. For the ensuing discussion, it is important to differentiate nonspecific (or general) and specific LDs. Conventionally, the term nonspecific LD is used to refer to generalized problems of learning, such as mental retardation, and the term specific LD (SLD) is used to refer to disorders in a particular domain of acquisition or learning, such as reading, writing, or mathematics.

In this chapter, I use the concept of LD even though, as mentioned earlier, it does not correspond directly to any particular nosological category in the two predominant diagnostic schemes of the developed world. Throughout the chapter, I argue that LD best captures the common thread of all developmental disorders of learning.

## 2.38.2 The Concept of Learning Disabilities

Fundamentally, the concept of LD encompasses society's capacity

> . . . to monitor (and recruit) children for unexplained school failure in a way that was not possible before the LD category was reified and passed into law in 1969. (Reid and Valle, 2004: 467)

The LD category replaced a variety of 'loose' definitional references to previously used qualifiers such as 'slow learner,' 'backward children' (Franklin, 1987), and 'minimal brain dysfunction' (Fletcher et al., 2002).

In terms of its 'realization' in the context of current practices, the LD label typically assumes the presence of the following process. Under normal circumstances, LDs are not diagnosable prior to a child's engagement with schooling and the opportunity to master key academic competencies. While in school, a child is assumed to be assigned grade-appropriate tasks. These tasks assume some degree of variability in children's performance; these theoretical ranges constrain the definitions of acceptable and worrisome variability in performance (*See* Chapter 2.40). It is when the child's performance consistently falls out of the acceptable range in one or more academic subjects that the child becomes the focus of intense observation and documentation and is referred for evaluation to appropriate professionals (e.g., educational psychologists, neuropsychologists, and clinicians such as pediatricians, clinical psychologists, or psychiatrists). An important qualifier here is that such observation, documentation, and evaluation are considered only for children whose performance is below that expected based on their general capacity to learn; thus, the concept of 'unexpected' school failure is central to the definition of LD. When reports on the child's performance in the classroom, testing results, and clinical evaluations are compiled, the child and his or her family are referred to a special education committee, which determines eligibility for individualized special education services. If eligibility is established, an Individualized Education Program (IEP) is created. The IEP refers to a specific diagnostic label carried by the child and cites the proper category of public laws that guarantees services for an individual with such a diagnosis.

## 2.38.3 Definition

The definition that currently drives federal regulations was produced by the National Advisory Committee on Handicapped Children in 1968 and subsequently adopted by the U.S. Office of Education in 1977 (Mercer et al., 1996). According to this definition,

> Specific learning disability means a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which may manifest itself in an imperfect ability to listen, think, speak, read, write, spell, or to do mathematical calculations. The term includes such conditions as perceptual handicaps, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia. The term does not include children who have learning problems which are primarily the result of visual, hearing, or motor handicaps, of mental retardation, or emotional disturbance, or of environmental, cultural, or economic disadvantage. (U.S. Office of Education, 1977: 65083)

Again, neither DSM-IV nor ICD-10 uses the term learning disabilities. DSM-IV makes a reference to learning disorders (American Psychiatric Association, 1994), which, according to DSM-IV, can be diagnosed,

> . . .when the individual's achievement on individually administered, standardized tests in reading, mathematics, or written expression is substantially below that expected for age, schooling, and level of intelligence. (American Psychiatric Association, 1994: 46)

Of interest here is that this is one of the very few categories of DSM-IV where a reference is made explicitly to psychological tests, although DSM-IV does not provide specific guidelines as to what 'substantially below' means. Thus, DSM-IV implicitly refers to evidence-based practices (Fletcher et al., 2002) in the field. The problem, of course, is that there are multiple interpretations of these best practices (see discussion to follow). Yet, assuming there are consistent and coherent guidelines in place for establishing a diagnosis of LD, DSM-IV classifies types of LDs by referencing the primary academic areas of difficulty. The classification includes three specific categories and a residual diagnosis: Reading Disorder, Mathematics Disorder, Disorder of Written Expression, and Learning Disorder NOS. A common practice in the field is to view a diagnosis of a learning disorder as established by DSM-IV as an equivalent to 'specific learning disability,' which qualifies a child for special services under federal regulations (House, 2002).

## 2.38.4 History

The introduction of the concept of LD is typically credited to Samuel Kirk (then a professor of special education at the University of Illinois), who, while presenting at a parent meeting in Chicago on April 6, 1963, proposed the term learning disabled to refer to "children who have disorders in development of language, speech, reading, and associated communication skills" (Strydom and du Plessis, 2000). The category was well received by parents and promoted shortly thereafter by an established parent advocacy group known as the Association for Children with Learning Disabilities. Prior to the formal introduction of this concept, the literature had accumulated numerous descriptions of isolated cases and group analyses of children with specific deficits in isolated domains of academic performance (e.g., reading and math) whose profiles were later reinterpreted as those of individuals with specific LDs (e.g., specific reading and math disabilities). It is those examples in the literature and the experiences of many distressed parents who could not find adequate educational support for their struggling children that, in part, resulted in the creation of the field of LDs as a social reality and professional practice (Hallahan and Mercer, 2002). Subsequent accumulation of research evidence and experiential pressure led to the formulation of legislation protecting the rights of children with LDs.

Congress enacted the Education for All Handicapped Children Act (Public Law 94-142) in 1975 to support states and educational institutions in protecting the rights of, meeting the individual needs of, and improving the results of schooling for infants, toddlers, children, and youth with disabilities and their families. This landmark law is currently enacted as the Individuals with Disabilities Education Act (IDEA, Public Law 105-17; although the precise title of the law in its 2004 amendment is Individuals with Disabilities Education Improvement Act, it is still referred to as IDEA), as amended in 2004. The importance of this law is difficult to overstate: In 1970, U.S. schools provided education to only one in five children with disabilities (U.S. Office of Special Education Programs, 2000). By 2003–2004, the number of children aged 3–21 served under IDEA was more than 6.6 million (National Center for Education Statistics, 2005b).

SLDs make up 50% of all special education students served under IDEA. The term has proliferated very successfully and very quickly within the last two decades. There are multiple reasons why the concept of LD has enjoyed such success, among which are a lack of social stigma (i.e., parents are much more comfortable with the label of LD than with categories such as minimal brain dysfunction or brain injury), absence of implication of low intelligence or behavioral problems, and access to services (Zigmond, 1993).

In its 2004 amendment, IDEA recognized 13 categories under which a child can be identified as having a disability: autism; deaf–blindness; deafness; emotional disturbance; hearing impairment; mental retardation; multiple disabilities; orthopedic impairment; other health impairment; specific learning disability; speech or language impairment; traumatic brain injury; and visual impairment including blindness. It is notable that LDs as described in IDEA are referred to as 'specific learning disabilities' to emphasize the difference between children with SLDs and those with general learning difficulties characteristic of other IDEA categories (e.g., autism and mental retardation). The consensus in the field is that children with LDs possess average to above-average levels of intelligence across many domains of functioning but demonstrate specific deficits within a narrow range of academic skills. Finally, as stated earlier, exclusionary factors have been central to diagnoses of LDs since the authoritative definition of LD was introduced in 1977. As per these exclusionary criteria, a child cannot be diagnosed with an LD unless factors such as other disorders or lack of exposure to high-quality age-, language-, and culture-appropriate educational environments have been ruled out. It is the desire to rule out the exclusionary factor of lack of exposure to high-quality environments that prompted the introduction of the concept of Response to Treatment Intervention (RTI) (Deshler et al., 2005) in the 2004 amendment of IDEA. RTI signifies

> . . . individual, comprehensive student-centered assessment models that apply a problem-solving framework to identify and address a student's learning difficulties. (Deshler et al., 2005: 483)

It is important to note that RTI might appear counterintuitive at first: How can a disorder be defined through treatment if treatment is prescribed for a particular disorder? This 'circularity' of RTI, however, is only superficial. An implicit assumption behind RTI is that teaching is inadequate, and that is why schools 'produce' such a high level of LDs. A closer analogy would not be with treatment, but with prevention with vitamins; if vitamins are delivered properly, then many deficiencies can be avoided. Thus, if all children get extensive preventive instruction, the frequencies of LDs will diminish (see more detail on RTI in the section titled 'Presentation and diagnoses').

## 2.38.5 Epidemiology

Since the 1968 statutory introduction of LD as a legislated disability (i.e., within ~35 years of its existence as a category), approximately 50% of all students receiving special educational services across the nation have received them under the category of LD (Donovan and Cross, 2002). Among these students, the majority (80–90%) demonstrate substantial difficulties in reading (Kavale and Reese, 1992), and two of every five were identified because of persistent difficulties in reading acquisition (President's Commission on Excellence in Special Education, 2002).

There are two main sources for estimates of prevalence rates of LDs.

The first and most obvious one is linked to the number of children served under this category of IDEA. When this number is mapped on the total number of school-age children in the United States, although the number fluctuates from year to year, the average estimates of prevalence rates for LDs are around 5–6% of the total school-age population. To illustrate, in 2003, 2.72 million children were identified as having LDs. This represents a 150–200% increase in the number of students aged 6–17 with LDs compared with that number in 1975.

Yet, it is important to note that prevalence rates vary substantially from district to district and from state to state. For example, in 2004, under the SLD category, in Kentucky, 1.8% of all students aged 6–21 received special education services, compared with 5.9% in Iowa. Thus, based on these numbers, the prevalence rates of LDs in Iowa are about 3.3 times as high as in Kentucky, two states in close geographic proximity! This observation stresses the mosaic-like situation of LD diagnosis – there is no unified approach to these diagnoses across different local education agencies in the United States.

When IDEA-related prevalence rates are considered, LDs are observed more frequently in boys than in girls (64.5% vs. 33.5% for boys and girls aged 6–17, respectively) and more frequently in underrepresented minority groups than in Asian Americans or Whites. Risk ratios (which compare the proportion of a particular racial/ethnic group served to the proportion of all other racial/ethnic groups combined) are 1.5, 0.4, 1.3, 1.1, and 0.9 for American Indian, Asian American, African American, Hispanic American, and White students, respectively. A risk ratio of 1.0 indicates no difference between the racial/ethnic groups.

The second source for these rates is research studies. Per results from these studies, it is assumed that, although 10–12% of school-age children show specific deficits in selected academic domains, high-quality classroom instruction and supplemental intensive small-group activities can reduce this number to ~6% of children. It is assumed that these 6% will meet strict criteria for LDs and require special education intervention.

It is important to note that most of the research in the field of LDs is currently conducted with reading and, correspondingly, Specific Reading Disability (SRD). There is little established evidence that reliably points to prevalence rates of disorders of math and writing.

To illustrate, according to the results of current research on early reading acquisition, 2–6% of children do not show expected progress even in the context of the highest quality evidence-based reading instructions. Based on U.S. national data, the risk for reading problems as defined through failure to reach age- and grade-adequate milestones ranges from 20–80%. Specifically, data from the 2005 National Assessment of Educational Progress show that 36% of fourth graders do not possess the adequate reading skills required for completion of grade-appropriate educational tasks (National Center for Education Statistics, 2005a). However, it is clear that far from all of these children have SRD. The majority of these children mostly likely underachieve because of inadequate educational experiences and causes other than SRD.

Some changes in the 2004 version of IDEA were invoked directly because of concerns regarding the overidentification of students as learning disabled. The category of LDs has often been the largest single category of children served under IDEA (for latest relevant statistics, see IDEA Data, 2006). The reality of everyday practices in school districts was such that most diagnoses prior to the 2004 reauthorization were based on so-called aptitude–achievement discrepancy criteria, which required a severe discrepancy between IQ and achievement scores (e.g., two standard deviations, 2 years of age equivalence), although IDEA had never specifically required a discrepancy formula (Mandlawitz, 2006). Correspondingly, it has been argued that these discrepancy-based approaches are flawed (Francis et al., 2005) and might have led to overidentification. In light of this hypothesis, IDEA 2004 emphasizes that there is no explicit IQ–achievement discrepancy requirement for diagnosis of LDs. As a possible alternative approach for identification and diagnosis, IDEA 2004 states that local educational agencies may use a child's RTI in lieu of classification processes (Council of Parent Attorneys and Advocates, 2004). A local educational agency (e.g., a school) may choose to administer to the child in question an evidence-based intervention program to determine his or her eligibility for special education services under IDEA based on the child's response to this program.

Specifically, the statutory language of IDEA 2004 (Public Law 108-446) states:

> (6) Specific Learning Disabilities.
>
> (A) In general.
>
> Notwithstanding section 607(b), when determining whether a child has a specific learning disability as defined in section 602, a local educational agency shall not be required to take into consideration whether a child has a severe discrepancy between achievement and intellectual ability in oral expression, listening comprehension, written expression,

basic reading skill, reading comprehension, mathematical calculation, or mathematical reasoning.
(B) Additional authority.
In determining whether a child has a specific learning disability, a local educational agency may use a process that determines if the child responds to scientific, research-based intervention as a part of the evaluation procedures described in paragraphs (2) and (3). (§614(b) (6))

As a consequence of this language, although aptitude–achievement discrepancy has been and continues to remain the common, although not required, practice for local educational agencies, there is a new 'entry point' for RTI. Needless to say, these changes are of great theoretical and practical importance. The tradition and system of specific LD identification in the United States are now fluid, and rather few specific recommendations exist to help local educational agencies smoothly transition into the implementation of IDEA 2004.

## 2.38.6 Presentation and Diagnoses

As stated earlier, it is crucially important in a diagnosis of LD to establish a child's 'typical' intellectual performance and to document that the child's performance in the area of difficulty (e.g., reading or mathematics) does not correspond to what would be expected, given average intellectual functioning. Although this general principle is relatively easy to grasp, the field of LDs has struggled since its inception in the early 1960s to establish specific steps that should lead to the establishment of the diagnosis.

Prior to the 2004 reauthorization of IDEA, the most common way of establishing an LD diagnosis was the discrepancy criterion. The introduction of the discrepancy between ability and achievement criteria in the 1977 law was not based on empirical research, but rather driven by a need for a more objective approach to the diagnoses than those commonly used and largely discredited at the time (Gresham et al., 2004). Two decades of research and practical explorations of the discrepancy model resulted in its discreditation from points of view of theory (Sternberg and Grigorenko, 2002), reliability of diagnosis and classification (Francis et al., 2005), robustness of implementation (Haight et al., 2002), and treatment validity (Aaron, 1997). In response to the overwhelming amount of evidence for the inadequacy of the discrepancy model, however realized (through psychometric indices, age equivalences, regression approaches, or expert opinions), a number of alternative models have been proposed. The major dividing line between these new models and previous discrepancy-based models is in their theoretical orientation. Previous diagnostic models attempted to identify children diagnosable with LDs by looking for characteristic cognitive deficits, so that an intervention could be delivered to children with such deficits (Reschly, 1996), whereas the modern models argue for the need to deliver best pedagogical practices to all children and then best remediational-intervention approaches to those children who do not respond as well to good teaching (Reschly and Ysseldyke, 2002).

As per the 2004 reauthorization of IDEA, local educational agencies have some choice in selecting diagnostic models. At this point, the most widely discussed and evidence-supported model of LD identification is the Responsiveness/Response to Intervention (RTI) model (Vaughn and Fuchs, 2003). The RTI model has a number of features. First, the performance of the student in question is compared with the performance of his/her immediate peers on academic tasks. Specifically, RTI assumes tracking the academic performance and rate of its growth for all students within a given class, with a goal of identifying those students in a class whose performance differs from that of their peers both in absolute (i.e., level) and relative (i.e., rate of growth) terms. Second, the model is structured primarily by intervention, so students identified by these means are offered individualized accommodations and interventions with a goal of maximizing the effectiveness of the learning environment for a given student in need. Third, the model is multilayered, so that each layer offers an opportunity for further differentiation and individualization of education for students who need it. Typically, three layers are recommended: The first tier covers regular classroom environment; the second tier is characterized as 'supplemental' to tier 1; and the third tier is 'intensive,' 'individualized,' and 'strategic.' Fourth, only if these multilayered attempts to modify the regular classroom pedagogical environment are unsuccessful is the prospect of an LD diagnosis considered. In summary, a child could be identified as having an LD if he or she consistently failed to perform at a level and progress at a rate comparable with the child's peers in general education after having participated in an evidence-based intervention.

Although there is considerable agreement in the field on the promise of RTI as a diagnostic paradigm, there are a variety of opinions regarding how, specifically, RTI should be quantified. Currently, the following paradigms are on trial: (1) Administer norm-referenced assessment batteries at the beginning and end of every school year to quantify the growth in response to intervention – students whose growth rate is below 'appropriate' should receive additional intervention, and (2) administer norm-referenced assessment batteries with a particular performance threshold (i.e., 25th percentile) – students whose performance is below this threshold should receive intensive interventions, and their performance should be monitored at least four times a year. There is also significant theoretical and experimental evidence suggesting the need for and importance of continuous progress monitoring with frequent (e.g., weekly) assessments of improvement. Currently, however, there are concerns about both approaches because of a lack of trained educational and practical professionals equipped to translate and implement research-based interventions into the everyday life of American schools. Since the 2004 reauthorization of IDEA, local education agencies have been in search of new robust solutions for identifying LDs that will meet the regulations of federal laws. RTI-based approaches to LD diagnosis present considerable challenges for all professionals involved in the realization of IDEA: general and special education teachers, diagnosticians (psychologists and psychiatrists), and school psychologists. The heart of this challenge is the lack of operationalization and practical guidelines that can be easily implemented at the 'frontiers' of diagnosing and treating children with LDs.

The majority of students with LDs are identified in middle and high school: Early years of schooling might simply be insufficient for exposing and making evident a deficit in a particular academic domain. As mentioned, the core conceptual piece of the LD definition is that the deficit could have not been predicted reliably prior to the child's school entry because a child with LDs demonstrates otherwise typical levels of cognitive functioning.

Previously when the discrepancy criteria were applied, the diagnosis of LD was different from other forms of learning difficulties because of its stress on the specificity of the deficit (i.e., a discrepancy was expected not in all academic domains, but in a specific academic domain). The introduction of RTI-based approaches to diagnosis makes the question of differential diagnosis somewhat difficult to address. In fact, students with mental retardation, emotional or behavior disorders, ADHD, and other childhood and adolescent disorders might also exhibit low responsiveness to intervention. Yet, their nonresponsiveness will occur for reasons very different from those of students with LDs. In other words, if RTI cannot differentiate LDs from other diagnoses where learning difficulties are present but nonspecific, can RTI even be considered as a classification/diagnostic instrument (Mastropieri and Scruggs, 2005)?

Although this question has been raised, it has not yet been answered. The pre-2004 conceptualization of LDs assumed that the texture of LDs was in deficient (or different, atypical) psychological processing of information. In other words, the field was driven by the assumption that LDs were likely to represent a dysfunction in one or more basic psychological processes (e.g., phonological processing, sustained attention, different types of memory, executive functioning). These deficient processes in turn can slow down or inhibit mastery of a particular academic domain (e.g., reading or mathematics). Under this assumption, intensive academic instruction could improve performance in specific academic domains but could not treat the disorder. Even if reading improves as a result of intervention, in this paradigm the disorder might remanifest as a deficiency in a bordering domain (e.g., writing). In other words, although reading skills might be enhanced, the deficient psychological skills might impede some other academic domain of functioning.

Throughout the existence of the category of specific LDs, there has been a consistent and strong drive from parents, researchers, and educators for differentiating these disorders from generic learning difficulties. In its current iteration, RTI does not differentiate nonspecific and specific learning difficulties, because nonresponsiveness to intervention can occur with a variety of developmental disorders. In sum, because IDEA preserved the category of SLDs, there is a new huge task to differentiate specific and nonspecific learning difficulties by means of RTI and possibly other methods in the field.

One of these 'other' methods has to do, of course, with psychological testing. Many researchers argue for the necessity of maintaining the role of psychoeducational and neuropsychological tests on a variety of indicators, including IQ, in establishing LD diagnosis (Mastropieri and Scruggs, 2005; Semrud-Clikeman, 2005).

## 2.38.7 Etiology

There is a consensus in the field that LDs arise from intrinsic factors and have neurobiological bases, specifically atypicalities of brain maturation and function. There is a substantial body of literature convincingly supporting this consensus and pointing to genetic factors as major etiological factors of LDs. The working assumption in the field is that these genetic factors affect the development, maturation, and functional structure of the brain and in turn influence cognitive processes associated with LDs. Yet the field is acutely aware that a number of external risk factors, such as poverty and lack of educational opportunities, affect patterns of brain development and function and, correspondingly, might worsen the prognosis for biological predisposition for LDs or act as a trigger in LD manifestation.

Although this model, in main strokes, appears to be relevant to all LDs, far more research on relevant genes and brain structure and function is available for children with SRD than for any other LD. Thus, illustrative findings are presented here from SRD (for a more comprehensive review, see Grigorenko, 2007).

Multiple methodological techniques, such as electroencephalograms, event-related potentials, functional resonance imaging, magnetoencephalography, positron emission tomography, and transcranial magnetic stimulation, have been used to elicit brain–reading relationships (for recent reviews, see Price and Mechelli, 2005; Shaywitz and Shaywitz, 2005; Simos et al., in press). When data from multiple sources are combined, it appears that a developed, automatized skill of reading engages a wide bilateral (but predominantly left-hemispheric) network of brain areas passing activation from occipitotemporal, through temporal (posterior), toward frontal (precentral and inferior frontal gyri) lobes. Clearly, the process of reading is multifaceted and involves evocation of orthographical, phonological, and semantic representations that in turn call for the activation of brain networks participating in visual, auditory, and conceptual processing. Correspondingly, it is expected that the areas of activation serve as anatomic substrates supporting all these types of representation and processing.

Somewhat surprisingly, per recent reviews, there appear to be only four areas of the brain of particular, specific interest with regard to reading. These areas are the fusiform gyrus (i.e., the occipitotemporal cortex in the ventral portion of Brodmann's area 37, BA 37), the posterior portion of the middle temporal gyrus (roughly BA 21, but possibly more specifically, the ventral border with BA 37 and the dorsal border of the superior temporal sulcus), the angular gyrus (BA 39), and the posterior portion of the superior temporal gyrus (BA 22).

It is also important to note the developmental changes in patterns of brain functioning that occur with increased mastery of reading skill: progressive, behaviorally modulated development of left-hemispheric 'versions' of these areas and progressive disengagement of right-hemispheric areas. In addition, there appears to be a shift of regional activation preferences. The frontal regions are used by fluent more than by beginning readers, and readers with difficulties activate the parietal and occipital regions more than the frontal regions.

In an attempt to understand the mechanism of the 'deficient' pattern of brain activation while engaged in reading, researchers are looking for genes that might be responsible, at least partially, for these observed differences in functional brain patterns. This search is supported by a set of convergent lines of evidence (for reviews, see Fisher and DeFries, 2002; Grigorenko, 2005; Barr and Couto, in press). First, SRD has been considered a familial disorder since the late nineteenth century. This consideration is grounded in years of research into the familiality of SRD (i.e., similarity on the skill of reading among relatives of different degree), characterized by studies that have engaged multiple genetic methodologies, specifically twin (Cardon et al., 1994, 1995; Byrne et al., 2005), family (Wolff and Melngailis, 1994; Grigorenko et al., 1997; Cope et al., 2005) and sib-pair designs (Francks et al., 2004; Ziegler et al., 2005). Although each of these methodologies has its own resolution power to explain similarities among relatives by referring to genes and environments as sources of these similarities and obtaining corresponding estimates of relative contributions of genes and environments, all methodologies have produced data that unanimously point to genetic similarities as the main source of familiality of SRD.

Today, it is assumed that multiple genes contribute to the biological risk factor that runs in families and forms the foundation for the development of SRD. Specifically, nine candidate regions of the human genome have been implicated (Grigorenko, 2005). These regions are recognized as SRD candidate regions; they are abbreviated as *DYX1–9*

(DYX for dyslexia, a term often used to refer to SRD) and refer to the regions on chromosomes 15q, 6p, 2p, 6q, 3cen, 18p, 11p, 1p, and Xq, respectively. Each of these regions harbors dozens of genes, so clearly, the field offers empirical validation that multiple genes contribute to the manifestation of SRD. A number of different research groups are actively at work on these genetic regions in an attempt to identify plausible candidate genes. Four successful attempts have been announced in the literature: one for the 15q region, the candidate gene known as *DYX1C1* (Taipale et al., 2003); two for the 6p region, the candidate gene known as *KIAA0319* (Francks et al., 2004; Cope et al., 2005) and the candidate gene knows as *DCDC2* (Meng et al., 2005; Schumacher et al., 2006); and one for the 3cen region, *ROBO1* (Hannula-Jouppi et al., 2005). Although the field has not yet converged on 'firm' candidates, it is remarkable and of great scientific interest that all four current candidate genes for SRD are involved with biological functions of neuronal migration and axonal crossing. Thus, all these genes are plausible candidates for understanding the pattern of brain functioning in SRD described earlier.

## 2.38.8 Relevant Theoretical Models and Considerations

As mentioned earlier, the literature on LDs is uneven, with the vast majority relating to SRD. Correspondingly, here I summarize the so-referred overarching model of LDs (Fletcher et al., 2007). Subsequently, I illustrate this model with detailed references to SRD. The overarching LD model delineates multiple levels of analyses and evidence.

According to this general model, LDs are anchored in a domain of particular academic difficulties (e.g., reading, spelling, computing, and writing). Correspondingly, the identification of an LD assumes that a diagnosis can be validly and reliably established on the basis of observed repeated patterns of weaknesses in a particular academic domain in the presence of strengths in all or some other academic domains. Thus, concerns, referrals, and diagnostic assessments are always centered on a particular academic domain that defines the content of LD. Correspondingly, the first step in LD identification is documenting the presence of a consistent failure or academic skill deficits, when compared with peer performance, on a set of specific tasks. Thus, behavioral presentation in a particular academic domain is the first level of analysis in the pyramid of LD diagnoses. However, the presence of an academic deficit is a necessary but insufficient condition for establishing an LD diagnosis.

The second level of analysis pertains to capturing individual characteristics of the child for whom an LD diagnosis is considered. Specifically, at this level, clusters of child characteristics are considered within the paradigm of inclusion and exclusion criteria of the LD category. Typically, at this level, the information is gathered in four directions: (1) pertaining to the academic domain of concern and cognitive processing known to be relevant to this particular domain, (2) pertaining to other academic domains in which the child demonstrates average or above-average levels of performance, (3) indicators of general cognitive functioning, and (4) other noncognitive and nonacademic domains of child's functioning (e.g., motivation, neurological and psychiatric indicators). Obviously, the information gathered at (1) is used within the context of inclusion and the information gathered in (2)–(4) within the context of exclusion criteria. It is critically important that there are well-developed psychological models available both for (1) and (2). For example, to identify LD in reading (SRD), it is important to know what cognitive processes constitute the texture of this academic skill. Similarly, since academic skills tend to correlate substantially in typically developing children, it is important to know what SRD and, for example, specific math disability (SMD) have in common and how they differ in terms of overlapping and specific psychological processes. To illustrate this level of analysis, I discuss modern psychological models of SRD below.

The third level of analysis involves both causal and associated etiological factors of LD. Specifically, a number of risk and protective factors rooted in the child's biology (e.g., gene and brain factors) and environment (e.g., school, neighborhood, and family environment factors) are considered at this level. The point here is to capitalize on the evidence in the field to differentiate LDs and underachievement, specific and nonspecific LDs, and specific LDs and comorbid conditions.

It is important to note that this model allows a diagnostician to move both up and down. The expectation is that the information converges across all three levels of analysis, and the diagnosis of LD is reliably established. However, it is possible, especially with young children, that the first 'level of entry' into the model is through cognitive processes that constitute the texture of the skill and thus emerge prior to the acquisition of the skill; for example, a child having difficulty mastering rhymes and letters might be identified as at risk for reading failure prior to entering formal reading instruction (Lonigan, 2003). Similarly, it is possible to enter the model through the level of biological risk factors; for example, given that SRD appears to be genetic, a child whose parents both have difficulty reading is at higher risk for SRD than is a child from a risk-free family (Gallagher et al., 2000; Lyytinen and Lyytinen, 2004). But, again, no matter what level of analysis this overarching model is entered through, it is very important that there are evidence-based models of acquisition of a particular skill (e.g., reading or mathematics) that is challenged in an LD.

Although psychological models of other LDs have been developed, here only those for SRD are exemplified for illustration purposes.

So far, there have been only generic references to the disruption of both the acquisition and mastery of reading skills that constitute the texture of SRD. When this generic reference is closely considered, another massive body of literature materializes: (1) cognitive psychology literature on types of representation of information involved in reading (i.e., reading involves the translation of meaningful symbolic visual codes (orthographical representation) into pronounceable and distinguishable sounds of language (phonological representation) so a meaning (semantic representation) arises) (Harm and Seidenberg, 2004); (2) developmental psychology literature on when these representations develop and what might cause the development of a dysfunctional representational system (Karmiloff-Smith, 1998); and (3) educational psychology literature on how the formation of functional representations can be aided or corrected when at risk for malfunction (Blachman et al., 2004).

Here only brief commentaries relevant to these literatures are offered. Today, given the predominance of the phonology-based connectionist account of SRD, behavioral manifestation of SRD is captured through a collection of highly correlated psychological traits. Although different researchers use different terms for specific traits, these can be loosely structured into groups aimed at capturing different types of information representation, for example: (1) performance on orthographic choice or homonym choice judgment tasks for quantifying parameters of orthographical representation; (2) phonemic awareness, phonological decoding, and phonological memory for quantifying phonological representation; and (3) vocabulary and indices of comprehension at different levels of linguistic processing for quantifying semantic representation. Correspondingly, in studies of the etiology, development, and educational malleability of SRD, the quantification of the disorder is carried out through these various traits (or components of SRD). Thus, many studies attempt to subdivide SRD into its components and explore their etiological bases, developmental trajectories, and susceptibility to pedagogical interventions separately as well as jointly.

Of note is that similar developments with regard to dissection of an academic skill and differentiation of componential psychological processes contributing to this skill have been taking place in the studies of acquisition of other academic skills, for example, mathematics (Butterworth, 2005; Geary, 2005; Fuchs et al., 2006; Fletcher et al., 2007).

## 2.38.9 Manifestation and Life Course

There is an accepted understanding in the field that LDs are typically lifelong disorders, although their manifestations might and often do vary depending on developmental stage and demands of the environment (e.g., school, work, retirement) imposed on an individual at a particular time. This understanding assumes that LDs do not manifest themselves exclusively in academic settings. In fact, although it might be successfully remediated during schooling, a particular LD might need further assistance and remediation in later years (e.g., as a part of the workforce). Although the literature on adults with LDs is still somewhat limited, there is an accumulation of evidence that LDs constitute a serious public health problem even after schooling. Such evidence is particularly rich in the field of studies of SRD.

LDs are comorbid with a number of other disorders typically diagnosed in childhood or adolescence, especially attention deficit (Semrud-Clikeman et al., 1992) and disruptive behavior disorders (Grigorenko, 2006). LDs also often co-occur with anxiety and depression (Martinez and Semrud-Clikeman, 2004). Correspondingly, individuals with LDs are at higher risk for developing other mental health problems.

Yet, the main drawback for individuals with specific LDs has to do with their educational achievement. On average, only ~50% of students aged 14 and older diagnosed with LDs graduate with regular high school diplomas. The dropout rate among these students is very high (~45%), and it is even higher for underrepresented minority students. The employment prospects of these students are also troublesome – only about 60% of student ages 14 and older diagnosed with LDs have paid jobs outside the home.

Thus, it is important to realize that the impact of LDs is not limited to any one academic domain (e.g., reading or mathematics); these are lifetime disorders with wide-ranging consequences.

## 2.38.10 Treatment, Remediation, Intervention, and Prevention

Currently, there are no approved medical treatments for children with LDs. There is a consensus in the field that children with LDs should be provided special education and related services upon establishment of their eligibility and determination of the necessity, content, duration, and desired outcomes of such education and services.

Yet, in much of the literature, many educators have expressed concern with the possible presence of faulty identification procedures in states and districts across the country, which has resulted in the possible abuse of the classification and service systems. The ever-growing number of children identified with LDs might indicate that this category has become a 'trap' for lower-performing students, irrespective of an LD diagnosis.

In response to this concern, the 2004 reauthorization of IDEA makes reference to a set of prevention mechanisms intended to establish a better classification strategy for identifying children with LDs. By law, schools need to implement systemic models of prevention that address (1) primary prevention: the provision of high-quality education for all children; (2) secondary prevention: targeted, scientifically based interventions for children who do not respond to primary prevention; and (3) tertiary prevention: the provision of intensive individualized services and interventions for those children who have not responded to high-quality instruction or subsequent intervention efforts. As per new regulations, it is assumed that this third group of children, namely those children who have failed to respond to age-, language-, and culture-appropriate, evidence-based, domain-specific instruction (e.g., in reading or mathematical cognition), can be identified as eligible for special education services. These prevention mechanisms are also assumed to be used as diagnostic mechanisms (see earlier discussion of RTI). This circular system of an outcome of intervention being also an entry point to diagnosis is currently creating significant turmoil in the literature and in practice.

In general, RTI approaches are conceived as a twofold simultaneous realization of high-quality, domain-specific instruction and continuous formative evaluation of students' performance and learning (Mellard et al., 2004a,b). In other words, RTI refers to ongoing assessment of students' response to evidence-based pedagogical interventions in particular academic domains. Thus, it is assumed that LDs can be identified only when underachievement related to poor instruction is ruled out. (It is also important to note that the primary diagnosis of LD is established only in the absence of other neuropsychaitric conditions.) Although it exists in a number of alternative forms, RTI includes eight central features and six common attributes. Among the central features linking all forms of RTI are: (1) high-quality classroom instruction, (2) research-based instruction, (3) classroom performance measures, (4) universal screening, (5) continuous progress monitoring, (6) research-based intervention, (7) progress monitoring during intervention, and (8) fidelity measures. Among common attributes of different RTI models, there are concepts of (1) multiple tiers; (2) transition from instruction for all to increasingly intense interventions; (3) implementation of differentiated curricula; (4) instruction delivered by staff other than the classroom teacher; (5) varied duration, time, and frequency of intervention; and (6) categorical or noncategorical placement decisions (Graner et al., 2005). Clearly, the concept of RTI is centered on the field's definition of high-quality research-validated instruction. It is important to note that, although there is growing consensus on the critical elements for effective reading instruction (e.g., Foorman et al., 2003), other domains of teaching for academic competencies are far from consensus-driven (*See* Chapters 2.37, 2.43).

There are numerous examples of RTI-based treatment of LDs; two often-cited ones are the Minneapolis Public School's Problem Solving Model, in action since 1994 (Marston et al., 2003), and the Heartland (Iowa) Area Education Association's Model, implemented in 1986 (Ikeda and Gustafson, 2002). The Minneapolis model is a three-tier intervention model where the referral to special education is made only after consecutive failures to benefit from instruction throughout all three tiers of pedagogical efforts. The Iowa model originally included four tiers, where the third tier was subdivided into two related steps, but it was then collapsed into one tier, similar to the

Minneapolis model. Unfortunately, neither model has published empirical data on its effectiveness. Yet, years of implementation have resulted in appreciation from the communities they serve and in a stable, relatively small special education population.

Currently, the concept of RTI is under careful examination by researchers supported by both the U.S. Department of Education and the National Institute of Child Health and Development. The future of RTI and its role in diagnosing and treating specific LDs is dependent on answers to critical questions: (1) whether an RTI model can be implemented on a large scale; (2) how an RTI model can be used for LD eligibility determination; (3) whether an RTI is an effective prevention system; and (4) whether RTI enhances LD determination and minimizes the number of false positives.

## 2.38.11 Conclusion

I began this chapter with a brief discussion of the concept of developmental disorders of learning and with the concern that there is no single definition of this concept. In fact, the discussion of the 'multi-representativeness' of this concept in the two main diagnostic schemes (DSM-IV and ICD-10) led me to substitute it with the concept of LD. The discussion of the category of LD in this chapter hopefully stresses the importance of this concept and, indirectly, the concept of developmental disorders of learning. The LD concept is important because of its (1) prevalence, (2) implications for countless school-age students and adults, and (3) importance for the development of fundamental models of acquisition of cognitive skills and strategies of prevention and remediation of failure of acquisition.

Currently, students with specific LDs constitute about half of all students served under IDEA. Effective identification of such students and their efficacious and efficient remediation are crucial steps to address their individual educational needs and to provide them with adequate and equal life opportunities.

Given changes in IDEA 2004, it is no surprise that RTI is been central to current discourse on specific LDs. RTI is essential to the professional discussions of educators, diagnosticians, and policy makers because of its promise to alleviate many long-standing concerns with the IQ/aptitude–achievement discrepancy model predominant in the field of LDs for the last 30 years. At this point, however, RTI has yet to deliver on its promise. If RTI succeeds, numerous benefits to educational systems and individuals might be realized (Graner et al., 2005). Specifically, as for the system, many inappropriate referrals might be eliminated to increase the legitimacy and fair nature of 'true' referrals; the costs of special education services might be reduced; various gender and ethnicity biases might be minimized; and accountability for student learning might increase. As for individuals, because the 'labeling' criteria will change, there will be less time for a student to demonstrate a 'true' failure in achieving the stipulated discrepancy value – prevention and remediation efforts are expected to start as early as possible; instruction will be individualized; identification will be focused on achievement rather than on aptitude–achievement discrepancy; and minimized labeling should result in less social stigma.

Yet, these are only expectations for now, and the immediate future will show whether RTI is a viable replacement to the discrepancy criteria.

## Acknowledgment

Preparation of this chapter was supported by grants R206R00001 from the Javits Act Program administered by the Institute for Educational Sciences, U.S. Department of Education, and TW006764 and DC007665 from the National Institutes of Health (PI: Grigorenko). Grantees undertaking such projects are encouraged to express freely their professional judgment. This chapter, therefore, does not necessarily represent the position or policies of the IES or the NIH, and no official endorsement should be inferred.

# 2.39 Learning in Autism

**M. Dawson and L. Mottron**, University of Montreal, Montreal, QC, Canada

**M. A. Gernsbacher**, University of Wisconsin-Madison, Madison, WI, USA

## 2.39.1 Introduction

Learning in autism is not a topic characterized by consensus. For example, the ability of autistics (see Sinclair, 1999, to appreciate our respectful use of the term 'autistic' rather than 'person with autism') to learn is considered nonexistent in the typical everyday environment (Lovaas and Smith, 2003) and fundamentally impaired (Klinger et al., 2006), but so astounding that the cognitive literature as a whole is insufficient to explain it (Atkin and Lorch, 2006). Autistic learning is recognized as distinctive (Volkmar et al., 2004) and singled out as subhuman (Tomasello et al., 2005), but is also considered unremarkable compared to nonautistic learning (Thioux et al., 2006). These apparently disparate accounts may be the result of autistic learning, in contrast to autistic perception, attention, and memory, being investigated in a piecemeal, *ad hoc* manner. This chapter will summarize a range of current and emerging proposals about autistic learning, examining each proposal's empirical basis and adding historical and thematic perspectives.

## 2.39.2 Autism: Classification and Description

Autism is a neurodevelopmental difference, classified as a pervasive developmental disorder in the DSM-IV (American Psychiatric Association, 1994) and diagnosed by atypical social interaction (e.g., "a lack of spontaneous seeking to share ... achievements with other people," American Psychiatric Association, 1994: 70), atypical communication (e.g., difficulty "sustain[ing] a conversation," American Psychiatric Association, 1994: 70), focused interests (e.g., "persistent preoccupation with parts of objects", American Psychiatric Association, 1994: 70), and atypical body mannerisms (e.g., "hand or finger flapping", American Psychiatric Association, 1994: 70). While autism is innate, the overt behaviors used to diagnose autism may not appear until the second year of life, but always appear before age 3. Autism is polygenic (with as yet no agreed-upon loci) and highly heritable, with a male:female ratio of approximately 4:1 and a prevalence of approximately 20/10 000. Two less well-defined pervasive developmental disorders are considered, with autism, to form the autistic spectrum. The first is Asperger syndrome, which shares the behavioral characteristics of autism but presents with a different developmental trajectory, featuring no delay in the onset of speech and measured intelligence in the normal range (Szatmari et al., 2000). The second is Pervasive Developmental Disorder, Not Otherwise Specified (PDD-NOS), defined as a subthreshold presentation of the behaviors used to diagnose autism. Prevalence across the autistic spectrum is roughly 60/10 000, and has been shown to be stable over time, as has autism prevalence (Chakrabarti and Fombonne, 2001, 2005). This review will concentrate on autism itself, as the bulk of the relevant research concerns this specific diagnosis.

In research, autistics are often divided into high- and low-functioning subgroups, based on a snapshot measurement of intelligence or developmental level. While this division is an efficient shorthand to denote whether participants fall into the range of diagnosable mental retardation, instruments normed for the nonautistic population are potentially misleading when applied to autistics (e.g., Mottron, 2004), and individuals' measured IQs may change dramatically over time, particularly before age 6 (e.g., Eaves and Ho, 2004; Gernsbacher, 2004). Autistics' average scores on intelligence test batteries (e.g., Wechsler scales) mask widely scattered subtest scores, raising the question of whether level of functioning can definitively be assigned even at any single point in time. The difficulty of assessing autistic intelligence is illustrated by recent epidemiology: The percentage of autistics who also meet current day criteria for mental retardation is reported as anywhere from 25–70% (Honda et al., 1996; Baird et al., 2000; Kielinen et al., 2000; Chakrabarti and Fombonne, 2001). The difficulty of assessing autistic intelligence is also illustrated via a speed-of-processing task known to be correlated with intelligence: Autistics assumed to be high- or low-functioning perform equally well, and as well as, nonautistics with Weschler IQs more than 2 or 3 standard deviations higher, respectively (Scheuffgen et al., 2000). Similarly, autistics' performance on Raven's Progressive Matrices, the preeminent measure of fluid intelligence, may significantly exceed their performance on Wechsler scales, suggesting that the high- versus low-functioning division is of questionable validity (Dawson et al., 2007).

Autism has no known etiology in the majority of cases, but in a minority of cases, an associated syndrome can be identified (e.g., tuberous sclerosis, West syndrome). In research, such syndromes are frequently cited as exclusion criteria or possible confounds, and the distinction between etiological autism (associated with such syndromes) and idiopathic autism (not associated with such syndromes) has been important in ascertaining whether epilepsy is associated with autism or with other conditions associated with autism. Indeed, evidence points to epilepsy not being associated with idiopathic autism (Pavone et al., 2004; Battaglia and Carey, 2006).

Another division is often drawn between savant autistics, whose uneven profile of abilities encompasses exceptional expertise in one or more characteristic areas (e.g., calendar calculation, drawing in perspective), and nonsavant autistics, whose uneven profile of abilities has not progressed to that level of atypical expertise. Savant abilities are far more prevalent in the autistic than in the nonautistic population (1 in 10 versus 1 in 2000; Hill, 1977; Rimland, 1978), and are consistently linked with autistic traits (Heaton and Wallace, 2004). Savant abilities and their significance for the study of autistic learning will be explored in later sections.

Few aspects of neurology have not been proposed as being atypical in autism. For example, regions of reported neurofunctional atypicalities range from the brainstem to the inferior frontal gyrus, while reported neuroanatomical atypicalities range from increased white and gray matter volume (e.g., Hazlett et al., 2005) to more densely packed cells and increased numbers of cortical minicolumns (Casanova et al., 2002). Neurofunctional connectivity has been suggested to be atypical (e.g., Just et al., 2004), and neural resources may be atypically allocated or rededicated (e.g., Turkeltaub et al., 2004; Koshino et al., 2005). Virtually every fundamental human cognitive and affective process, singly or as part of an overarching model, has been proposed to be dysfunctional or absent in autism, while persistent findings of superior performances by autistics are often interpreted as evidence of neurological and cognitive pathology (e.g., Langdell, 1978; Shah and Frith, 1983, 1993; Heaton et al., 1998; Beversdorf et al., 2000; Ropar and Mitchell, 2002; Toichi et al., 2002; Chawarska et al., 2003; Just et al., 2004; for analysis and perspective, see Baron-Cohen, 2005; Gernsbacher et al., 2006; Mottron et al., 2006). Thus, autism has been prolifically studied but remains poorly understood.

## 2.39.3 History and Background: Accounts of Autistic Learning

Accounts of recognizably autistic learning date back more than a century and precede the establishment of autism as a diagnosis. There are reports of individuals with an incongruous repertoire of abilities: Apparently general cognitive impairment coupled with outstanding performance in specific areas, such as music, drawing, calculation, and memory (see Treffert, 1988, for a review). The branding of these individuals as 'idiot savants,' a practice that endured until recently, is evidence of how autistic learning has been and may still be conceptualized.

Kanner (1943) first proposed autism as a distinct condition. His landmark description of 11 autistic children included observations about their unusual pattern of learning, evident from early development. The children precociously acquired quantities of specific information, from the names of objects, people, and presidents; to numbers and the alphabet; to fine discriminations between musical compositions; to the texts of psalms, poems, and nursery rhymes (sometimes in several languages); to lists of plants and animals as well as "long and unusual words" (p. 243); to the contents of encyclopedias. Kanner characterized much of this learning, particularly in 2- and 3-year old children, as a "valueless" (p. 243) obstacle to genuine communication, but also reported excellent abilities in reading, spelling, and vocabulary. There were no difficulties with plurals, tenses, and grammar; an early reversal of pronouns (e.g., using 'you' for 'I') became less evident over time. The children were characterized as having strong and independent interests; one child "displayed astounding purposefulness in the pursuit of self-selected goals" (Kanner, 1943: 232).

Kanner observed that mute autistic children, a minority in his original sample, had "astounded their parents by uttering well-formed sentences in emergency situations"; he concluded that mute autistic children may demonstrate that they have, while apparently silent, accumulated a "considerable store" of information about language (Kanner, 1949: 417–418). In a later paper, Kanner observed that autistic children were extremely difficult to teach in conventional ways: They "learn while they resist being taught." For example, they remained unimpressed with persistent attempts to prompt them to walk, then spontaneously walked when this was "least expected." One autistic boy's parents undertook strenuous efforts, involving many hours per day, to teach and exhort him to speak. These efforts failed, but "at about $2\frac{1}{2}$ years of age, he spoke up and said 'Overalls,' a word which was decidedly not part of the teaching repertoire." (Kanner, 1951: 23–24).

Independently of Kanner, Asperger (1944/1991) also proposed autism as a distinct condition. In his seminal paper, Asperger recorded observations about autistic learning that were strikingly similar to Kanner's. Autistic children, some of whom were described as learning to read "particularly easily" (p. 75), were "almost impossible to teach" (p. 49) and could not "learn from adults in conventional ways" (p. 56) or "assimilate the ready-made knowledge and skill that others present" (p. 63). These children were poor in what Asperger called mechanical learning, or learning to do as others do automatically. However, they excelled in a kind of original thinking that Asperger called autistic intelligence. Asperger described an autistic child who spontaneously learned basic principles of geometry by age 3, and cubic roots shortly thereafter, but "learnt or did not learn as the whim took him" (p. 88), with unfortunate results in school.

Both Kanner's and Asperger's accounts resonate with earlier reports of 'idiot savants.' In 1945, Scheerer and colleagues discussed Kanner's observations (1943) within an extensive descriptive and empirical account of a child, L., who today would be considered an autistic savant. Alongside apparently comprehensive limitations in behavior and intelligence, L. had excellent abilities in calendar calculation and music, as well as in learning and recall of words, events, facts, and numbers. Interest in these areas first appeared when L. was 3. L. was reported to be incapable of learning by instruction; he had "an inherent difficulty in learning by following instructions and explanations in a systematic way" (p. 2) and "never absorbed or learned in a normal fashion" (p. 59). He had absolute pitch and enjoyed playing the piano "for hours without being taught" (p. 2). His unusual range of abilities was hypothesized to arise from impaired abstraction, which resulted in "abnormal concreteness" (p. 61) and a facility in acquiring and manipulating information that typical individuals would judge as "senseless or peripheral or irrelevant" (Scheerer et al., 1945: 61).

Kanner considered that the atypical strengths and not the obvious difficulties of autistic children reflected their true potential, but Kanner provided limited empirical evidence to support his position, which has accumulated opposition over the years. For example, Klin et al. (1997) contended that autistics' 'splinter skills' overestimated their true abilities, had little relevance to real life, and existed against a context of pervasive deficiency (see also DeMyer et al., 1974; Prior, 1979; Volkmar and Klin, 2005). Similarly, focused abilities and interests have been characterized primarily as interfering with learning in autism and Asperger syndrome, rather than representing it (Volkmar and Klin, 2000; Klin et al., 2005). Distinctly autistic learning and intelligence have thus been considered pathological, misleading, and uninformative, if not mythical (e.g., Epstein et al., 1985; Shah and Frith, 1993; Green, 1999). This judgment leaves no plausible explanation for the conspicuous success of some autistics (e.g., a child who "did phenomenally well in mathematics, was sent to an accelerated school, and is now finishing the eleventh grade with top marks"; Kanner and Eisenberg, 1956: 86).

Specific traits investigated in follow-up studies (e.g., speech fluency or measured intelligence) have not been consistently predictive of outcomes (Howlin, 2005) or explanatory of why some autistics have done notably well (Asperger, 1944; Kanner, 1973; Szatmari et al., 1989). Indeed, both Kanner (1973) and Szatmari et al. (1989) reported that fortunate outcomes were unexpected; they could not have been predicted from early presentation or development. The success in university, including one MBA, of half of Szatmari et al.'s sample (less than 70% of whom had useful speech before age 5) was achieved by individuals who, like the successful autistics reported by Kanner, grew up before the era of early intervention programs. Similarly, an individual who Asperger (1944) followed for 30 years was "grossly autistic" (p. 88) throughout his life, with "impossible behavior" (p. 89), failure, and ineptness in multiple areas (language, daily life, social behavior). This individual pursued his early interest in mathematics and rapidly became a successful, if unusual, academic. Like Asperger, Kanner (1973) underlined the importance of focused interests and abilities through development as the means by which autistics could participate in and contribute to society.

Less fortunate autistics were placed in institutions, denied education, subject to useless and harmful treatments (e.g., "tranquilizers . . . pushed to the point of toxicity"; Kanner, 1971: 125), and were found to have poor outcomes (Rutter et al., 1967; Lockyer and Rutter, 1969; Kanner, 1971, 1973). In Rutter's (1966, 1970) sample, 56% of the 63 children had fewer than 2 years of school, and many had none at all, regardless of their measured abilities. More than half were institutionalized, and many endured deleterious or spurious treatments (e.g., electroconvulsive therapy, insulin coma, prefrontal lobotomy, prolonged psychoanalysis; from Rutter et al., 1967). Against this hazardous backdrop, many in Rutter's sample acquired reading abilities, several were employed, and some had academic achievements (e.g., in the areas of music and computer science). DeMyer et al. (1973) observed in their sample, 44% of whom were institutionalized, that a decrease over time in the performance IQs of poor-outcome autistics was related to an observed loss of their 'splinter skills.'

Descriptive and empirical accounts of autistics learning in unusual and successful ways have sporadically appeared and remained unexplained throughout the history of autism research. Autistics are no longer routinely institutionalized and are entitled to public education, but there continues to be a dearth of data linking early autism interventions to adult outcomes. Instead, there are data indicating that currently popular interventions may be unrelated to child outcomes (Gernsbacher, 2003; Eaves and Ho, 2004; Lord et al., 2006; Magiati et al., 2007). The educational and psychosocial intervention literature in autism, despite undeniable quantity and prominence, has failed to produce "a clear direct relationship between any particular intervention and children's progress" (National Research Council, 2001: 5).

## 2.39.4 Learning in the Autism Intervention Research

Comprehensive early intervention programs in autism have borrowed extensively from each other and have become progressively more similar (Dawson and Osterling, 1997; National Research Council, 2001; Kasari, 2006). A typical curriculum may, at the outset, involve series of trials for training eye contact ('look at me'), commands ('sit down,' 'stand up,' 'come here,' 'turn around'), motor imitation ('do this . . .'), followed by commands to point ('point to the . . .'), match, verbally imitate, and verbally label (see, e.g., Maurice et al., 1996). Comprehensive programs vary in their use of settings and structure (e.g., highly structured trials vs. more naturalistic approaches), in their use of procedures and techniques (e.g., prompting, reinforcement), in their incorporation of developmental and other theoretical considerations, etc. (Rogers and Ozonoff, 2006). Apart from their intensity (usually, more than 20 h per week) and their ideal of intervening as early as possible, they share the premise that autism represents a harmful deviation from (or multiple deviations from) typical development. They also share the goal of achieving, to the greatest extent possible, a typical developmental trajectory encompassing typical social, communicative, and adaptive behaviors. Failing to address presumed deviations or delays in early development is believed to result in autistics falling further and further behind, as autistic traits and abilities, which are seen as inadequate, inappropriate, or maladaptive, become entrenched obstacles to achieving the ideal typical trajectory. The promise that very early intervention will interrupt, reverse, prevent, and stop autism 'in its tracks' is avidly pursued (Cecil, 2004: 2).

The effectiveness of comprehensive early intervention programs is judged against autism's presumed poor prognosis, and according to the extent to which typical skills have successfully been acquired and atypical autistic behaviors have successfully been extinguished (Smith, 1999; Handleman and Harris, 2001). The possibility that a typical developmental trajectory and repertoire of behaviors may not be adaptive for autistics or beneficial for autistic learning has not yet been considered. Researchers have "studied the effectiveness of programs, not the appropriateness of various goals" (National Research Council, 2001: 41), while as yet providing no empirical foundation for the popular contention that intensive early interventions result in successful, independent typical adults. The best adult outcomes in the peer-reviewed literature belong to autistics whose early development predates the availability of these interventions and was in no way typical (e.g., Kanner et al., 1972). Indeed, in Szatmari et al. (1989), all children retrospectively judged as only probable for a diagnosis of autism had poor outcomes as adults, while many children whose diagnosis – according to the strictest criteria for autism ever devised – was not in doubt went on to considerable achievement: "severity of early autistic behavior was a poor predictor of outcome" (p. 213).

Early interventions have been widely speculated both to prevent atypical brain activity in autism and to promote desirable typical activity (e.g., Lovaas and Smith, 1989; Perry et al., 1995; Mundy and Crowson, 1997; Smith and Lovaas, 1998; Howard et al., 2005). This speculation is as yet unsupported by studies involving measures of neural activity. The promotion of very early interventions to exploit neural plasticity in the developing brain (Dawson and Zanolli, 2003) appears to be supported solely by a report of a very early (starting at 14 months) applied behavior analysis-based intervention involving a child considered 'at risk' for autism (Green et al., 2002). However, such a young age (2 years) has been cited as an explanation for why other autistic participants failed, rather than succeeded, in another intervention study and why such young participants could not continue in an optimal applied behavior analysis-based intervention (Howard et al., 2005). Thus, promises that autistic brain activity and development can be altered by early interventions in controlled and predictable ways appear to be highly premature.

Training programs that involve older autistics (school-aged children, adolescents, and adults) and that target what are presumed to be core deficits in autism have also been speculated to correct faulty autistic neural mechanisms (Tanaka et al., 2005). However, the only empirical investigation to date found that autistics acquired the specific trained behaviors (labeling pictures expressing facial affect), but did so without producing the desired neurofunctional changes (increased task-related activity in the fusiform gyrus; Bölte et al., 2006). Demonstrations that untrained autistics display this desired brain activity when previous oversights in experimental design are addressed (e.g., Hadjikhani et al., 2004; Pierce et al., 2004) raise questions about the foundations of interventions that target core deficits and exploit task-related brain activity as outcomes.

A common finding arising from both targeted and comprehensive intervention studies is that autistics, when explicitly taught typical skills, fail to generalize those skills across contexts or to related typical skills (e.g., Lovaas et al., 1973; Lovaas and Smith, 1989; Ozonoff and Miller, 1995; Hwang and Hughes, 2000). This failure to generalize is widely regarded as an autistic learning deficit, but such a failure cannot always be attributed to specifically autistic limitations. Young so-called feminine boys who underwent early intensive behavioral interventions to impose stereotypically male behaviors also demonstrated a failure to generalize (Rekers and Lovaas, 1974; Rekers et al., 1974). Thus, the explicit teaching of typical behaviors may result in a failure to generalize in atypical individuals. Accordingly, autistics who fully understand typical, expected social behaviors (e.g., behaviors associated with pretend play or joint attention) may not spontaneously display these behaviors, which are adaptive for nonautistics but may not necessarily be adaptive for autistics (e.g., Boucher, 1989; Klin et al., 2002). Regulation of atypical autistic visual and auditory perception (Mottron et al., 2006; Samson et al., 2006) is currently the most plausible explanation for characteristic autistic behaviors (e.g., in the areas of eye contact, Gernsbacher and Frymiare, 2005; joint attention, Gernsbacher et al., in press; and orienting to stimuli, Mottron et al., 2007); therefore, attempts to train typical but less adaptive behaviors may not easily generalize. Further, Szatmari (2004) has argued that autistics' enhanced perception results in independent, spontaneous learning of which nonautistics are incapable.

## 2.39.5 Applied Behavior Analysis and Autistic Learning

The first reports of operant conditioning in autism in the early 1960s (e.g., Ferster and DeMyer, 1961) are considered by behavior analysts as the first demonstrations that autistics could learn (Schreibman and Ingersoll, 2005). Behavior analysts henceforth characterized autistics as being governed by the same laws of learning as all other organisms, while being distinguished by failing to learn from the typical, everyday environment (e.g., Lovaas, 1987; Green, 1996; Smith and Lovaas, 1998; Koegel et al., 2001; Lovaas and Smith, 2003). Applied behavior analysis (ABA), summarized by Green (1996: 29) as employing procedures derived from the principles of behavior to "build socially useful repertoires" of observable behaviors and reduce or extinguish socially "problematic ones," has become the basis for an extensive autism intervention literature and service industry. The behavior analytic literature in autism presents autistics as having an extremely restricted behavioral repertoire that is not recognizably human, as lacking in human experience to the point of being *tabula rasa*, as requiring the explicit teaching of virtually every human behavior, and therefore as being an ideal proving ground for interventions based on learning theory (Lovaas et al., 1967; Lovaas and Newsom, 1976; Lovaas, 1977, 1993, 2003; Lovaas and Smith, 1989; Smith, 1999; Schreibman, 2005).

Stimulus overselectivity, wherein autistics "respond to only part of a relevant cue, or even to a minor, often irrelevant feature of the environment," has been identified by behavior analysts as underlying autistics' failure to learn and generalize (Lovaas et al., 1979: 1237; see also Schreibman, 1996). However, demonstrations of overselectivity in autistics (e.g., Lovaas et al., 1971b; Lovaas and Schreibman, 1971) exist alongside findings showing overselectivity in nonautistics, as well as the absence of overselectivity in autistics (e.g., Koegel and Wilhelm, 1973; Schover and Newsom, 1976; Litrownick et al., 1978; Gersten, 1983). An apparent failure of autistics to attend to and therefore learn from relevant social information using dolls as stimuli (Schreibman and Lovaas, 1973) contrasts with the empirical finding that autistic children (IQ ~60) perform better than age-matched typical controls in recognizing their classmates' faces (Langdell, 1978). Moreover, Lovaas and Schreibman's (1971) and Lovaas et al.'s (1979) overselectivity-based prediction that classical conditioning would be impaired in autism, with a consequent failure to acquire conditioned reinforcers, was found to be incorrect. In a classical eyeblink conditioning paradigm, autistics more rapidly learned an association between multimodal contiguous stimuli than did nonautistics (Sears et al., 1994). Regardless, overselectivity's enduring theoretical influence is demonstrated in the behavior analytic practice of breaking all skills down into small steps with each step being explicitly taught through repetition, and of minimizing and simplifying the information in an autistic's environment when teaching basic skills (Maurice et al., 1996; Leaf and McEachin, 1999; Lovaas, 2003).

The need to suppress the high prevalence of so-called self-stimulatory behaviors in autistics (e.g., rocking the torso, smelling objects) is a consistent theme across the behavior analytic literature. While it is believed that self-stimulatory behaviors interfere with learning explicitly taught behaviors (e.g., Lovaas et al., 1971a, 1987; Koegel and Covert, 1971), that is not always the case (e.g., Klier and Harris, 1977; Chock and Glahn, 1983; Dyer, 1987), and self-stimulatory interests (e.g., maps, calendars, movies) have also been used productively as reinforcement (e.g., Charlop et al., 1990). Self-stimulatory behaviors have not been consistently defined by behavior analysts; for example, immediate echolalia (repeating back what another person just said) was classified as self-stimulatory in one model (Epstein et al., 1985; Lovaas, 2003) but not in another (Gardenier et al., 2004; MacDonald et al., 2007).

Self-stimulatory behaviors are often defined as serving no obvious or apparent function (Gardenier et al., 2004; MacDonald et al., 2007), but in one extensive behavior analysis to understand the origin of self-stimulatory "ear covering that was reported by the [autistic] child's teachers to serve no identifiable function" the "[r]esults of a descriptive analysis revealed a correlation between ear covering and another child's screaming. An analog functional analysis showed that ear covering was emitted only when the screaming was present" (Tang et al., 2002: 95).

While self-stimulation has been defined as a subclass of stereotypy, characterized by its autonomy from social reinforcement (Lovaas et al., 1987), it has also been found to be socially mediated (Durand and Carr, 1987). Self-stimulation and stereotypy are sometimes regarded as interchangeable (e.g., Charlop-Christy and Haymes, 1996, in which 'stereotypy,' 'aberrant behaviors,' 'obsessions,' and 'self-stimulation' are equivalent terms), and self-stimulatory behaviors have been expanded to encompass all autistic focused interests and abilities. Absolute pitch, calendar calculation, hyperlexia, expertise in prime numbers, accurate drawing, and the like have been classified as self-stimulatory (Epstein et al., 1985; Lovaas, 2003); autistics' spontaneous, untrained learning (in the absence of either teaching or reinforcement) has been classified as "generative self-stimulatory behavior" (Lovaas et al., 1987: 58). Epstein et al. (1985) described a 5-year-old autistic boy in an intensive ABA program who "suddenly emerged" (p. 292) with excellent calendar calculation skills; this and other spontaneous 'genius' behaviors were then discouraged and suppressed.

Indeed, exceptional and savant abilities are listed by behavior analysts as among autistics' abnormal behavioral deficits and excesses (e.g., Koegel and Koegel, 1995). Exceptional abilities in children who exhibit high levels of self-stimulatory behaviors, which are considered by behavior analysts to prevent autistics from learning, remain unexplained. For example, there is no explanation for how a 3-year-old autistic "engaged in lengthy periods of self-stimulatory behavior, such as lying down and sifting sand through his hands" learned to read at a grade 1 level (Koegel et al., 1997: 236), or how a 4-year-old autistic, with no basal score on standardized language measures and "high levels" of "stereotypic hand flapping, finger manipulation, body rocking and noise making" learned how to "decode written words" and "discriminate numerous varieties of automobiles" (Mason et al., 1989: 173). The behavior analytic observation that autistics have spontaneously learned various skills that they do not demonstrate on demand (e.g., Taylor and MacDonough, 1996) also remains unexplained, though the possibility that autistics' inconsistent responding in some situations results from 'boredom' has been raised (Dunlap and Koegel, 1980).

In attempting to address autistics' failure to learn, behavior analysts have created environments of extreme food deprivation (Lovaas et al., 1967); electric shock (Lichstein and Schreibman, 1976) or other contingent aversives (Lovaas, 1987; Lovaas et al., 1987); and extreme repetition (e.g., 90 000 discrete trials to teach an autistic boy one verbal discrimination; Lovaas, 1977). One autistic child underwent more than 24 000 discrete trials and failed to learn any receptive language (Eikeseth and Jahr, 2001). The same child acquired language skills in fewer than 100 trials when provided with text, rather than speech or signs, but environments created by behavior analysts to train some autistics (now deemed to be 'visual learners') with text have produced very limited results (Lovaas and Eikeseth, 2003). While physical punishment within behavior interventions became illegal in many jurisdictions and was replaced by other methods (but see Foxx, 2005), a nonrandomized controlled trial that depended on contingent aversives (Lovaas, 1987; McEachin et al., 1993) continues to be cited as the primary evidence that ABA-based interventions are effective. The only randomized controlled trial of an early comprehensive ABA program reported poor short-term results (Smith et al., 2000, 2001). When unmatched variables in a nonrandomized trial were accounted for, differences in outcome measures between the experimental and control groups (with the exception of classroom placement) were not significant (Cohen et al., 2006; see also Magiati et al., 2007). Further, none of the few existing small-sample controlled trials, in a vast literature dominated by single-subject designs, has reported a correlation between increased amount or intensity of treatment and better short-term outcome measures. Instead, data from an uncontrolled trial show that neither intensity nor quality of early ABA programs is related to short-term outcomes (Sallows and Graupner, 2005).

## 2.39.6 Autistic Learning in the Cognitive and Savant Literatures

The cognitive literature in autism provides few empirical findings directly related to learning, despite speculative claims about autistic learning impairments and 'learning style' (see Volkmar, et al., 2004, for a review). Among empirical findings, autistics have demonstrated enhanced discrimination of novel highly similar stimuli but an absence of a typical perceptual learning effect (Plaisted et al., 1998); and nonautistics, but not autistics, showed a training effect when copying drawings of objects and nonobjects, although overall performance of the two groups was equal (Mottron et al., 1999). In both cases (perception and procedural memory), procedures (e.g., repeated performance of tasks) that reliably resulted in learning in nonautistics appeared not to do so in autistics, while autistics appeared to learn in ways (e.g., apparently passive exposure to materials) that did not necessarily benefit nonautistics.

In the area of language, echolalia is common in typical development (e.g., a mother asks, 'Do you want a cookie?' and a child responds, 'a cookie?'), but echolalia occupies an atypical role in language acquisition in autism. Echolalia, which serves numerous functions (Prizant and Duchan, 1981; Prizant, 1983; Prizant and Rydell, 1984), is one example of how autistics atypically access the meaning of language by first learning its complex structure, the reverse of the typical pattern (Dunn and Sebastian, 2000). For example, an autistic child, quite fond of the Teletubbies show on Public Broadcasting Service, initially repeated the scripted sentence, "One day in Teletubbie land, all of the Teletubbies were very busy when suddenly a big rain cloud appeared," and weeks later, using mitigated echolalia, stated, "One day in Bud's house, Mama and Bud were very busy when suddenly Daddy appeared" to express the construct of his father returning home. Initially, when this child wanted to play ball, he would approach his mother or father and say, "Quick, Dipsy. Help Laa Laa catch the ball." As his spoken language developed, the syntactic structure of echolalic sentences remained intact, but he replaced the nouns (e.g., "Quick, Daddy. Help Bud catch the ball"), and he eventually isolated single words and morphemes and began generating original phrases (e.g., "Daddy ball?" and "Dad, wanna play ball?"; Mom-NOS, 2006).

Hyperlexia (Silverberg and Silverberg, 1967), a spontaneous (uninstructed), precocious, interest-driven ability to decode written words, is also strongly associated with autism (Grigorenko et al., 2002). Atkin and Lorch (2006) extensively tested Paul, a 4-year-old autistic boy who intensively studied newspapers before age 2 and recited the alphabet and read printed words aloud by age 3. Paul's mental age was placed at 1 year and 5 months, and his comprehension of language was markedly delayed (though not absent), but he tested as having "extremely advanced decoding skills" (p. 266), including a reading vocabulary exceeding that of typical 9-year-olds. The authors concluded that these results "suggest the possibility of an atypical route to language acquisition" (p. 267) and that "existing cognitive accounts are inadequate to account for the development of literacy in this child" (p. 267).

With respect to the role of categories in learning, autistics may not necessarily use concepts to organize information (Hermelin and O'Connor, 1970; Bowler, 2007, for a review), but are able to do so, including the use of basic level and more abstract superordinate categories as well as prototypes (e.g., Tager-Flusberg, 1985a,b; Ungerer and Sigman, 1987). In a test of novel category learning, Klinger and Dawson (2001) found that autistics categorized using both explicit and implicit rules, but when answering an ambiguous question, failed to show the same response to prototypes as nonautistics. Molesworth et al. (2005), who instead used a false recognition procedure, found typical learning of novel categories in autistics, including typical prototype formation. At the level of perceptual categorization, autistics demonstrated typical category formation in a categorization task, but in contrast to typical controls, autistics showed no influence of categories in a discrimination task. The influence of categories may therefore be optional in autistics, while being mandatory in nonautistics (Soulières et al., 2007).

Klinger et al. (2006) have proposed a fundamental implicit learning (Reber, 1967, 1993; Frensch, 1998; Frensch and Rünger, 2003) impairment in autism based on the prototype paradigm in Klinger and Dawson (2001) and on preliminary data from two artificial grammar learning experiments. Their first study found equivalent autistic and nonautistic above-chance performance in the implicit learning of artificial grammars, while in their second study autistics with lower IQs than their nonautistic controls performed far above chance, but the nonautistic group performed significantly better. Reber (1967) reported a similar discrepancy between typical undergraduates and typical high-school students performing well above chance, without the latter being deemed impaired in implicit learning. Using a serial reaction time task (Nissen and Bullemer, 1987) involving a sequence of lighted circles, Mostofsky et al. (2000) found no evidence of implicit learning in autistics. However, using the same kind of task, Smith (2003) found robust implicit learning of a sequence of geometric figures in autistics, with response accuracy superior to that of typical controls. Results from Smith's (2003) second experiment using a sequence of emotional face images suggest that the presence of social information may demand more attentional resources from autistics than nonautistics, therefore disproportionately interfering with autistics' implicit learning of nonsocial material (in this case, a sequence).

Associative learning has been reported as intact in autism (e.g., Boucher and Warrington, 1976; Williams et al., 2006), but autistics were also found to associate paired stimuli more rapidly than nonautistics (Sears et al., 1994). Reviewing a wide range of evidence, Baron-Cohen (2003) posited systemizing, a form of intrinsically reinforced associative learning, as being a strength in autism, "a condition where unusual talents abound" (p. 138). Systemizing requires an exact mind and is motivated not by extrinsic reinforcement but by a drive to understand systems. Baron-Cohen (2003) describes an autistic 5-year-old boy whose mother accidentally discovered that, by walking down the same street every day, he had correctly associated hundreds of houses with the hundreds of cars (parked on the street) of their occupants, along with the expiration dates and serial numbers of the cars' parking stickers.

In contrast, Tomasello et al. (1993, 2005; see also Tomasello, 2001) posited a form of social learning – cultural learning – as the defining achievement of uniquely human cognitive abilities, which autistics, along with apes, were deemed to lack. However, despite claims that the essential uniquely human ability is the learning of intentionality, which according to Tomasello autistics lack (Tomasello et al., 1993; Tomasello, 2001), empirical studies have demonstrated robust understanding of intentions in autistic children (Aldridge et al., 2000; Carpenter et al., 2001; Russell and Hill, 2001) and adults (Sebanz et al., 2005). The current model of cultural learning and cognition (Tomasello et al., 2005) is now founded not on the learning but the sharing of intentionality, which Tomasello has argued is absent in autistics and apes. The defining of humanity according to attributes that autistics are judged to lack is a hallmark of normocentrism (Mottron et al., in press).

After a long history of reductive explanations for savant abilities (e.g., photographic or phonographic memory), the savant literature largely recognizes that these abilities represent both spontaneous learning and creative manipulation of the structures and regularities underlying complex information (e.g., music, numbers, written language, visual proportions and perspective). Experimental studies of savants have concentrated on whether and how learned information and abilities are recalled, applied, modified, transformed, or transferred (Miller, 1999; Heaton and Wallace, 2004). Therefore, while savant abilities in autistics can be considered the equivalent of expertise in nonautistics (Mottron et al., 2006), there is only indirect evidence as to how this expertise is acquired. Overtraining with specific materials may (Howe et al., 1998) or may not (e.g., Selfe, 1977; Epstein et al., 1985) be observed prior to the full manifestation of exceptional abilities, which may also be discovered by accident (Sacks, 1985).

Thioux et al. (2006) proposed that savant abilities are driven by autistic focused interests, but depend on spared areas of typical learning abilities; in this model, as in Klinger et al. (2006), savant abilities are explicitly learned, with no role for implicit learning. However, implicit learning is widely considered to play an essential role in savant abilities (e.g., Hermelin and O'Connor, 1986; O'Connor, 1989; Miller, 1989, 1999; Spitz, 1995; Heaton and Wallace, 2004; Pring, 2005; Mottron et al., 2006). Miller (1999) has related the sophistication found in savant abilities to both enhanced processing at the perceptual level and the implicit learning of regularities, while suggesting that extensive exposure to materials may, for savants, be more effective than typical forms of teaching or rehearsal, which in turn may impede learning in savants. He concluded that "savants may provide a special perspective on the mixture of implicit and explicit learning that produces noteworthy performance" (p. 43).

Treffert (2000) has argued that savant abilities should be encouraged and nurtured; this results in a broadening of focused abilities and the flourishing of previously limited social abilities. For example, Miller (1989) denies that a young musical savant could be autistic, regardless of his fitting the relevant criteria, on the grounds that by age 5, he "showed obvious pleasure in social interaction" (p. 10). However, prior to the availability of a piano, the same boy was described as "not very responsive" (p. 9), "spending hour after hour gazing out the window" (p. 210), and "for a very long time, nonverbal and withdrawn" (Newman, 1989: 239). Further, autism does not preclude pleasure in social interaction, which for example is observed in autistics spontaneously sharing the same interest with each other (LeGoff, 2004).

Savant and nonsavant autistics are best considered as belonging to the same group, based on multiple behavioral and cognitive similarities. The performance of savants predicts the performance of nonsavant autistics in multiple areas. For example, savant musicians invariably have absolute pitch, while absolute pitch (Brown et al., 2003) and superior pitch labeling, pitch memory (Heaton et al., 1998; Heaton, 2003), and pitch discrimination and categorization (Bonnel et al., 2003) characterize nonsavant autistics. In a music imitation task, nonsavant autistic youths (mean IQ <70) with no musical experience performed as well as or better than age-matched controls who had considerable musical training (Applebaum et al., 1979), echoing the superior musical imitation found in savant autistics (e.g., Slodoba et al., 1985; Young and Nettlebeck, 1995). A savant draftsman (Mottron and Belleville, 1993) and nonsavant autistics (Mottron et al., 1999) shared a facility in copying impossible figures and a recognizable, locally oriented drawing strategy. Savant (Park, 1986; Steel et al., 1984; Hermelin and O'Connor, 1990; Young and Nettlebeck, 1995; Anderson et al., 1999) and nonsavant (Scheuffgen, 2000; Dawson et al., 2007) autistics may present with exceptional performance in tests of processing speed and/or high-level abstract reasoning. Many other empirically documented similarities are available, but it is also true that regardless of being extensively studied, both autism and savant syndrome remain unexplained. So does the overlapping relationship between the two, along with the learning processes underlying both variations in neurological functioning and information analysis.

## 2.39.7 Summary: Characterizing Autistic Learning

Learning in autism is characterized both by spontaneous – sometimes exceptional – mastering of complex material and an apparent resistance to learning in conventional ways. Learning that appears to be implicit seems to be important in autism, but autistics' implicit learning may not map directly onto nonautistics' implicit learning or be governed by the same constraints. An understanding of autistic learning, of how and why autistics learn well and learn poorly, may therefore require a nonnormocentric approach and an investigation of the possibility that autistic and nonautistic cognition may be complementary in learning and advancing different aspects of knowledge.

# 2.40 Individual Differences in Episodic Memory

**M. J. Kane and T. M. Miyake**, University of North Carolina at Greensboro, Greensboro, NC, USA

## 2.40.1 Introduction

> Wide individual differences in learning and memory abilities have long been noted, and have been addressed in psychometric research. Unfortunately, there has been little interplay between experimental and psychometric approaches to these areas, with the result that little can be said about the relations between processes studied in experimental investigations and the dimensions of individual differences isolated in psychometric research. (Carroll, 1993: 248)

> It is shortsighted to argue for one science to discover the general laws of mind or behavior and for a separate enterprise concerned with individual minds. (Cronbach, 1957: 673)

This chapter will selectively review the vast empirical terrain regarding normal individual differences in adult human memory for newly learned information. In so doing, we will consider research conducted within both the experimental and psychometric traditions (with the latter often referred to as 'correlational,' 'differential,' and 'individual'). These two research traditions have each yielded a wealth of data and theory about varieties of memory phenomena and their structural or taxonomic relations to one another (e.g., French, 1951; Atkinson and Shiffrin, 1968; Tulving, 1985; Sherry and Schacter, 1987; Carroll, 1993; Engle et al., 1999b; Baddeley, 2000), but the work in one domain has had regrettably little impact on the other. Indeed, one could argue the same for virtually all psychological phenomena that are studied by experiment on one hand and correlations among mental tests on the other (Cronbach, 1957).

Episodic memory, in particular, provides an interesting history regarding the hesitant dance between experimental and psychometric approaches to psychological science. For while the empirical study of human memory began by deriving nomothetic principles from the intense examination of one man (Ebbinghaus, 1885), the pursuit of individual differences in memory, and their relation to the broader intellect, was very close behind. Indeed, Jacobs's (1885) review of Ebbinghaus's book, and his subsequent (1886) call to create a Society for Experimental Psychology, predicted that the new science of memory would provide psychologists a window into people's mental abilities and a means by which to rank them:

> May we hope to see the day when school registers will record that such and such a lad possesses 36 British Association units of memory-power...? If this be visionary, may we at least hope for much of interest and practical utility in the comparison of the varying powers of different minds which can now be laid down to scale. (Jacobs, 1885: 456)
>
> There is, I submit, a certain number of syllables up to which each person can repeat a nonsense word like *borg-nap-fil-trip* after only once hearing; and it is probable, though we cannot know for certain, that this number varies with different persons, giving a sort of test of their linguistic capacity. (Jacobs, 1886: 53)

Jacobs was right: People differ in their immediate memory capacity, and these differences are associated with other linguistic, and nonlinguistic, abilities. We know this, in part, because Jacobs (1887) invented the venerable memory span task for one of the first systematic individual-differences studies of memory. Schoolchildren heard and attempted to repeat lists of unrelated syllables, letters, or digits, and the largest set that each could perfectly reproduce was termed his or her span of prehension. Jacobs found this span to increase with chronological age and with higher school marks. The theoretical and practical links between memory span and intelligence, thus forged, persist to this day (albeit with controversy; Ackerman et al., 2005; Kane et al., 2005; Oberauer et al., 2005).

Ebbinghaus's and Jacobs's work represents the roots of parallel traditions of modern memory research. In caricature, the experimental approach discovers and explains lawful regularities of memory by analyzing the learning and remembering yielded by various laboratory conditions with univariate, ANOVA-based analyses; the differential approach discovers and explains lawful variation in memory by analyzing the learning and remembering yielded by a variety of valid and reliable tests with multivariate, regression-based analyses. The reality, of course, is more nuanced, with some cross-fertilization of theory, method, and analysis between experimental and psychometric traditions. We view such integration as critically important to the health of our discipline, and we argue that it is nowhere more prominent or promising today than in the study of working memory (WM). Thus, after discussing further the persisting tension between differential and experimental psychology in general, and then reviewing the largely atheoretical psychometric literature on individual differences in broad aspects of episodic memory, we will focus on theoretically motivated research that combines experimental and correlational methods to examine variation in WM (for a variety of theoretical views on WM variation, see Conway et al., 2007).

## 2.40.2 Psychology's 'Two Disciplines'

About once every generation, a prominent psychologist has called for a unification of experimental and psychometric psychology. As early as 1924, Terman argued against the looming notion that psychometric tests served mainly diagnostic and technological purposes, whereas experiments (and their 'tasks') sought discovery and theoretical advance. While acknowledging that mental tests often serve practical interests, Terman (1924) also highlighted the 'testing' research by theorists such as Spearman, Cattell, Hall, and Thorndike that firmly aimed to illuminate the basic nature of mental phenomena. He concluded that:

> One would probably be safe in predicting that the next decade will see a large interaction between the psychology of mental tests and the experimental psychology of thinking. On the one hand, the opening up of problems of individual differences by means of tests will inevitably lead to the more intensive study of such differences by the usual laboratory methods; and, on the other hand, the success attained by tests in the diagnosis of abilities for useful purposes is likely in turn to have a considerable effect upon the technique of experimental psychology. (Terman, 1924: 113)

### 2.40.2.1 Separate but Equal

If Terman (1924) had been right, of course, Cronbach's (1957) classic lament on the rift between "the two disciplines of scientific psychology," over a quarter century later, would have been unnecessary. Cronbach colorfully characterized the distinction between experimental and correlational psychology in their reactions to individual differences. For experimental psychology, they represent 'error variance,' an intolerable nuisance to be minimized. For correlational psychology, in contrast, individual differences represent the results of important physiological, environmental, and developmental causes: "The correlational psychologist is in love with just those variables the experimenter left home to forget" (p. 674). Cronbach noted some examples of methodological integration with optimism, such as in experimental approaches to development, and, like Terman, he hoped that experimental and psychometric psychology would eventually capitalize on each other's strengths.

What can (and should) these disciplines offer one another? Cronbach (1957) suggested that, on one hand, experimental evidence can provide a source of construct validation for the psychometrician. If, for example, individual differences in some test scores are thought to reflect a particular construct, such as memory confidence, then scores should vary with experimental manipulations of confidence. On the other hand, the experimentalist would benefit from the psychometrician's multivariate methods, which yield optimally reliable and valid measures of hypothetical constructs. That is, experimental tests of theories about multifaceted phenomena need not focus on only a single, impure dependent variable, nor do ostensible classes of independent variables need to be categorized via intuition or tradition. Instead, correlational techniques such as factor analysis may provide simplification and organization of complex patterns of treatments and outcomes. Thus, for Cronbach, the experimentalists' study of variation among treatments and the psychometrician's study of variation among individuals should be combined in the pursuit of individual-by-treatment interactions. Such interactions are exactly what Melton later urged memory researchers to pursue:

> . . .the sooner our experiments on human memory and human learning consider the differences between individuals in our experimental analyses of component processes in memory and learning, the sooner we will have theories and experiments that have some substantial probability of reflecting the fundamental characteristics of those processes. (Melton, 1967: 250)

### 2.40.2.2 A Crucible for Theory Testing?

Unfortunately, no federation of psychological disciplines had yet been established by 1975 when Underwood found it necessary to convince experimental psychologists that an individual-differences approach could be useful to theory testing. A verbal-learning experimentalist, Underwood advocated that correlational studies could provide a useful 'go ahead' signal to new theories. His argument was that most nomothetic theories of mental process make idiographic predictions, and that these predictions should be tested early on to determine whether a theory warrants pursuit. That is, if individual-differences predictions fail to materialize, such falsification indicates that the theory requires revision. In Underwood's words, individual-differences research provides a 'crucible' in which to test general theory.

Cronbach's (1957) and Underwood's (1975) *American Psychologist* articles are both psychology classics, with over 1000 scientific citations combined. One might expect, then, that psychologists have finally gotten the message and are regularly testing their theories with individual-by-treatment interactions. On the contrary, this millennium saw yet another call for uniting experimental and psychometric disciplines, but here to bridge psychology and biology. Kosslyn et al. (2002) described studies in which experimental and correlational approaches to theoretical questions regarding mental imagery, avoidance, mood, stress, and immune function had yielded compelling theory confirmation, ruled out alternative explanations, clarified conflicting results, or illuminated biological mechanisms that had been obscured by averaging over subjects. They concluded that neither approach, by itself, would have accomplished these ends:

> Neither group nor individual differences research alone is sufficient; researchers need to combine the two. Indeed, by combining the two, one may discover that the group results reflect the combination of several strategies, each of which draws on a different (or partially different) system. Thus, the group and individual differences findings mutually inform each other, with the synergy between them illuminating the complex relations between psychology and biology. (Kosslyn et al., 2002: 348)

### 2.40.2.3 A Crucible for Theory Testing!

As an example of this combined experimental-psychometric approach to the study of memory, Underwood put his money where his mouth was in a large correlational study of episodic memory tasks. Underwood et al. (1978) tested whether the attributes of episodic memory that had been proposed to account for experimental results (Underwood, 1969, 1982) also influenced individual differences in remembering. They administered, to 200 subjects, 24 different word-memory tests (e.g., free recall, paired-associate learning, serial recall, memory span, recognition), which measured six ostensible memory attributes: imagery, implicit associative, acoustic, temporal, affective, and frequency.

To test whether episodic memory could, in fact, be carved at its attributes, Underwood et al. (1978) factor analyzed the 24 memory tests. Factor analysis is a statistical procedure that reduces a large number of manifest test variables into a smaller number of unobserved, latent factors by examining the correlations between tests. Simply put, a factor represents the common variance among a group of measures. A test's factor loading indicates how much of its variance is captured by the factor, with higher loadings indicating a stronger association. Factors are easiest to interpret when tests are dominated by a single factor, that is, when they have high loadings on one factor and small loadings on others. Imagine, for example, that a collection of memory-span and immediate free-recall and recognition tests all load onto one factor, and a collection of span, free-recall, and recognition tasks requiring delayed memory all load onto another, with each task having near-zero loadings on the other factor. Such factor loadings would provide psychometric validation for the theoretical distinction between short- and long-term memory. In a sense, then, factors are theories about the tasks they represent (Carroll, 1993).

Five interpretable factors emerged from the Underwood et al. (1978) tasks, but they were disappointing for contemporary theory. First, the factors corresponded to the task categories rather than to attributes: factor 1 reflected primarily the paired-associate tasks, factor 2 the free-recall tasks, factor 3 the memory-span tasks, factor 4 the recognition and frequency-estimation tasks, and factor 5 the verbal discrimination tasks. None of the attributes of interest appreciably affected the factor loadings of tasks, despite some having significant and substantial experimental effects (e.g., concrete words were better remembered than abstract words). Second, the recognition and verbal discrimination tasks loaded onto separate factors. This was surprising because verbal discrimination and recognition memory were both explained by frequency theory, according to which the cue used to discriminate between two words is the perceived difference in linguistic frequency. Verbal discrimination and recognition tests, therefore, should have loaded on the same factor, but they did not. As Underwood et al. put it,

> Perhaps never before has a theory that evolved from experimental work been so savagely attacked by a correlational approach. (Underwood et al., 1978: 416)

Of course, this is just as Underwood (1975) would have had it.

(For Underwood et al. (1978), these findings did not falsify the claim that memory attributes are distinguishable and important to memory theory. Subtleties in their data suggested that subjects could strategically attend to particular attributes depending on their prior experiences and task demands, and so memory attributes were important phenomena to continue considering.)

Before considering more recent research that has attempted to meet the appeals of Terman, Cronbach, Underwood, and Kosslyn, by uniting the correlational and experimental approaches to memory research, we first highlight the key findings and conclusions drawn from the psychometric study of healthy young adults. The rest of this volume will amply review the fruits of experimental approaches, and individual chapters by Naveh-Benjamin (*See* Chapter 2.41), Ornstein (*See* Chapter 2.37), and Rovee-Collier (*See* Chapter 2.36) will consider memory's lifespan development.

## 2.40.3 The Psychometric Approach to Memory

Memory tasks have appeared within standardized intelligence test batteries since their inception (e.g., Cattell and Galton, 1890; Binet and Simon, 1905; Wechsler, 1997; Roid, 2003). Until recently, however, particular memory processes have only sporadically been linked theoretically to aspects of 'intelligent' behavior, such as complex learning, comprehension, or reasoning (e.g., Blankenship, 1938; Bachelder and Denny, 1977a,b; Dempster, 1981, 1991). In fact, most of the twentieth century saw research on memory variation take a distinctly bottom-up, atheoretical approach, by 'throwing into the hopper' a number of different mental tests, including some involving memory, and examining the resulting factor structure. We discuss these studies before reviewing more theoretical, top-down approaches to individual differences in memory.

### 2.40.3.1 The Structure of Memory, from the Bottom Up

Prototypical studies tested between 30 and 200 subjects on a battery of popular, standardized tests assessing a range of cognitive abilities, from pitch perception, to motor speed, to mental rotation, to mechanical knowledge, to reading comprehension, to abstract reasoning. Fewer than five memory tests usually appeared in these batteries, selected more for their availability than for their utility in evaluating theoretical questions. Indeed, most of these studies assessed the structure of intellect, broadly defined, rather than examining the structure or processes of memory, proper. The memory tests that were used most often were memory span, paired-associates, recognition, and free recall. We described memory span earlier, and subsequent studies did not veer far from Jacobs's (1887) original methods. Paired-associate tests usually tested subjects on novel stimulus pairings, such as between unrelated words, words and digits, or first and last names, with the test presented almost immediately after learning. Recognition and free-recall tasks varied widely in their methodological details, but most presented verbal material and imposed only brief study–test delays.

#### *2.40.3.1.1 Factor-analytic findings*

French (1951) and Carroll (1993) have reported comprehensive reviews of factor-analytic studies of intelligence (the former qualitative, the latter quantitative). Because Carroll's analyses subsumed most of French's, our discussion relies heavily on Carroll (1993).

##### *2.40.3.1.1(i) First-stratum memory factors*

'First-stratum' memory factors refer to those that represent associations among individual psychometric tests assessing relatively narrow cognitive abilities. Carroll's (1993) review, which included reanalyses (via exploratory factor analysis) of 117 datasets on intelligence, found strong evidence for four distinct memory factors: memory span, associative memory, free-recall memory, and meaningful memory (other potential factors, such as visual memory, were identified more provisionally).

Seventy datasets provided strong evidence that memory-span tests comprised a separate factor from other memory tests, usually as a single factor regardless of stimulus type or modality. At the same time, some studies indicated modest separation between verbal and nonverbal tests, and most did not include enough tests to draw strong conclusions about the unity of memory span. Limited evidence also suggested that the use of supraspan lists and the induction of interference by interpolation of lists yielded a factor separate from the standard span test (e.g., Hunt et al., 1973, 1975). We will discuss related findings in our subsequent treatment of theoretically motivated psychometric research.

Although their respective datasets were fewer (51 and 12, respectively), Carroll also provided evidence that associative-memory and free-recall factors were separate from memory span. As in French's (1951) earlier review, paired-associate tests were the best indicators of the associative-memory factor, but it also loaded (more weakly) on recognition tests and serial-recall tests. Associative processes may thus be involved in learning for, and cuing in, both recognition and serial recall. Stimulus type did not appear to affect the correlations among paired-associate tests, as was true for memory span. Free-recall tests were also frequently discriminable from both memory span and associative memory, thus forming a separate factor of their own, and this was especially so when the tests presented supraspan lists. For example, in Games (1962), letter-span tests with list lengths of ten loaded with other free-recall tests rather than with traditional span tests.

##### *2.40.3.1.1(ii) Higher-stratum memory factors*

Individual differences in memory span, paired-associate recall, and free recall are psychometrically separable. Should we therefore propose that they measure discrete mental abilities and cognitive processes? The answer is yes and no, depending on the stratum we consider within memory's hierarchical structure. Carroll (1993) showed that these factors emerge reliably at the first stratum, reflecting the correlations among individual memory tests. But their factorial separation does not imply stochastic independence. This is because memory tests of all types tend to correlate positively, and studies that include enough tests of each first-stratum memory factor find that their factors correlate, too. Indeed, Carroll's analyses yielded a higher-stratum 'general memory' factor, that is, a single memory factor at a higher level of the hierarchy that subsumed all the memory factors at the lower level. So, while it is true that people's performance on a memory-span test correlates more strongly with other span tests than it does with paired-associate tests or free-recall tests, these different memory tests all correlate more strongly with one another than they do with other kinds of mental tests. Individual differences thus suggest a general ability to remember recently experienced events or newly learned information.

Of importance, the finding of a general memory factor comprising memory span, associative/recognition memory, and free recall replicates across multiple investigators, using a variety of statistical techniques, working under different hierarchical theories of intelligence. For example, the Horn-Cattell theory of general fluid and crystallized intelligence (Gf-Gc theory; Horn and Cattell, 1966), which is based on a wealth of lifespan development data, proposes a 'short-term acquisition and retrieval' (SAR) factor at a second stratum that bears striking resemblance to Carroll's (1993) general memory factor. As described by Horn (1988), SAR factors typically comprise memory-span, associative-memory, and free-recall memory tests that impose brief delays between study and test. Horn thus describes SAR as reflecting attention to, and maintenance of, information for use in other cognitive processes (by analogy to Baddeley and Hitch's (1974) notion of WM).

The reliable presence of a higher-order memory factor that is general to many varieties of episodic memory tests indicates that, despite differences that are indicated by separate first-order factors, some abilities or processes are common to episodic memory tasks, and they vary reliably among adults. As such, any compelling theory of performance in an episodic-memory task must explain both the processes that are unique to it and the processes that are shared with other episodic memory tasks (Carroll, 1993).

#### *2.40.3.1.2 Summary*

Early factor-analytic studies of intelligence tested no particular theory of memory and selected tasks more for their convenience than for representativeness or utility in testing claims about memory process or function. Despite this important limitation, we can draw a few broad conclusions about individual differences in memory. First, paired-associate and recognition-memory tests measure some common processes or abilities that cause them to correlate strongly with one another, and more strongly with one another than with memory-span and free-recall tests, which are also discriminable from each another. Second, despite their differences, these memory tests all correlate more strongly with one another than they do with other, nonmemory tests, indicating some common processes or abilities across tests that assess memory for information learned some seconds or minutes ago.

### 2.40.3.2 The Structure of Memory, from the Top Down

The last decade has witnessed a surge in the application of individual-differences analyses to theoretical questions about memory, and we are especially interested in research on the ostensible distinction between short-term memory (STM) and WM, in part because a growing and controversial literature suggests that WM, more than STM, provides clues about the nature of general intelligence (e.g., Ackerman et al., 2005; Kane et al., 2005; Oberauer, et al., 2005). Before we review this research, it is worth noting that the recent WM literature is not unique in taking a top-down psychometric approach to theory testing. Recall the Underwood et al. (1978) use of correlational data in testing frequency theory as well as some broader claims regarding memory attributes. Moreover, factor analyses of putative STM versus long-term memory (LTM) measures have provided evidence for their conceptual, if not structural, distinction (e.g., Robertson-Tchabo and Arenberg, 1976; Geiselman et al., 1982), as have analyses of tests reflecting episodic versus semantic memory (e.g., Carroll, 1993; Nyberg, 1994).

#### *2.40.3.2.1 A distinction between STM and WM*

The terms 'STM' and 'WM' are sometimes used interchangeably as generic labels for phenomena or tasks where little time intervenes between the study and test of a limited amount of information. Other times they are used to represent competing theoretical conceptions of immediate memory, with STM commonly designating a monolithic limited-capacity memory structure involved in active rehearsal of information and its transfer into LTM (e.g., Atkinson and Shiffrin, 1968), and WM referring to a joint memory and attention system that keeps information accessible in the service of ongoing and complex cognitive activities, such as comprehension or problem solving, with separate representational and rehearsal systems for different kinds of information (e.g., Baddeley, 2000). Recent psychometric research has asked the simple question: Do individual differences distinguish these hypothetical constructs?

Cantor et al. (1991) seem to have first addressed this question rigorously. They tested 49 undergraduates in three kinds of immediate serial-recall tasks with verbal or numerical stimuli. Two probe-recall tasks presented lists of nine items, with each list followed by a cue to recall either the first, second, or third three items from the list (with the latter two assessing immediate memory). Two traditional memory-span tests (or 'simple-span,' or 'STM-span' tests) presented sequences of three to nine items for immediate recall. Two complex memory-span tests (or 'WM span') presented to-be-recalled sequences of two to seven stimuli interpolated with a secondary processing task; both presented a sentence to be read aloud between memory items. The complex span tasks were thought to reflect WM, as conceived by Baddeley and Hitch (1974), because they demanded subjects to do more than simply retain information within a storage buffer via overlearned rehearsal strategies. Their requirement that subjects maintain access to stimuli in the face of a simultaneous processing demand sought to bring attentional, executive processes to bear on maintenance (see Daneman and Carpenter, 1980). Factor analyses yielded two factors, one representing the variance common to simple span and probe-recall tasks ('STM,' with factor loadings from .54 to .95), and one representing variance common to complex span ('WM,' with factor loadings of .74 and .82). It thus appeared that tasks requiring the immediate serial recall of stimuli without the imposition of secondary tasks (i.e., STM tasks) measured at least some different cognitive processes than did those with the imposition of secondary tasks (i.e., WM tasks).

Engle et al. (1999b) took a more sophisticated analytic approach to this issue. They tested 133 subjects on three simple and three complex span tasks (all with verbal or numerical stimuli), and used confirmatory factor analysis (CFA) to test a one- versus two-factor solution to the data. CFA allows researchers to impose a theoretically informed factor model on the data and statistically test whether it fits; it also allows for statistical comparison of competing models. Here, a single-factor model did not fit the data, but a two-factor model distinguishing simple (STM) from complex (WM) span did (and the two-factor model fit significantly better than the unitary model). STM and WM span factors were correlated, but not strongly enough to yield a single memory factor. Thus, with verbal materials, simple and complex span tasks measure some independent mental processes and support the view that WM is, in part, a separate cognitive system from STM. Although we cannot review the relevant findings in detail, the WM-STM distinction is reinforced by numerous reports of WM span factors correlating more strongly and broadly with factors representing complex cognitive abilities (e.g., comprehension and reasoning) than do STM span factors (e.g., Engle et al., 1999a; Conway et al., 2002; Bayliss et al., 2003).

Engle and his colleagues have argued that, even though both WM and STM tasks involve some shared processes such as storage, rehearsal, and executive-attention control, WM span's imposition of secondary tasks increases the executive-attention contribution relative to that in STM span (e.g., Engle et al., 1999a; Engle and Kane, 2004; Kane et al., 2005). These executive-attention processes help maintain access to memoranda in the face of attention shifts away from their representations and toward the execution of the secondary task; that is, WM span tasks bring executive control to bear on keeping representations accessible when they are outside conscious focus. STM span tasks, because they provide no secondary task to interfere with stimulus maintenance and rehearsal, require less executive involvement.

#### *2.40.3.2.2 A distinction between STM and WM?*

But wait – subsequent research using visuospatial materials suggests a different conclusion, namely that STM and WM may be inseparable (or, at least, less separable than verbal STM and WM). Miyake et al. (2001) tested 167 undergraduates in two STM span tasks presenting sequences of visuospatial stimuli (e.g., dots within different locations of a grid), and two WM tasks interpolating a spatial processing task (e.g., mental rotation of letters) between the spatial memoranda. CFAs indicated that a model separating STM from WM fit the data well, but the correlation between these factors was very high (.86) with a 95% confidence interval including 1.0. Fixing the correlation between these factors to 1.0, thus deriving a unitary memory factor, did not significantly hurt model fit, indicating that, in the spatial domain, STM and WM were equivalent as measured by span tasks.

Although subsequent studies have not found spatial STM and WM to be indistinguishable, they have found STM and WM to be somewhat more strongly associated in the spatial than in the verbal domain (Park et al., 2002; Kane et al., 2004). One interpretation of these findings is that, because people have fewer and less-practiced rehearsal strategies for visuospatial than for verbal sequences, even 'simple' STM tasks with spatial materials draw heavily on executive-attention processes for effective maintenance. Given our emphasis in this chapter on convergence between psychometric and experimental findings, we note that the 'executive' interpretation of spatial STM-WM correlations dovetails nicely with conclusions drawn from dual-task experimental studies, which have suggested domain-general executive and attention processes are more important to short-term retention of spatial than verbal stimuli (e.g., Klauer and Stegmaier, 1997; Awh et al., 1998).

In any case, the tidy distinction between STM and WM is rapidly becoming more complicated. First, as mentioned, spatial STM and WM tasks are highly correlated and may sometimes be indistinguishable. Second, Oberauer and colleagues have demonstrated that immediate-memory tasks need not involve secondary-processing tasks to correlate strongly with WM span tasks; for example, tasks that require the updating of mental representations of several stimuli, without the imposition of irrelevant information, are just about indistinguishable psychometrically from WM span (e.g., Süß et al., 2002; Oberauer, 2005). At the same time, Unsworth and Engle (2007) have shown that non-recency portions of immediate-free-recall lists correlate so strongly with WM span that they are also psychometrically indistinguishable from each another. If WM can be measured without dual tasks, then what really distinguishes it from STM? Third, Colom and colleagues have recently argued, based on reanalyses of old datasets and analyses of new ones, that WM and STM span, even in the verbal domain, are much more highly correlated than has been recognized, and that the shared variance between WM and STM is more important to their broad power to predict cognitive individual differences than is the variance that is unique to WM (e.g., Colom et al., 2006a,b).

It now appears that the key to understanding the WM-STM relation, as assessed by span and other tasks, is to resist the reification of tasks onto hypothetical constructs. Instead, we must consider more carefully the shared and unique mental processes that determine performance. Although Engle and colleagues have emphasized the multiply determined nature of both STM and WM span (e.g., Engle et al., 1999a; Engle and Kane, 2004; Kane et al., 2005), noting that storage, rehearsal, and executive processes contribute to both tasks, many researchers assume their view to be that 'STM' tasks simply measure storage and rehearsal and 'WM' tasks measure exclusively executive control (e.g., Ackerman et al., 2005; Colom et al., 2006a).

Fortunately, Unsworth and Engle (2006, 2007) have clarified the mappings of these tasks to their underlying constructs. In short, WM span tasks, STM span tasks with long (more than four item) lists, and nonrecency portions of free-recall lists all measure just about the same thing ('WM'), and all seem to account for similar variance in higher-order cognitive abilities. Why should this be? Unsworth and Engle argue that, in all of these cases, subjects must recover some or all of the target information from 'secondary,' inactive memory in the face of competition from other memory representations. To do so, subjects use cues to guide memory search and delimit a search set that discriminates target from competing information. Higher WM subjects appear to generate and use better cues, or to use the same cues more effectively, than do lower WM subjects, and this accounts for their better performance on these varied memory tests.

#### *2.40.3.2.3 Summary*

The individual-differences literature on STM and WM yields an irony. Tasks such as STM and WM span are assumed to measure immediate-memory and attention-related processes that are quite different from those involved in LTM encoding and retrieval. However, current evidence suggests that search and retrieval from inactive secondary memory (or LTM), rather than maintenance within active primary memory, drives individual differences in memory-span and span–ability correlations. These conclusions seem quite consistent with those from experimental studies suggesting that, aside from a very limited number of highly active and accessible representations we might call primary memory, retention and recall over both the short and long term is driven primarily from the cue-driven search and retrieval of inactive memory (e.g., Wickelgren et al., 1980; Wixted and Rohrer, 1994; McElree, 1998; Cowan, 2001; Nairne, 2002; Davelaar et al., 2005). The clear lesson is that we should not assume that the processes engaged by tasks follow from the labels, such as 'STM span,' that we have traditionally affixed to them.

## 2.40.4 Individual-by-Treatment Interactions in Memory

In both applied and general scientific work, psychology requires combined, not parallel, labors from our two historic disciplines.... In the search for

> interactions we will invent new treatment dimensions and discover new dimensions of the organism. We will come to realize that organism and treatment are an inseparable pair and that no psychologist can dismiss one or the other as error variance. (Cronbach, 1957: 683)

Cronbach (1957) called for a united psychology to bring the strengths of experimental and psychometric methods to bear on theoretical and practical problems of human behavior, in particular by seeking interactions among individuals and experimental treatments. We believe that the literature on individual differences in WM is rich with examples of this approach, and so we review briefly two categories of such studies. In the first, experimental manipulations of the WM span task, itself, are tested for their effect on correlations between WM span and some criterion variables, such as language comprehension or reasoning. In this way, researchers isolate some of the cognitive processes that are most important and least important to the predictive power of WM span (e.g., retrieval of information in the face of proactive interference, and engaging in particular mnemonic strategies, respectively). In the second category, WM-related individual differences are assessed within other, nonspan tasks that feature various experimental manipulations designed to be more or less vulnerable to WM variation. This correlational technique may often yield significant advances in general theory about cognitive tasks and task domains.

### 2.40.4.1 Individual-by-Treatment Interactions within WM Span Tasks

WM span tasks are complex. They require timesharing between two unrelated tasks, such as memorizing letters and solving equations, they afford numerous strategies for managing the dual-task requirement and for encoding memoranda, and they present processing material that may be more or less demanding for subjects with different skills. So which of these variables, if any, are important to the correlations between WM span and various complex cognitive abilities?

Individual differences in skill on the processing task (Conway and Engle, 1996), or in strategy use (Dunlosky and Kane, in press), are not. Let us consider strategy use in more detail. If differential strategy use (or efficiency) were largely responsible for WM span correlating with, say, reading comprehension scores, then experimentally manipulating strategy use should alter the span–comprehension association. What actually happens? When subjects are allowed to pace themselves through WM span tasks, thus allowing more time to study the items and employ complex mnemonics, mean scores go up. This experimental effect is not surprising. What is more important is the individual-by-treatment interaction: the span–comprehension correlations either remain unchanged, or get weaker, as a result of this experimental manipulation (Engle et al., 1992; Friedman and Miyake, 2004).

The fact that, if anything, span correlations get weaker when we allow subjects more freedom in their approaches to the task suggests that normal individual differences in these approaches or strategies are not responsible for the strong correlations normally observed. In fact, strategic variation appears to contribute noise to span correlations rather than causing them. If strategic variation were actually causal, then allowing strategies to vary more freely should increase the correlations, not decrease them. Indeed, in studies that teach subjects to use one particular memory strategy within WM span, the correlations get stronger compared to those from uninstructed subjects (Turley-Ames and Whitfield, 2003). By forcing all subjects to use the same strategy, nuisance variation in strategy selection is reduced, and the true (stronger) span–ability association is revealed.

What do individual-by-treatment interactions tell us about what is important to WM span variation? They tell us that the buildup of proactive interference (PI) is important. Like most immediate-memory tasks, WM span tasks present many different lists of similar items within a single test. As experimental studies of memory have long indicated, this is a recipe for PI and rapid forgetting (e.g., Underwood, 1957; Keppel and Underwood, 1962). We might expect, then, that experimental manipulations of PI should affect mean span scores, driving them up or down. Like the effect of strategy use on mean span scores discussed earlier, this would not be surprising. The really interesting question, again, is about the individual-by-treatment interaction: Do experimental manipulations of PI affect individual differences in WM span and its correlation with other tasks?

Indeed they do. May et al. (1999) presented WM span trials in one of two orders to younger and older adults. In ascending orders, smaller memory sets were presented before larger sets. Thus, larger sets, which by convention contribute more to span scores than do smaller sets, were encountered only after PI had built up from prior trials. In descending orders, the high-impact larger sets were presented first and, therefore, before PI had much effect. May et al. found not only that descending administrations yielded higher mean scores than did ascending, but also that age differences in WM span, which are usually robust, arose only in the ascending administration. By minimizing the effect of PI on subjects' scores via descending administration, the ubiquitous age-by-span correlation was eliminated. Lustig et al. (2001) and Bunting (2006) have further demonstrated that experimentally reducing PI during span tasks dramatically reduces their correlations with comprehension and reasoning tests. Likewise, Gray et al. (2003) used neuroimaging techniques to show not only that increasing the contribution of interference to WM tasks increases their correlation to reasoning tests, but also that this correlation is almost completely accounted for by individual differences in the recruitment of brain areas that are important to executive control. The fact that reducing interference reduces WM span correlations, and increasing interference increases span correlations, suggests that PI and individual differences in the ability to resist it are important causal variables in the relation between WM span and higher-order cognition. Only investigations of individual-by-treatment interactions could have led to such conclusions.

### 2.40.4.2 Individual-by-Treatment Interactions in the Effects of WM on Other Tasks

As we have seen, one effective method to investigate the strong empirical associations between WM span and various cognitive abilities is to manipulate variables within span tasks and then measure their effects on span–ability correlations. Another common strategy in this literature is to test for WM-related individual differences in the performance of other tasks under varying experimental conditions. In the domain of complex cognitive abilities, for example, WM span and language comprehension correlate significantly under some experimental conditions, but not others, suggesting theoretical distinctions between more resource-demanding and more automatic referential and parsing processes (e.g., Just and Carpenter, 1992; Caplan et al., 2007). Regarding somewhat more simple cognitive processes, such as selective attention and visual search, WM span also correlates strongly and selectively with performance in only some task contexts, and these differential correlations have fueled novel theoretical proposals for how such attention tasks are performed (e.g., Kane and Engle, 2003; Kane et al., 2006; Heitz and Engle, 2007).

As we emphasized the importance of PI to span–ability correlations earlier, let us consider here what WM-by-treatment interactions tell us about PI and the executive control of memory processes, quite generally. Nomothetic theory derived from experiments has suggested that executive selection and inhibitory processes play significant roles in producing and combating PI (e.g., Postman et al., 1968; Anderson, 2003). Because WM variation has been thought to reflect, in part, variation in such executive-control processes, Kane and Engle (2000) investigated the relation between WM span and PI buildup in a variant of the Brown-Peterson task. Subjects who had been previously identified as having high WM span scores (i.e., from the top quartile of a large university distribution) or low WM scores (i.e., from the bottom quartile) studied and recalled three consecutive lists of ten words drawn from one semantic category (animals, occupations, or world nations). Immediately following each list, subjects engaged in a rehearsal-prevention task for 16 s before recalling the list. High- and low-WM subjects did not differ in recall of the first list but, as expected, WM span predicted PI susceptibility, with low-WM subjects showing greater PI on lists 2 and 3 than did high-WM subjects. Although this finding represents an individual-by-treatment interaction, with WM span predicting recall across late but not early lists, more generally important findings came from a higher-order interaction.

While Kane and Engle (2000) tested for WM-related individual differences in PI susceptibility, they also manipulated subjects' capacity for executive control by dividing their attention. During either the encoding or retrieval of each list, subjects continuously tapped a pseudorandom finger sequence under time pressure. The logic here was similar to that in neuropsychological studies of brain injury: task components that normally elicited executive control would suffer under dual-task conditions, as those executive processes were thwarted by the tapping task. Two relevant results warrant mention. First, divided attention increased the PI effects for high-WM subjects and had no effect on their list 1 recall, suggesting that high spans engaged attention-control processes only to meet the increased encoding and retrieval demands of PI-vulnerable lists. In fact, high WM performance in the dual-task conditions matched low WM performance under single-task conditions, and so dividing attention turned high-WM subjects into functional low-WM subjects. Second, and in contrast, divided attention hurt low-WM subjects' list 1 recall while having no subsequent effect on their PI susceptibility. This suggests that low-WM subjects exhausted their attention-control processes to meet the basic encoding and retrieval requirements of single lists with little PI potential, leaving nothing additional to exert against the interference on subsequent lists. These findings suggest some interesting hypotheses about the nature of WM-related individual differences, but they also paint a much more complicated picture regarding the attentional demands of encoding and retrieval than is typically considered (e.g., Craik et al., 1996). We suggest that further investigation of span-by-treatment interactions would be informative to nomothetic theoretical pursuits regarding the nature of episodic memory and retrieval and their interaction with attentional processes.

## 2.40.5 Summary and Conclusions

The psychological investigation of memory, like psychological investigations of other behavioral and cognitive phenomena, has been slow to integrate the experimental and correlational approaches to theory testing. We hope to have convinced experimentally inclined cognitive researchers that they should consider the psychometric literature on individual differences in memory in forming hypotheses about memory processes and tasks. Moreover, they should consider incorporating individual differences into their own experimental tests of such hypotheses. Our plea, like Terman's, Cronbach's, Melton's, Underwood's, and Kosslyn's before us, is that students of memory whose interests span traditional areas of memory research (so well represented in this volume) will recognize the potential benefits of a united experimental–psychometric approach to important theoretical questions about memory structure and process.

# 2.41 Aging and Memory

**M. Naveh-Benjamin and S. R. Old**, University of Missouri-Columbia, Columbia, MO, USA

This chapter is a review of studies assessing age-related changes in memory – that is, the changes that occur in different memory systems and processes from young adulthood to old age – with the intention of establishing the major empirical findings reported in the literature, the theoretical interpretations of these findings, and directions for future research. Most of the chapter is based on the comparison of performance of young people in their twenties to older adults between 65 and 85 years old. We limit the discussion to normal age-related changes, focusing on behavioral studies in which the older participants have no apparent pathological changes related to dementia or other similar conditions (*See* Chapter 3.28 for a discussion of some of the mediating brain structures of these changes). As this research field has gone through a vast expansion in the last 25 years, the review is necessarily selective, covering several representative topics studied in the literature that use different types of conceptualizations in terms of memory stores, memory systems, and memory processes.

## 2.41.1 Introduction

One of the most intriguing aspects regarding age-related changes in memory is the variability in the changes; whereas some memory abilities decline significantly in old age, others are held fairly constant throughout older adults' years. Explaining this variability in performance is a major purpose of research in the area, and although we still lack comprehensive explanations, several promising approaches have been suggested to explain components of this variability.

Many studies have addressed questions regarding changes in different types of memory established in general memory research. For example, one distinction is between declarative (explicit) and nondeclarative (implicit) memory systems (e.g., Squire, 1986). The former involves conscious intentional retrieval (e.g., trying to remember the name of the person you met last night), whereas the latter involves memories that can be inferred by subsequent behavior without any intention to be retrieved (e.g., riding a bike, or responding faster to a stimulus because you have seen it several times before). Within the domain of declarative memory, a distinction has been made between episodic memory – that related to a particular time and place in an individual's personal history (e.g., remembering whom you met last Thursday for lunch) – and semantic memory, which involves knowledge of general facts not related to a particular time and place (e.g., knowing the capital of France). Another distinction is based on memory stores; short-term memory, for example, involves the ability to retain a recently experienced event for a brief period (such as listening over the phone for a meeting time and then writing it down), whereas long-term memory involves the retention of information for an extended period of time (e.g., remembering the names of the people you met last night for dinner). A further distinction is between retrospective memory – memory for a past event – and prospective memory – memory to perform a future action (such as remembering to show up for a dental appointment). Finally, viewing memory in terms of processing phases allows for the assessment of age-related differences in learning (encoding) the information, in maintaining it during the retention interval, and in accessing (retrieving) it when necessary.

As mentioned above, research shows differential patterns of age-related changes in tasks involving these different memory types. For example, whereas semantic memory seems to be maintained relatively well into old age, episodic memory shows an appreciable decline (**Figure 1(f)**). In addition, in contrast to explicit (declarative) episodic memory, implicit memory, as one type of nondeclarative memory, shows very few changes in old age.

We begin by describing age-related patterns in different types of memory based on empirical findings and then discuss theoretical frameworks that have been suggested to explain these patterns. We end with a discussion of some further issues, including the uniqueness of memory changes within the larger realm of general cognitive changes, tasks, and circumstances in which older adults seem to show adequate memory performance, and limitations on conclusions based mostly on laboratory research.

## 2.41.2 Empirical Findings

In order to establish reliable conclusions based on numerous studies, we have resorted, wherever possible, to meta-analytical studies of age-related differences in various memory domains. Such studies involve quantitative summaries of a large number of studies investigating specific questions and, hence, help us to draw conclusions based on replicable results. After establishing the patterns in a given domain based on each meta-analysis, we describe a few illustrative studies to provide the reader with characteristic methods and representative results for each domain. Among other issues, we discuss age-related changes in short and long-term memory, explicit (semantic and episodic) and implicit memory, and prospective memory. We also assess age-related changes in autobiographical and false memory and in encoding and retrieval processes. Most of the research is based on experimental studies, although some studies use multivariate correlational approaches.

It should be noted that most of the meta-analytical studies representing the type of studies conducted on memory and aging are based on cross-sectional designs, in which different age groups are tested at a given point in time. This method usually shows larger age-related differences than are obtained in the rather less frequently used longitudinal studies, in which groups of people are followed over time (e.g., Rönnlund et al., 2005). This point is further discussed at the end of this chapter.

### 2.41.2.1 Implicit/Indirect Memory Versus Explicit/Direct Memory

One area of memory research that received substantial attention in the 1980s and 1990s is related to the distinction between tasks in which participants are aware of the fact that their memory is being probed (explicit/direct) and those in which they are unaware of performing a memory task (implicit/indirect/procedural). Interestingly, most of the research in this area indicates different patterns of age-related changes in these two classes of memory tasks. A meta-analysis carried out by Light and La Voie (1993), based on 33 experiments, concluded that there are small age-related declines on implicit memory measures (d = −0.18, where d is the mean effect size in terms of unit standard deviations over all the studies included). However, these are much smaller than the decline shown for explicit measures such as recognition or recall, in which d ranges from −0.5 to −1.5, as found in other meta-analytical studies reviewed here (see **Figure 1(c)**).

One example of such a pattern was reported by Light and Singh (1987). In their study, older and younger adults viewed lists of words and rated each word by its pleasantness. Later, subjects were provided with the first three letters of various words, some of which had been presented earlier. Half of the participants (the implicit group) were told simply to complete each stem with the first word that came to mind, whereas the others (the explicit group) were asked to try to fill in each stem with a word they had seen earlier. Finally, all subjects completed a recognition test, in which they chose studied words from a list of both targets and distractors. The results indicated that, whereas cued recall scores and recognition scores were impaired in old age, the priming effect (i.e., providing a previously rated word following implicit instructions) did not differ significantly between age groups. Similar results were obtained by Light and Albertson (1989), who used lists of semantically categorized words with explicit cued recall and implicit exemplar generation tasks (see **Figure 2**).

Differential age-related decline in implicit versus explicit memory measures has been further supported by a longitudinal design employed by Fleischman et al. (2004). Results of several implicit and explicit tests administered once a year for 4 consecutive years showed that explicit memory declined significantly over the four assessment periods, and this decline was largest in participants who were the oldest. Implicit memory, however, was unrelated to age at baseline and did not decline over the 4-year period.

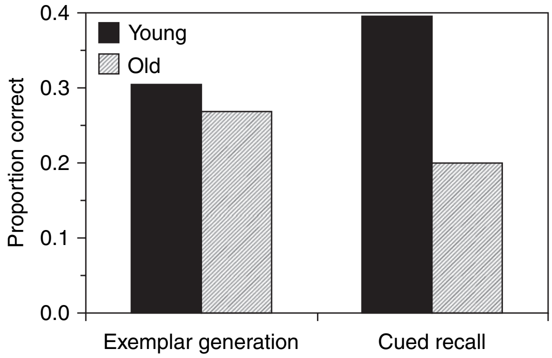

**Figure 2** Performance of older and younger adults on an implicit exemplar generation task and an explicit cued recall task. From Light LL and Albertson SA (1989) Direct and indirect tests of memory for category exemplars in young and older adults. *Psychol. Aging* 4: 487–492. Copyright 1989 by the American Psychological Association.

Altogether, older adults are impaired more on explicit than on implicit memory measures. Thus, it is important to consider whether a task requires deliberate or nondeliberate memory when evaluating and predicting age-related declines.

### 2.41.2.2 Short-Term and Working Memory

Short-term memory (STM) was originally suggested as the mechanism that allows temporary storage of information (Atkinson and Shiffrin, 1968). Later, Baddeley and Hitch (1974) proposed the concept of working memory (WM), which involves both the temporary storage and simultaneous manipulation of information. For example, when listening to a conversation, we must maintain individual words while concurrently relating them together into a coherent message. Aging seems to differentially affect these two functions of passive maintenance and active on-line processing. A meta-analysis by Bopp and Verhaeghen (2005) examined age differences in several verbal STM and WM tasks. Relatively small age differences were found in tasks that require simple temporary maintenance of materials. For example, forward digit span tasks, which involve storage without processing, showed a relatively modest age-related decline (d = −0.53). In contrast, tasks requiring both storage and processing showed robust age differences, and the impairment of older adults was largest when the processing component of the task became more dominant relative to the maintenance one (e.g., d = −1.01, −1.27, and −1.54, for sentence span, listening span, and computation span, respectively).

An example of a relevant study was conducted by Li (1999), who assessed age-related differences in storage and processing of verbal materials. In the STM condition of this experiment, older and younger adults were simply required to recall lists of digits. In the WM condition, subjects recalled similar lists of digits, but each digit was presented following a math problem in which subjects indicated whether the provided answer was correct or incorrect. Thus, the STM and WM tasks were similar, except that the former required only storage, whereas the latter required both storage and processing. Results showed that older adults were impaired more on the WM span than on the STM span measure. The authors conclude that older adults were more impaired, relative to younger adults, on the task that required both processing and storage than on the task that required only storage. This pattern of results seems to characterize memory not only for verbal materials but also for visuospatial materials, as shown by Vecchi and Cornoldi (1999).

### 2.41.2.3 Long-Term Memory: Semantic Versus Episodic Memory

One interesting question addressed in previous research is the degree to which there are age-related changes in memory for general knowledge (semantic memory) and whether such changes are different than those involving memory for specific events (episodes). Are older adults worse than younger adults in their ability to name the capital of Italy or to indicate whether a whale is a mammal or TOTBASHI is a word in English? Moreover, are age-related differences in the ability to respond to such questions unlike age-related differences in the ability to answer questions about specific events that tap episodic memory?

A relevant indicator for the differential patterns of performance in younger and older adults in episodic and semantic memory tasks comes from a recent large-scale study by Park et al. (2002). The study used tests of both episodic and semantic memory given to 345 people from 20 up to 92 years of age. Measures of episodic memory included visuospatial memory tests, such as the Rey visual design learning test and the Benton visual retention test, both of which required the viewing and reproduction of a specific drawing. Verbal tests involving free and cued recall of words were also included. The semantic memory tasks concentrated on verbal abilities and included the vocabulary section of the Shipley Institute of Living Scale, a synonym vocabulary test, and an antonym vocabulary test. The results, which can be seen in **Figure 1**, indicated that the age-related pattern observed was very different for episodic versus semantic memory. There was a substantial age-related decline in all measures of episodic LTM (see **Figure 1(c)**). In contrast, all three semantic memory tests showed a significant increase with age (see **Figure 1(e)**). The conclusion reached by the authors was that semantic memory does not decline – and may in fact increase – with age, whereas episodic memory exhibits a substantial age-related decline. Similar results were reported in a longitudinal study by Lövdén et al. (2004).

Several other studies also indicate that semantic memory is relatively stable over the adult lifespan. Semantic priming effects measure the amount of activation that occurs in the organized system of concepts that are connected together by associative networks (Collins and Loftus, 1975; *See* Chapter 2.28) and, as such, can provide information about age-related changes in people's structure of knowledge. Studies comparing age-related differences in semantic priming have shown either no differences or a larger semantic priming effect in the old. For example, a meta-analysis by Laver and Burke (1993) concluded that semantic priming effects showed a pattern of an increase in old age ($d = +0.10$).

One relevant study was conducted by Madden (1988), who asked older and younger adults to read sentences with one word presented at a time. The last item of each sentence, presented in all capital letters, was a target item for a lexical decision task; subjects indicated whether it was a word or a non-word as quickly as possible. Two factors were varied: one was the clarity of the target word, with some target items presented in a normal fashion and others degraded by the separation of letters by asterisks (e.g., B*O*O*K*S). The other factor was congruency, with some of the target words being congruent with the sentence context (e.g., "The accountant balanced the BOOKS"), others being incongruent (e.g., "The train went over the CLOUDS"), and still others being neutral in terms of congruence. The results showed that for nondegraded target words, neither age group responded more quickly to target words when they were congruent versus neutral in relationship with the sentences. For degraded target words, however, both age groups benefited from sentence context. Interestingly, this benefit was larger for older (117 ms) than for younger (52 ms) adults. There was also an overall context cost (i.e., the slowing of RTs for incongruous compared with neutral-context trials), which was larger for older (336 ms) than for young (167 ms) subjects. The authors conclude that these results indicate that older adults show an "increase in the influence from the semantic information that is activated automatically by a sentence context" (Madden, 1988: 171).

Another study, by Balota and Duchek (1988), manipulated the strength of the association between the prime and the target. For trials with a short delay between the prime and the target (200 ms), younger and older adults showed the same advantage in responding faster to highly associated pairs. However, when the delay between the prime and the target was longer (800 ms), older adults showed smaller benefits from the relatedness of the pairs in comparison to younger adults. Balota and Ducheck interpreted this finding to reflect intact automatic spread of activation within the semantic memory network in older adults (in the 200-ms delay condition), coupled with some decline under conditions that demand more attention (when the activation has to be maintained over a longer period of time).

There are, however, some indications that access to certain forms of semantic memory may suffer in old age. For example, it has been shown that, while they are able to name uncommon objects relatively well, older adults exhibit an impairment in naming famous people shown in pictures (e.g., Rendell et al., 2005). Overall, however, it seems that semantic memory is mostly spared of age-related changes. Episodic memory, in contrast, seems to be highly affected by advancing age; we discuss this in more detail in the next section.

## 2.41.2.4 Episodic Memory

In this section we survey research on different aspects of episodic memory changes, including memory for context versus content, the effects of intentional and incidental learning, the effects of reliance on semantic memory, performance on different episodic memory tasks, and encoding and retrieval factors.

### *2.41.2.4.1 Memory for context versus content*

One hallmark of episodic memory is its relation to time and place. That is, major characteristics of an episode involve when and where it occurred. If I am asked about what I had last night for dinner, unless I eat the same dish every night, I have to go back in my memory and use different contextual aspects of the episode, including the time (last night) and the place (a specific restaurant) where I had dinner, in order to retrieve the relevant information about the meal. Research indicates that aging impairs memory for such contextual elements as time and place to a greater degree than memory for the content of an event. For example, Spencer and Raz (1995) reviewed evidence from 46 studies. They found that the magnitude of age-related changes in context ($d = -0.90$) was significantly larger than for content ($d = -0.72$).

One representative empirical study was conducted by Puglisi et al. (1985), who compared age-related differences in memory for individual items (content) to that for occupied spatial locations (which served as context). Older and younger adults viewed target objects placed within a grid. During test, subjects were given a recall and then a recognition test over the objects and were then placed given objects in their studied location within the grid. The results showed an age-related impairment in memory for item location but not in item recognition. The authors concluded that older adults are able to recognize objects as well as younger adults but are less able to remember the spatial location of those objects (i.e., the context). Similar results were obtained by Kausler and Puckett (1980), who looked at age-related differences in memory for another contextual element – the case (upper or lower) in which a given word appeared. Their results provide support for the notion that aging has a greater effect on memory for contextual information (case of a given word) than on memory for content information (a word itself).

### *2.41.2.4.2 Intentional versus incidental learning*

A question relevant to both theory development and everyday life performance is whether age-related differences in memory are mediated by the type of learning used. Specifically, are there differences between younger and older adults in memory if, during encoding (learning), they do not expect any memory tests (as happens, e.g., when one is introduced to new people on a social occasion)? Furthermore, are these age-related differences larger or smaller than when learning occurs intentionally (such as when one learns a chapter in a textbook over which a later test is expected)?

The meta-analysis by Spencer and Raz (1995), mentioned earlier, looked at this issue and found larger age effects in studies involving memory for content and context that used intentional learning (d = −0.62) than those using incidental learning (d = −0.41). Similar results were reported in a meta-analysis by Verhaeghen et al. (1993), based on 120 studies, which found a trend toward larger age differences in list recall under intentional learning (d = −1.00) than incidental learning (d = −0.87). Finally, a meta-analysis by Johnson (2003) showed that when subjects were provided during study with advance knowledge about the upcoming test over textual information, age differences were larger (d = −0.85) than when this information was not provided (d = −0.55).

One representative study was conducted by Hogan et al. (2006). In this study, older and younger adults viewed several series of nouns and made simple judgments about each one. The word 'learn' appeared above some of the presented words, which made participants aware that memory for those specified words would be tested. Participants completed a recognition test, in which they indicated whether or not given words had been presented previously. This test included words from both the 'learn' (i.e., intentional learning) condition and words presented without 'learn' instructions (i.e., incidental learning). Results showed an interaction between age and instructions, with older adults showing greater impairment in the intentional than in the incidental learning condition. Similar results were reported by Troyer et al. (2006), who found age-related impairments in memory for people's names when encoding was intentional (the 'learn' condition), but not when encoding occurred incidentally (through physical, phonemic, or semantic processing; see Figure 3).

The results of the aforementioned studies indicate that older adults can encode information incidentally quite well relative to younger adults. However, when they have to encode information intentionally, older adults show a disadvantage relative to younger adults. This differential effect could stem from an age-related impairment in the spontaneous use of effective strategies at encoding and retrieval (e.g., Dunlosky and Hertzog, 2001). This issue is further discussed later in the chapter.

### 2.41.2.4.3 Episodic memory support by semantic memory

As previously mentioned, older adults seem to retain their semantic memory quite well. An important issue involves the degree to which this intact semantic knowledge can be used to support episodic memories. A meta-analysis by Verhaeghen et al. (1993) provides an indication that increasing categorizability (the ability to categorize new information into previously learned semantic categories) of to-be-remembered information leads to a decrease in age differences in memory (d = −0.78 and −1.07 for lists high and low in categorizability, respectively). Similarly, a more recent meta-analysis by Johnson (2003) showed larger age differences in memory for unconnected sentences (d = −0.89) than for textual passages, which are easier to connect to previously learned semantic knowledge (d = −0.62).

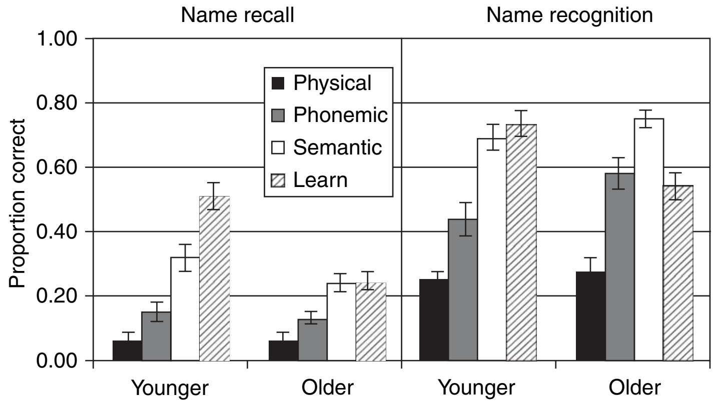

**Figure 3** Memory for names following three types of incidental learning instructions (physical, phonemic, or semantic processing) and intentional learning instructions. From Troyer AK, Häfliger A, Cadieux MJ, and Craik FIM (2006) Name and face learning in older adults: Effects of level of processing, self-generation, and intention to learn. *J. Gerontol. Psychol. Sci.* 61B: P67–P74. Copyright 2006 by The Gerontological Society of America.

One relevant study was reported by Wingfield et al. (1998), who examined age-related differences by looking at temporal patterns of free recall from categories. Older and younger adults studied lists containing words from each of several semantic categories (e.g., the animal category included bear, cat, cow, dog, and horse), until they were able to freely recall each list perfectly. At that point, participants' recall times were recorded. Results showed that nearly all responses by both younger and older adults were clustered, that is, once one word from a category was recalled, all words from that category were recalled before the participant moved to the next category. Furthermore, older adults' within-category inter-response times were similar to those of younger adults. Thus, once they were able to retrieve category names, older adults were just as fast as younger adults. However, between-category inter-response intervals were generally longer for older than for younger adults (see **Figure 4**). The authors conclude that when words are from a single semantic category, older adults' memories are just as effective as those of younger adults, indicating that older adults can in fact make use of semantic knowledge to support episodic memory performance.

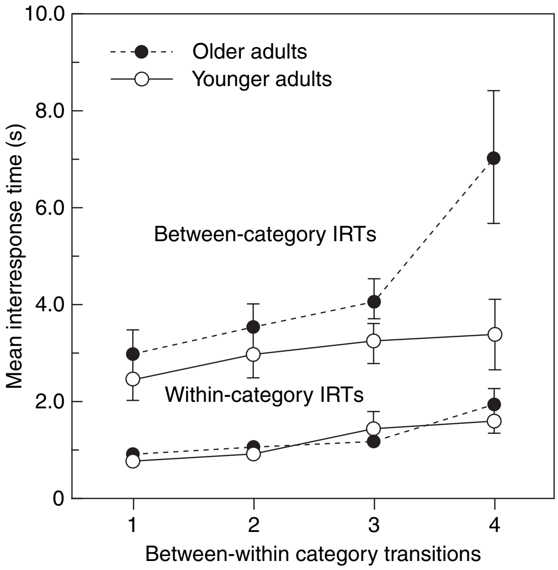

**Figure 4** Mean between-category interresponse times (IRTs) for younger and older adults over four transitions between five recalled categories, and mean within-category IRTs averaged across the five categories recalled. From Wingfield A, Lindfield KC, and Kahana MJ (1998) Adult age differences in the temporal characteristics of category free recall. *Psychol. Aging* 13: 256–266. Copyright 1998 by the American Psychological Association.

Another study, by Naveh-Benjamin (2000), assessed this issue by testing memory for related and unrelated pairs of words. After studying these pairs, participants were given a recognition, cued recall, or free recall test. Results showed that, overall, age differences were much larger in memory for unrelated word pairs than for related word pairs, and this was the case for each of the memory tasks (see **Figure 5**). The author concluded that older adults are more disadvantaged in memory for unrelated pairs but can benefit from previously learned information (schematic support, Craik, 1986; see section titled 'Attentional resource limitations') that can be utilized in related pairs to bring their episodic memory performance close to that of the younger adults.

#### 2.41.2.4.4 Retrieval from memory

As discussed, processes involved in the encoding of information are important; however, processes used to access the information (i.e., retrieval processes) are also crucial to explicit memory tasks. One factor shown to be an important facilitator at retrieval is the number and quality of the cues available. The issue of whether there are age-related differences in the ability to use those cues can be studied by employing different types of memory tasks. For example, by comparing age-related differences in a free recall task (in which no cues are provided), those in a cued-recall task (in which some cuing is provided), and those in a recognition test (in which copies of the original events serve as cues), we can assess the degree of cue utilization by younger and older adults.

**2.41.2.4.4.1 Test type** In a meta-analysis of studies on memory using different types of tests, Johnson (2003) showed (with the analysis including one mean effect size per study) that age effects were smaller in recognition tests ($d = -0.67$) than in free recall ($d = -0.82$) or cued recall ($d = -0.88$) tests. Similarly, Spencer and Raz (1995), in their meta-analysis, found larger age differences in tests of recall ($d = -1.01$; including both free and cued recall) than in recognition tests ($d = -0.57$).

An example of a study that directly compared age-related differences in recall and recognition is one by Craik and McDowd (1987). Old and young adults studied lists of phrases with target words (e.g., A body of water – pond), then completed two auditory tests, one using cued recall and the other testing recognition. In addition, during retrieval, all subjects carried out an additional reaction time (RT)

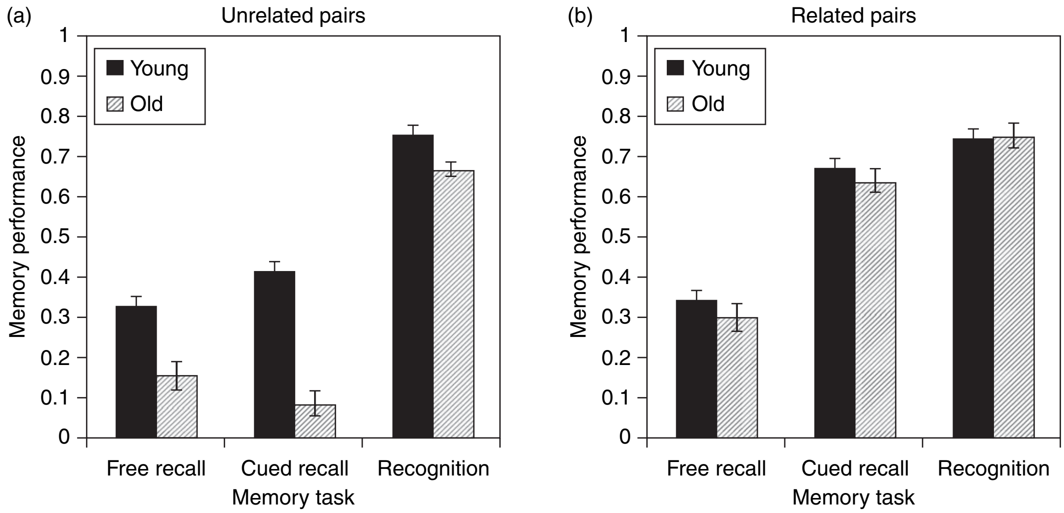

**Figure 5** Memory performance of older and younger adults for unrelated (a) and related (b) word pairs. task in which they pressed one of four keys according to whether a visually presented stimulus was a vowel, consonant, odd digit, or even digit. Results showed that older adults did significantly worse than young in recall test performance but performed similarly to young on the recognition test (**Figure 6**, left). In terms of RTs on the concurrent task, younger adults performed similarly during the recall and recognition tests, whereas older adults were slower in responding to the concurrent task while they were performing recall than recognition (**Figure 6**, right). Thus, recall may be especially taxing for older adults. Similar results were obtained using recall and recognition of names (Troyer et al., 2006), showing a significant age-related decline in recall performance but no differences in recognition.

Overall, older adults seem to be impaired more on tasks requiring recall than on those using recognition. Craik and McDowd (1987) use these patterns of results to support the notion that recall requires more processing resources than does recognition, and that older adults exhibit a decline in these resources. These resources are less necessary when environmental support is provided in the form of retrieval cues (see further discussion of this issue in the section titled 'Attentional resource limitations').

***2.41.2.4.4.2 Recollection and familiarity*** Recent discussions of memory retrieval distinguish between two types of retrievals, one based on the process of recollection and the other on processes driven by familiarity (e.g., Yonelinas, 2002). Recollection is required in order to retrieve contextual and other details of an episode (e.g., when, where), whereas familiarity is based on the feeling of having previously experienced the information without remembering any specific contextual details about the event.

One major paradigm used to assess recollection and familiarity is the process dissociation procedure

(PDP; Jacoby, 1991), which generally indicates an age-related decline in retrievals based on recollection but not on familiarity (e.g., Jacoby et al., 1996; Jacoby and Hay, 1998); this conclusion was supported by Prull et al.'s summary of 13 studies (as cited by Hoyer and Verhaeghen, 2006) using this procedure. An example of such a study was conducted by Jennings and Jacoby (1993). Older and younger adults, unaware of an upcoming memory test, read aloud a list containing names of fictitious, nonfamous people. Participants then took two recognition tests, each including old and new nonfamous names, as well as real famous names. In the inclusion test, subjects were to indicate whether or not a presented name was that of a famous person. They were told, incorrectly, that any name they recognized from the earlier phase was famous, and that they should respond 'yes' to such names. In the exclusion test, they were again asked to identify famous names but were told that names they recognized from the first phase were nonfamous, so they should respond 'no' to such names. The PDP was used to calculate estimates of familiarity and of recollection for each group of subjects, based upon the idea that yes responses to studied nonfamous names could indicate either recollection or familiarity on the inclusion test but could indicate only familiarity in the absence of recollection on the exclusion test. Results showed that aging produced large declines in recollection, but familiarity estimates did not differ significantly between the groups.

Other methods used to measure recollection and familiarity include assessment of receiver operating characteristics (ROC) curves and remember/know (R/K) judgments. The former procedure involves plotting hit rates against false alarm rates at various levels of confidence, and the latter provides estimates of recollection from items judged as 'remembered' and familiarity from items judged as 'known.' Both methods, like the PDP, show a definite age-related decline in recollection, but the picture regarding familiarity is less clear. For example, Prull et al. (2006) used all three procedures and showed clear age-related differences in recollection. The different methods, however, yielded different results in regard to familiarity estimates; the R/K and ROC methods showed an age-related deficit in familiarity, whereas the PDP method did not. Light et al. (2000) reported similar patterns in a summary of relevant literature.

To summarize, there is a great deal of evidence for an age-related decline in recollection. However, such a clear conclusion cannot be drawn about familiarity, as aging effects seem to depend on the method used to measure them.

### 2.41.2.4.5 *False memory*

Memory research has been slowly moving from an interest in variables that affect accurate performance to assessment of the errors that people make in their memory reports and the sources of these errors. One area of such research involves eyewitness testimony, with studies repeatedly showing that postevent information can be mistakenly thought to have happened in the original event (e.g., Loftus and Palmer, 1974). A review article by Jacoby and Rhodes (2006) concludes that older adults are more prone than younger adults to reporting inaccurate memories. Aging seems to lead to high susceptibility to misinformation, accompanied by unawareness of this susceptibility, as older adults are relatively confident in the accuracy of their false memories (Dodson et al., 2007).

An example of a study that assessed age-related differences in susceptibility to misinformation is one by Karpel et al. (2001). In this study, older and younger adults viewed slides showing a theft and were told to try to remember the objects and events shown in the slides. Fifteen minutes after study, subjects were questioned over the slides; two of the included questions contained misleading information, mentioning objects not actually seen in the slides (called critical objects; e.g., "Did the thief pick up the bottle of Elmer's glue that was on the second desk in front of the can of Coke?" when a can of Coke was not actually shown). Five minutes later, subjects took a final test, in which they indicated whether they had seen various objects in the slides; the two critical objects were included in this test. Subjects also provided a confidence rating for each response. Results showed that older adults were less able to reject critical objects but more confident in their incorrect endorsement of those items compared with younger adults. The authors concluded that older adults are more susceptible to misleading information than are younger adults. A recent study by Roediger and Geraci (2007) showed similar susceptibility of older adults to the misinformation effect. The age-related deficit, however, was smaller for those participating in a source-monitoring test condition who needed to indicate whether the tested information was derived from the original slides, the following misleading text, both, or neither, suggesting that older adults' vulnerability to misleading information may be reduced when source information is made especially salient.

**Figure 7** Mean recognition performance as a function of group. From Balota DA, Cortese MJ, Duchek JM, et al (1999) Veridical and false memories in healthy older adults and in dementia of the Alzheimer's type. *Cogn. Neuropsychol.* 16: 361–384. Copyright 1999 by Psychology Press.

Another paradigm used in the study of false memories is the DRM (named after its creators: Deese, 1959; Roediger and McDermott, 1995). Balota et al. (1999) used this paradigm, presenting lists of items related to a critical, unpresented word. For example, 'desk,' 'computer,' 'phone,' 'books,' and so on might be presented, all being associated with the unpresented critical word 'office.' Five groups of people were tested in this study, including young adults, healthy young-old (aged 60–79 years), healthy old-old (aged 80–96 years), and adults with mild or very mild dementia of the Alzheimer's type (DAT; aged 56–91 years). At test, both groups of healthy older adults tended to falsely recall or recognize more critical words than younger adults, as indicated in **Figure 7**.

These results and others indicate that in addition to having poorer memory for the presented information, under certain conditions older adults also show an increase in intrusions and false memory more than younger adults. Some explanations for these patterns – for example, intact activation in semantic memory coupled with poor source memory – are discussed later in this chapter.

### *2.41.2.4.6 Autobiographical memory*

A question that has received more attention recently involves the degree to which people at different ages can remember events in their personal past. These autobiographical memories provide information about what people remember from their own past with respect to the frequency of these memories, their type and nature, and the ease with which they are retrieved. The procedures used in these studies are different from most of the studies mentioned so far, in that researchers assess memories that have already been established but cannot be experimentally controlled. As a result, we cannot be as confident of the authenticity of these memories. Nevertheless, these are important memories, as they provide people with a sense of continuity over their lifespan.

Research on autobiographical memories shows that an important factor, in addition to the age of the participants during retrieval, is the age at which the memories were established. Not surprisingly, several studies have shown that people tend to remember recent events. Events that occurred between the ages of 10 and 30, however, are also especially well remembered. This effect, known as the reminiscence bump, has been attributed to "privileged encoding of experiences highly relevant to an individual during a critical phase of development and consolidation of the self" (Holmes and Conway, 1999: 30).

Fromholt et al. (2003) assessed age and cohort effects on autobiographical memory by comparing life narratives produced by centenarians with those of younger seniors. Fifteen centenarians, 30 healthy younger seniors (mean age, 78 years), depressed seniors (mean age, 80 years), and demented seniors (mean age, 81 years) were interviewed, being given 15 minutes to freely tell about important events from their lives. Although the healthy younger senior group reported more memories than the other groups, all groups exhibited a reminiscence bump, with a relatively high percentage of their memories being from their teens and twenties, as can be seen in **Figure 8**. These researchers also found a reminiscence bump in a sample of 22 centenarians using the cued recall method. Interestingly, Fromholt et al. further found that historical events (such as World War II) were more often reported if they had occurred during one's bump period than if they had taken place shortly after that period. This study, and others, highlight the importance of the age at which experiences are learned, in addition to their age at retrieval.

### *2.41.2.4.7 Prospective memory*

One type of memory important in everyday life involves remembering to perform future actions. This ability, termed prospective memory (PM), is required when we must remember to show up for an appointment, to meet a friend for lunch, or to take certain medications at specific times. Results of several studies conducted on age-related differences in

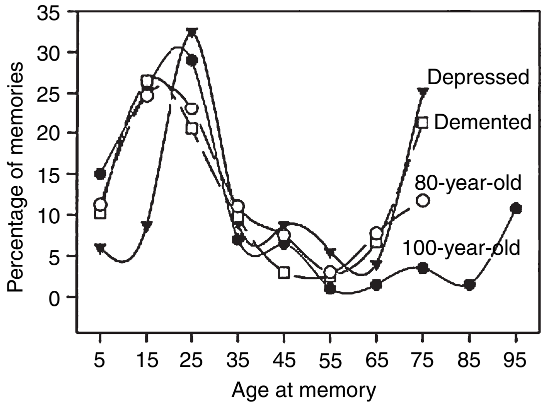

**Figure 8** The percentage of life-narrative autobiographical memories reported from each decade of life as a function of group. From Fromholt P, Mortensen DB, Torpdahl P, Bender L, Larsen P, and Rubin DC (2003) Life-narrative and word-cued autobiographical memories in centenarians: Comparisons with 80-year-old control, depressed, and dementia groups. *Memory* 11: 81–88. Copyright 2003 by Psychology Press.

PM are summarized in a meta-analysis reported by Henry et al. (2004), which indicates several patterns.

First, there seems to be a pattern indicating somewhat larger age-related declines in time-based (having to perform a specific activity at a certain hour) than in event-based (those with retrieval cues, such as having to give someone a message upon meeting him/her) PM tasks. This may be related to the former type of task relying more heavily on self-initiated processing (Craik, 1986). However, the specific results in a given task also depend on several other variables, including subject and task characteristics. For example, within event-based PM tasks, those tasks that create high strategic demands for controlled processing related to cue type, monitoring of the ongoing task, and retrieval demands, are more age sensitive than those tasks based on more automatic processing (e.g., Einstein et al., 1997; Park et al., 1997; Einstein and McDaniel, 2005). A second pattern of results within PM tasks is that older adults seem to show a larger impairment in remembering 'to' perform an action than in remembering 'which' action to perform (e.g., Cohen et al., 2001). Finally, in naturalistic studies (e.g., when people report about their performance in real-life situations, or when they have to respond to a meaningful prospective event in a laboratory situation, e.g., Rendell and Craik, 2000), rather than in typical laboratory studies, older adults do not show poorer PM than younger adults, and in some cases they even outperform younger adults. Possible reasons for this finding involve the higher relevance of ecologically valid tasks for older adults (to be discussed in the final section of the chapter) or their common use of external memory aids (e.g., writing appointments in a calendar and relying on it, as opposed to internal aids, which younger adults may use well in laboratory situations).

## 2.41.3 Theoretical Views

Considering the wealth of empirical evidence related to age-related changes in memory, some of which are reviewed above, it is not surprising that various theoretical accounts have been offered to explain the underlying mechanisms and processes that give rise to the different phenomena. Some of these mechanisms are more distal and relate to phenomena in cognitive aging in general, whereas others are more specific to age-related changes in memory. Following, we outline some of the major approaches and the way they explain the phenomena at hand. We then suggest an integrated approach.

### 2.41.3.1 General Mechanisms: Processing Resources Limitations

Several suggested frameworks claim that age-related changes in memory in particular, and in cognition in general, are the result of a decline in mental processing resources associated with age. These resources may be related to attention, speed, or capacity.

#### *2.41.3.1.1 Attentional resource limitations*

Several researchers (e.g., Hasher and Zacks, 1979; Craik and Byrd, 1982; Craik, 1983, 1986) have suggested that the pool of attentional resources needed to perform a given task is reduced in old age, and that this reduction is the cause of many age-related changes in cognitive tasks. This view predicts that older adults will be especially impaired on difficult tasks that require a significant amount of attentional resources. Evidence from Craik and Byrd (1982), Craik (1983, 1986), Rabinowitz et al. (1982), and Craik and McDowd (1987) is consistent with this notion, suggesting that a shortage of available attentional resources in older adults results in poorer memory because effortful cognitive operations, such as elaboration and effortful retrieval, require substantial attentional resources.

Furthermore, whereas recurring aspects of items can be encoded in a relatively automatic fashion, changing contextual elements of a situation demand a large amount of attentional resources. Thus, when these attentional resources are low – as in old age – there will be a tendency to encode items in terms of their general, stereotyped features, resulting in poor memory for the event. Results from several studies are consistent with this notion (e.g., Rabinowitz et al., 1982; Hess et al., 1989; Hashtroudi et al., 1990). Moreover, Craik and Byrd (1982) and Craik and Simon (1980) have shown that general retrieval cues (which require fewer attentional resources, as measured by secondary task performance) are relatively more effective for older subjects, whereas more specific contextual cues are relatively more effective for young adults.

Similar patterns have been reported for retrieval, as well. For example, as mentioned earlier, Craik and McDowd (1987) showed that older adults' performance was poorer on cued recall than on recognition tasks compared with younger adults. Such results can be interpreted in terms of the amount of attentional resources required by each type of task (as indicated by secondary task performance); cued recall requires substantial resources to search for the target word, whereas recognition, in which subjects are provided with a copy of the original target, requires fewer attentional resources.

Another line of research supporting the reduced attentional resources notion involves the effects of divided attention (DA) on memory. Several studies indicate that under DA conditions involving memory, older adults demonstrate a larger reduction in the combined performance on both the primary and the secondary tasks, relative to younger adults (e.g., Anderson et al., 1998; Li et al., 2001). Furthermore, several studies have found that younger adults whose available attentional resources are reduced by performing a secondary task exhibit a pattern of memory performance decline similar to that of older adults (e.g., Craik and Byrd, 1982; Rabinowitz et al., 1982; Jennings and Jacoby, 1993; Chen and Blanchard-Fields, 2000).

The notion of an age-related decline in attentional resources is in line with other memory impairments described in the previous sections. For example, the larger age-related decline in working memory than in short-term memory (e.g., Bopp and Verhaeghen, 2005) could be caused by a greater demand on attentional resources by the former. Likewise, explicit memory tasks require more attentional resources at retrieval than do implicit memory tasks, which usually do not require deliberate memory search. Furthermore, the encoding and explicit retrieval of contextual details and processes involved in recollection require more attentional resources than do familiarity responses (e.g., Troyer et al., 1999; Gardiner et al., 2006).

Craik (1986) elaborated on the notion of attentional resources to make the distinction between tasks that rely on environmental support and those that require self-initiation. Tasks that rely more on environmental support – for example, recognition memory, in which a copy of the presented stimulus is provided as a cue – require less self-initiation/attentional resources and hence should not show large age-related declines. In contrast, tasks that require more self-initiation, such as free recall, should show larger age decrements. Both notions are in line with empirical evidence (e.g., Craik and McDowd, 1987).

A related view of the age-related decline in memory addresses the distinction between controlled and automatic processes. According to this view, older adults will show a decline in memory tasks that require controlled, effortful processes but will exhibit no or only a small decline in tasks mediated by more automatic processes (Hasher and Zacks, 1979). This suggestion relates to the depleted attentional resources view, as tasks based on automatic processes should not require substantial attentional resources, whereas tasks that require controlled effortful processes should draw heavily on attentional resources; thus, age-related impairments should be largest on tasks that demand controlled processing. Such a position can explain why implicit memory, for example, seems to be intact in older adults, as it is driven largely by automatic processes. Likewise, recall tasks, which require relatively controlled processes, should be more affected by aging than recognition tasks. The controlled-automatic distinction is also consistent with results of studies suggesting that older adults' episodic memory impairments may be partially the result of the failure to spontaneously use effective strategies at encoding and at retrieval. Interestingly, these studies suggest that older adults can improve their performance by receiving appropriate instructions to use strategy, although this generally does not eliminate age differences altogether (e.g., Verhaeghen et al., 1992; Dunlosky and Hertzog, 2001; Naveh-Benjamin et al., 2005).

While the distinction between tasks based on automatic and controlled processes seems to have heuristic value, there are problems regarding the definition of each type of process and in task analyses to determine which processes are involved in a given task. Similarly, some researchers (e.g., Salthouse, 1988; 1991b) claim that the notion of attentional resources is too vague, at a framework level only, without enough details to be considered a model or a theory and is not well operationally defined.

To summarize, although there have been criticisms of the reduced attentional capacity framework on the grounds of vagueness, it seems to provide a heuristic functional explanation to age-related decline in memory performance. Further studies should employ different tasks to assess the construct validity of attentional resources, as well as to specify the mechanisms underlying depleted resources, potentially in terms of specific brain-related changes (see Carpenter et al., 1999).

#### 2.41.3.1.2 Speed of processing limitations

Another idea involving limited resources of older adults is in terms of the speed with which mental processes can be carried out. Several researchers have suggested that the execution of mental processes slows down in old age (e.g., Birren, 1965; Birren et al., 1979). Additionally, Salthouse (1996) suggested that slowing of basic information processing at the microlevel may result in poorer performance at a more macrolevel. For example, if a task involves several processing components, and the first few are slowed down with age, the input of these components will not arrive in time to feed later processing units, resulting in failure to complete the task. Using tools of multivariate statistics, such as path analysis and large-scale psychometric studies, Salthouse (1996) has shown that measures of basic speed mediate a significant age-related variance in several memory tasks. Verhaeghen and Salthouse (1997) conducted a meta-analysis of cross-sectional studies and found, for example, that speed can account for over 70% of age-related variance in episodic memory measures.

Although the slowing down notion seems reasonable, future studies using the speed approach should provide for a better understanding of the relations of speed to the specific differential decline patterns characterizing memory and aging. For example, the approach must be able to explain why intentional learning is more harmed by age than is incidental learning, why semantically related information is better remembered by older adults than is unrelated information, why context memory is especially poor in older age, and why recollection is more affected by age than is familiarity.

#### 2.41.3.1.3 Capacity (working memory) limitations

Some researchers (e.g., Welford, 1980; Parkinson, 1982; Hasher and Zacks, 1988; Puckett and Lawson, 1989) claim that reduced WM capacity is a major factor in age-related declines in many memory and other cognitive tasks. The notion is that to engage in any online processing required for different memory tasks – for example, encoding of spoken sentences – people must use processes to coordinate the interplay between temporary storage of the information and its integration into a cohesive message (Baddeley, 1986). According to this idea, older adults possess less efficient control processes, making, for example, the encoding of text more demanding and difficult (e.g., Light and Albertson, 1988). In support of this notion, Salthouse (1991a) has shown that when performance on measures of WM is statistically controlled, age-related declines in memory tasks are reduced by a substantial amount.

Whereas the original notion of WM capacity was somewhat similar to that of depleted attentional resources, mentioned above, more recently, more specific executive processes involved in WM have been suggested as the loci of memory decline in older adults. In particular, Hasher and Zacks (1988) and Zacks and Hasher (1997) claimed that older adults have a special problem in the recruitment of efficient inhibitory processes, making it difficult to block irrelevant information from entering WM. In this sense, it is not necessarily that WM capacity is smaller in old age but that it is cluttered with irrelevant information that was not appropriately filtered. This, in turn, hinders efficient processing – such as that involved in encoding and retrieval operations – of ongoing information. Support for the inhibition notion comes from studies showing, for example, that in contrast to young adults, irrelevant information is still held in older adults' WM despite being disconfirmed (e.g., Hartman and Hasher, 1991). Chapter 3.28 in this volume discusses such failures in terms of an age-related decrease in frontal lobe efficiency. Other relevant executive processes are those involved in task switching. Recent results indicate that older adults have difficulty rapidly switching between different aspects of a given task (e.g., Mayr et al., 2001).

The recent trend toward assessing the specific WM processes that decline as people age seems to be a fruitful direction that should be followed up in future research. This avenue of study could potentially explain one underlying root of the age-related decline in general cognition and in memory processes in particular.

Overall, although the above suggestions for the mediating role of age-related decline in processing resources in cognition are reasonable, for some their direct effects on memory performance have not yet been demonstrated. Further studies are needed to demonstrate empirically the precise way in which these different suggestions of decline in processing resources are responsible for the complex pattern of both decline and stability in memory in old age.

### 2.41.3.2 Memory-Specific Mechanisms

Whereas the above views are more general and relate not only to performance on memory tasks but also to cognitive processes in general, there have been some attempts to specify the particular mechanisms involved in age-related patterns in memory tasks.

#### *2.41.3.2.1 The source-contextual deficit approach*

According to this approach, older adults have problems at retrieval in distinguishing between different sources of original events (e.g., Johnson et al., 1993). In the eyewitness memory paradigm, for example, the claim made is that older adults, relative to young ones, cannot distinguish between the original information and related information that is subsequently presented. This idea can be extended to context in general, with the claim that one reason for older adults' memory decline is their inability to remember different aspects of the encoding context, including the time when an event took place, where it happened, the associated internal psychological context, and the social circumstances involved. The notion is that young people can better encode these contextual details, which can later serve as retrieval cues when a particular episode, or its components, must be remembered.

The source-contextual deficit suggestion is in line with studies reviewed earlier in this chapter that indicate a differential age-related decline in episodic versus semantic memory, as only the former relies on specific contextual details. This may help to explain the findings on eyewitness testimony, discussed above in the false memory section, in that older adults may fail to remember the source of specific information, thus leaving them susceptible to misinformation. Furthermore, as reviewed earlier, older adults show a particularly large deficit in memory for contextual/source details relative to their memory for the content/focal events. Finally, free and cued recall are more affected by contextual details than is recognition memory (e.g., Godden and Baddeley, 1975, 1980), and as mentioned earlier, older adults show more of a decline on recall tests.

#### *2.41.3.2.2 Associative-binding deficit approach*

Another suggestion in the literature is that older adults have a special problem in associating/binding different components of an episode into a cohesive unit (Chalfonte and Johnson, 1996; Mitchell et al., 2000; Naveh-Benjamin, 2000; Naveh-Benjamin et al., 2003). Naveh-Benjamin termed this the associative deficit hypothesis (ADH), which suggests that older adults have a relatively intact mechanism to encode and retrieve components of an episode but have a special problem in binding together the different components into a cohesive episode and in explicitly retrieving these associations. The ADH is more general than the source/context deficit notion, suggesting that the older adults have problems whenever explicit memory requiring the binding together of different components is involved. These bindings could be between an item and its context or between two items or objects.

The ADH is supported by evidence showing that older adults perform significantly more poorly than young adults on tasks requiring memory for associations but that age differences are relatively small when memory for individual components is tested. For example, Naveh-Benjamin et al. (2004) presented young and old participants with faces paired with names, with the task of trying to learn the names, the faces, and the associations between the name and the face in each pair. Three recognition tests were given. On the name test and the face test, participants were presented with either two names or two faces, respectively, and were asked to choose the stimulus that they had seen at study. The third test was an associative recognition test, in which subjects chose between two previously presented names that belonged with a given face or between two previously presented faces that belonged with a given name. Results, which can be seen in **Figure 9**, showed no age-related difference in name recognition and only a small age-related difference in face

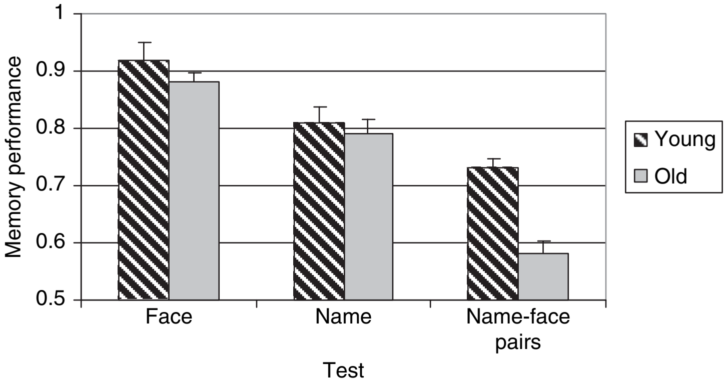

**Figure 9** Memory performance in recognition of faces, names, and name–face pairs, as a function of age group. From Naveh-Benjamin M, Guez J, Kilb A, and Reedy S (2004) The associative memory deficit of older adults: Further support using face-name associations. *Psychol. Aging* 19: 541–546. Copyright 2004 by the American Psychological Association.

recognition but a large age-related decline in the associative tests of names and faces. This associative deficit has been observed using various types of stimuli, including associations between Snodgrass drawings and their arbitrary colors (Chalfonte and Johnson, 1996; Mitchell, et al., 2000), pairings of words (Naveh-Benjamin, 2000, Experiment 2; Castel and Craik, 2003; Light et al., 2004; Healy et al., 2005), pairings between words and their fonts (Naveh-Benjamin, 2000, Experiment 3), and pairings of pictures (Naveh-Benjamin et al., 2003).

This ADH can accommodate several of the results reviewed earlier. For example, implicit memory should not be affected as much by aging as explicit memory, as it requires to a much lesser degree explicit retrieval processes involved in recovering information about binding of elements in an episode. In addition, semantic memory should be affected to a lesser degree than episodic memory because it does not require the specific binding of information to a place and time. There are also some indications that part of the deficit is due to the inability of older adults to spontaneously produce and efficiently use adequate associative strategies to bind together information. Studies inducing the use of a connective strategy (a sentence or an interactive mental image) during encoding and during retrieval have shown an increase in older adults' performance on memory tasks requiring associative information, in some cases more so than younger adults (Naveh-Benjamin et al., 2005; Naveh-Benjamin et al., 2007).

#### 2.41.3.2.3 *Recollection deficit approach*

This hypothesis, for which empirical results were cited earlier in this chapter (e.g., Jacoby et al., 1996; Jacoby and Hay, 1998), claims that older adults' memory deficit is largely a result of their inability during retrieval to access the details of an episode, resulting in recollection failure. According to this suggestion, the ability to remember via familiarity – for example, to notice that something was already presented before, without remembering detailed information about the event – is left mostly intact in old age. This hypothesis (e.g., Jacoby, 1999) is supported by many studies that used the process dissociation paradigm or the R/K procedure, which were reviewed earlier in the chapter. The hypothesis can explain the relatively adequate performance of older adults in implicit memory tasks and in those requiring semantic memory. In both cases, no detailed conscious recollection of the original event is required. Likewise, source memory, which requires recollection of detailed information, is especially prone to the effects of age.

### 2.41.3.3 An Integrated View

The above-suggested source-contextual, associative-binding, and recollection deficit hypotheses seem to have different emphases. For example, the source-contextual and the associative-binding approaches emphasize failure more at the encoding phase, whereas the recollection perspective deals more with processes that happen at retrieval. In addition, the paradigms used by each of the approaches are quite different. Nevertheless, there are some fundamental similarities between the three approaches. The common assumption held by all three is that age-related memory declines are caused by a lack of efficient episodic encoding and retrieval of detailed bound information. Difficulty in encoding specific features of an episode and in establishing associations among those features may result in, for example, the inability of an older adult to recall the name of a new acquaintance upon encountering that person, despite the fact that he or she may look familiar. This difficulty may be caused by a failure of conscious recollection of the contextual details or circumstances (e.g., time and place) regarding the original encounter with this person and/or to the fact that this person and not someone else they met on the same occasion is named, for example, George. The poor encoding of source-contextual features, as well as a reduced ability to bind together the different features of the event and its contextual elements, will increase the chances of a conscious recollection failure of the detailed information at the retrieval phase. In this sense, the three approaches are somewhat similar and complement each other.

Such an integrated approach can explain several of the empirical lines of evidence for age-related memory changes reviewed earlier in this chapter. For example, the fact that semantic memory is held relatively intact during adulthood and old age could be a result of the encoding of contextual details and their recollection being crucial in episodic – but not in semantic – memory. This is because the multiple repetitions of facts in semantic memory increase their familiarity, which is relatively intact with age. Such an integrated view can also explain the relatively minor age-related decrements in implicit memory, since this system is based more on familiarity and fluency and does not require detailed encoding and binding of contextual details or the recollection of specific encoded features (e.g., Roediger, 1990; Schacter et al., 1993).

This integrated approach can also explain age-related changes in false memory. As we reviewed earlier in the chapter, older adults tend to show an increase in the retrieval of incorrect memories. This finding could be caused by an age-related reduction in the ability to bind together bits of information from the original event and to keep these bindings separate from information included in the postevent episode. If during retrieval, older adults cannot recollect the contextual details of the original event, they may integrate bits of later-learned information into their memory of the original event, mistaking, for example, a person viewed in a mugshot at a police station for the true culprit. Similarly, in the DRM paradigm of false memory, older adults tend to recall or recognize, more so than young, the critical lure – the related event that did not happen. According to the suggested view here, this may be a consequence of their inability to bind together the content words and the context – either external (presented) or internal (generated). When the critical word is later presented in a recognition test, the reduced ability of older adults to recall contextual features related to the critical and target words, coupled with feelings of familiarity, could lead to false recognition.

One potential task of future research on memory and aging is to test specific predictions based on this integrated approach. For example, it seems reasonable that the more features and their bindings involved in an event, the more difficult it would be for older adults to encode and bind together the features and to recollect them during retrieval. Furthermore, if some of the features, for example, the contextual elements, are common to the different episodes, this might result in a nondistinct contextual encoding that will make recollection by older adults more difficult later on (see Hunt and McDaniel, 1993, for a discussion of distinctiveness). On the other hand, if the features of each event are unique and distinctive from each other, older adults might be better able to bind together and to recall those features (e.g., Johnson et al., 1995; Degl'Innocenti and Backman, 1996).

Such a unified view can be incorporated with the depleted resources framework reviewed earlier to provide the following hypothesis: It may be that the lack of resources in older adults – for example, reduced attentional resources both at encoding and at retrieval (e.g., Anderson et al., 1998; Naveh-Benjamin et al., 2005) – could mediate the source/context/binding failure at encoding, as well as recollection failure at retrieval. This suggestion makes several assumptions. First, the encoding of contextual elements and the binding together of features is more effortful and requires more resources than the encoding of the focal elements and each feature separately (Troyer, et al., 1999; Castel and Craik, 2003; but see different results by Naveh-Benjamin, et al., 2003). Second, the retrieval and recollection of bound and contextually detailed information requires more attentional resources than that of contextually impoverished information (e.g., Troyer, et al., 1999). Future studies could assess this suggestion, for example, by measuring the attentional resources associated with different types of feature, context, and associative (feature-binding) encoding and retrieval.

## 2.41.4 Further Issues

### 2.41.4.1 Uniqueness of Age-Related Memory Changes in General Cognitive Decline

One question that has consequences for the interpretation of age-related differences in memory is whether these differences constitute unique declines in the memory system or whether they are just a manifestation of more general changes in cognition. One statistical control approach to studying this question was employed by Salthouse et al. (2002), who assessed performance of different age groups on several variables, some related to memory and others to other cognitive tasks. Salthouse et al. then looked at the variance accounted for by age in a given memory task while statistically controlling the variance in some of the other cognitive tasks. The results showed that the proportion of age-related variance in a free recall memory task declined from 30% to less than 20% after statistically controlling the variance in a block design task (taken from the WAIS III, Wechsler, 1997) and to less than 5% after statistically controlling the variance in performance on the digit symbol task (also taken from the WAIS III). Similar findings were shown by Siedlecki et al. (2005), who administered a battery of different cognitive tests to 330 adults between the ages of 18 and 89, along with several tests of source memory. Using structural equation modeling, the researchers found no indication of a unique age-related variance on source memory only. Similar results have been obtained for other episodic memory measures (e.g., Salthouse et al., 2006). Such findings imply that age-related effects on memory measures and on other cognitive variables are not independent of each other.

These results raise interesting questions regarding the different approaches to studying the effects of age on memory and their respective outcomes and contributions. One approach, discussed throughout most of this chapter, is experimental, assessing the effects of specific manipulations on the memory performance of young and older adults. This approach reveals a variety of differential effects of aging on memory. The approach discussed in the previous paragraph, based on psychometric studies of individual differences, looks simultaneously at relationships between age and several memory and cognitive indices and often shows that the effects of age on memory are not unique but are shared with other cognitive variables. It seems that the research on age-related differences in memory would benefit from the integration of both approaches in order to provide a better understanding of the absolute changes in different tasks on one hand and the degree to which differences in one condition are statistically independent from differences in another condition.

### 2.41.4.2 Positive Modulators of Older Adults' Episodic Memory Performance

Even though older adults seem to show poorer episodic memory than younger adults, there are nevertheless variables that seem to positively modulate older adults' episodic memory. For example, studies indicate that older adults tend to remember emotional material relatively well, often performing just as well as younger adults on positively valenced material. This has been found both in working memory (e.g., Mikels et al., 2005) and in long-term episodic memory (see, e.g., Carstensen et al., 2006, for a review). The suggestion raised (e.g., Carstensen et al., 1999) is that socioemotional regulation becomes more important as people age, changing their motivation, which then leads to successful encoding and retrieval of emotional information, especially when it is positive. Such changes in priorities also result in the tendency to remember autobiographical events more positively as people age (see, e.g., Mather and Carstensen, 2005 for a review).

In addition, although older adults are relatively impaired in memory for verbatim information, they remember well the gist of information and add their interpretation to it, creating a richer narrative. For example, studies regarding memory of information presented in stories indicate that older adults do well on remembering the underlying messages and gist of the stories (e.g., Adams et al., 1997; Stine-Morrow et al., 2004).

Finally, time of day seems to make a difference in memory performance, with older adults doing relatively well when they are tested in their 'prime' time – in the morning. Yoon et al. (1999) administered the Morningness-Eveningness Questionnaire (MEQ) to over 2000 older and younger adults and report that approximately 75% of the older sample, but less than 10% of the young sample, could be classified as morning types; conversely, very few older adults and nearly 40% of younger adults were evening types. Interestingly, May et al. (2005) found that evening-type younger adults and morning-type older adults performed better on an explicit memory task – but worse on an implicit task – during their peak hours. Furthermore, it has been suggested that different circadian patterns in young and old can artificially enhance age-related declines in memory (May et al., 1993). This occurs because participants are often tested in the afternoon (the convenient time for the young research assistants), when younger adults, by their arousal patterns, are performing at their highest levels. When testing is done in the morning, older adults often perform quite well, for example, on working memory tasks (e.g., West et al., 2002).

#### 2.41.4.3 Negative Modulators of Older Adults' Episodic Memory Performance

There are several other factors that may have inflated some of the reviewed age-related declines in episodic memory. For example, older adults might not be as motivated as younger students to perform at their best in laboratory situations. The materials used in many episodic memory tasks (such as lists of words) may seem contrived and of little relevance to older adults, therefore decreasing their motivation to do well (e.g., Henry et al., 2004). This may be one reason why they perform relatively well on semantic memory tasks, which by their nature employ more ecologically valid, relevant, and interesting materials.

Another mediating factor might be a lack of recent practice in testing situations and the anxiety produced by such testing in the laboratory. Older adults usually do not frequently encounter explicit testing situations in their lives, as do younger adults, who are often university students and who take tests very frequently. This lack of recent testing practice may put older adults at a disadvantage. In addition, it may create higher anxiety in older adults (but see Birren, 1964), which in turn is known to reduce cognitive performance (Wetherell et al., 2002). Although this factor may not straightforwardly explain interaction effects – cases where older adults are doing worse on one episodic task than on another – it can increase the overall differences observed between young and old. An intriguing demonstration of the potentially mediating effect of anxiety on age-related differences in memory is a study by Rahhal et al. (2001), who found that age differences in recognition memory were eliminated when the terms 'memory' and 'testing' were completely omitted from task instructions. One interpretation of these results is that the latter condition did not induce the usual level of anxiety in older adults, which, in turn, helped them to perform well. Alternatively, knowing that they are in a memory experiment might evoke older adults' negative stereotypes about memory and aging, which might negatively affect their performance. These stereotypes are presumably not induced when the task does not seem related to memory.

Finally, as we mentioned at the outset, most of the studies reviewed in this chapter used a cross-sectional design and, as such, might have been affected by various factors, most notably, cohort effects (e.g., Schaie, 2000). It is important to note that, when data on the same memory phenomenon are collected using both cross-sectional and longitudinal designs, age-related differences tend to be smaller in longitudinal studies, with peak performance later in life (e.g., Rönnlund et al., 2005). Thus, the patterns of decline reported in this chapter, which are mostly based on cross-sectional designs, may be an overestimation of actual age-related declines in memory.

## 2.41.5 Summary

The evidence reviewed in this chapter indicates interesting differential patterns of development in adulthood and old age that depend on different factors, including the task and the memory type involved. Whereas implicit and semantic memory show little decline with age, tasks based on episodic memory, especially those that require the encoding and the explicit retrieval of detailed bound information about a given event, show appreciable decline. It seems that as long as the task does not require remembering specific details, and as long as performance can be supported by previous knowledge or environmental cues, older adults do quite well.

Several theoretical accounts at different levels of generality have been suggested to explain the age-related patterns of memory development, and especially of episodic memory deficits. A unified approach characterizes old age as being associated with a lack of detailed encoding and binding together of both contextual and focal components of an episode, coupled with difficulty in accessing and recollecting these details during retrieval, possibly because of the high demand of these processes for attentional resources. Such an approach may serve as a departure point to further investigate these important issues using both the manipulative and the psychometric approaches to advance our knowledge of age-related changes in memory.

# 2.42 Superior Memory of Mnemonists and Experts in Various Domains

**K. Anders Ericsson**, Florida State University, Tallahassee, FL, USA

## 2.42.1 Superior Memory of Mnemonists and Experts in Various Domains

One of the most striking individual differences between people concerns their ability to recall information and everyday events. Some people seem to remember an exceptional amount of details of past events – much more than others who also were present and thus presumably had a similar experience. It is difficult to validate any superior memory accounts because there are rarely objective records, such as video recordings. As a consequence, the recall of people with reputation for having a good memory is often simply accepted, even when other people cannot recall the same information. There are, however, bodies of cultural and professional knowledge, which are publicly accessible in the form of periodicals, books, and encyclopedias. Memory for this type of knowledge is measured regularly by schools, universities, and professional licensing boards. Based on such tests, we know that experts have a greater body of knowledge about their domain of expertise than other individuals. These tests also show substantial individual differences between experts who have the same educational background and thus similar opportunities to acquire the same knowledge. How is it possible to explain these large differences in memory and accumulated knowledge?

Ideas of individual differences in memory depend on one's general conception of the process of memory formation. Plato viewed the formation of memories as akin to the impressions made by a signet ring on a wax tablet (Yates, 1966). Due to differences in the hardness and quality of the wax, some people would be able to make sharp impressions (accurate memory), whereas others were diffuse and rough (poor memory). This account matches many people's introspective impressions that their memories are clear and vivid and sometimes even approach the vividness of the original experiences. Some people are even believed to possess the ability to store completely accurate visual images (photographic memory) (La Brecque, 1972). From this conception of individual differences in memory we would expect a superiority of memory that would generalize across all sorts of domains.

There are two types of evidence on superior memory. One type concerns the domain-specific superiority of experts to remember new information and experiences in their domain of expertise. Some elite athletes can, after a sports event, discuss the play-by-play action. Expert chess players can readily recall details of chess positions from their matches in recent tournaments. There are even numerous anecdotes that were collected as evidence of an unusual ability to store presented information rapidly in their domain of specialization. For example, Mozart was supposed to be able to reproduce a presented piece of music after hearing it a single time. Although these feats could be explained by a general superiority of memory, it is rarely supported by reliable evidence. Most experts' strikingly superior memory appears to be limited to information in their domain of expertise, with, if anything, poorer memory for other information and particularly more mundane material, such as information about people, appointments, and other everyday issues. This preoccupation with some domain does not preclude their having a generally superior memory when they attend to information with the intent to commit it to memory. Scientists realized that it is necessary to find experts who are willing to be tested to assess whether they have fundamentally different and generally superior memories. Their controlled memory studies have found that the memory advantage of experts was surprisingly specific to the domain of expertise, as will be described in more detail later in this entry.

The other type of evidence for superior memory is found when some individuals are able to memorize seemingly meaningless information, such as names of people, lists of digits and unrelated words, and verbatim text in an unfamiliar foreign language. Superior memory for this type of seemingly meaningless information was initially assumed to be mediated by some superior general capacity to store information in memory that would generalize to all types of materials. Laboratory studies testing the memory of people with this type of superior memory found that any time the performance was exceptional – outside the range of random sample of adults, then the performance was limited to a small number of types of material, such as digits, letters, and playing cards. Furthermore, these individuals were found to have engaged in extended memory training using various mnemonic memory strategies that allow seemingly meaningless information to be encoded with meaningful associates already in memory. For example, 9631492177 could be encoded as [1]963 (death of Kennedy) 1492 (Columbus) and 177[6] (American Revolution). In sum, recent research (Ericsson, 2003; Wilding and Valentine, 2006) has rejected the hypothesis of an exceptional innate memory capacity that generalizes across materials and has demonstrated that exceptionally superior memory is limited to some particular types of materials and domains of expertise and reflects the result of acquired skills and knowledge relevant to each specific domain.

## 2.42.2 Brief Historical Background

Sir Francis Galton (1883) innovated the method of interviewing many people by sending out a list of questions about mental imagery—said to be the first questionnaire. He was interested in how the memory and imagery of exceptional people, such as scientists, judges, and other famous people of his time, differed from regular people. He had been intrigued by reports of photographic memory and asked questions of the acuity of specific memories, such as the clarity and brightness of their memory for specific things such as their breakfast table. He found striking individual differences in the clarity or vividness, but no clear superiority of the eminent scientists: for example, Darwin reported having weak visual images. Now over a hundred years later, it is still unclear what these large individual differences in reported vividness of memory images reflect in objective performance, as will be discussed later in this section.

A few years later Ebbinghaus (1885/1964) published his seminal work on laboratory studies of memory, where he argued that individual differences in memory between adults in everyday life were primarily caused by differences between individuals' knowledge and prior experience. He consequently suggested that psychologists should present unfamiliar materials, such as nonsense syllables, under controlled conditions in the laboratory and then assess the number of repetitions necessary for successful reproduction. Ebbinghaus designed his studies so he could be a participant and based on the data from a single participant (himself) to uncover the general laws of human associative memory. All of his findings have been replicated thousands of times with large groups of naive participants (Slamecka, 1985a,b). One of the findings relevant to superior memory was that Ebbinghaus found that memory for nonsense syllables is much worse than memory for typical information encountered in everyday life – in fact, he needed ten times more time to memorize lists of nonsense syllables compared to the poems with the same number of syllables. Other contemporary psychologists, most notably Alfred Binet (1894), raised doubts about whether memory for nonsense syllables was mediated by the same types of processes as memory in everyday and exceptional memory by mental calculators and chess players.

Binet's (1893/1966) report on chess players' 'mnemonic virtuosity' was arguably the first published study on memory and expertise. Binet interviewed chess players about their ability to play chess blindfolded without seeing a chessboard. The ability required to maintain chess position in memory during blindfolded play did not appear to reflect a basic memory capacity to store complex visual images, but a deeper understanding of the structure of chess. Hence, to play chess blindfolded requires knowledge and skill to understand the reasoning that led to each chess move. It is the ability to discover the meaningful connections between these ideas that provides the basis for the superior memory and the ability to maintain a chess position in memory. However, Binet found that the verbal descriptions of the visual images of the mental chess positions differed enormously between blindfolded chess players. Some claimed to see the board as clearly as if it was shown perceptually with all the details and even shadows. Other chess players reported seeing no visual images during blindfolded play and claimed to rely on abstract characteristics of the chess position. Unfortunately, there was no independent evidence to support or question the validity of these diverse introspective reports. Binet (1893/1966) also studied mental calculators, who could multiply large numbers mentally, and other people with exceptional memory. He was able to show that memorization of a matrix of digits did not involve forming a visual image because subsequent retrieval was only rapid for retrieval of digits presented in the same row of the matrix (Ericsson and Chase, 1982).

Subsequent research was guided by the hypothesis that superior memory was mediated by innate talent and general basic capacities. In the early part of the twentieth century Djakow et al. (1927) measured the basic abilities of world-class chess players and compared their test performance to the average of a large sample of nonchess players. Contrary to the assumed importance of natural gifts, the international players were superior only on a single test – a test involving memory for chess positions. A few decades later de Groot (1946/1978) found that when chess players were instructed to select the best move for a briefly presented chess position, their ability to recall the positions of the chess pieces was closely related to chess skill. International chess masters were able to recall virtually all the pieces on the chessboard, whereas beginners could recall only a few pieces. Taken together, these two findings suggest that exceptional memory of chess masters is constrained to superior memory of meaningful chess positions – a claim that has been validated by subsequent research in the laboratory.

In parallel with the studies of chess experts' exceptional memory, several researchers conducted case studies of individuals with exceptional memory (for reviews, see Wilding and Valentine, 1997, 2006). The most influential series of studies was conducted by Luria (1968) on a newspaper reporter referred to as Subject S – an abbreviation for the last name of the participant, namely, Shereshevski. Luria (1968) found that S could memorize a wide range of materials, such as list of nonsense syllables and poetry in a foreign language, by forming eidetic images of meaningful associations. For example, to memorize the first few words in the first line of Dante's *The Divine Comedy*, namely, "Nel mezzo del cammin di nostre vita," S reported that he associated **Nel** by thinking, "I was paying my membership dues when there in the corridor, I caught sight of the ballerina **Nel**'skaya" (Luria, 1968: 47), and then associating mezzo with an image in the same context and then associating **del** by thinking, "There is a pack of **Del**i cigarettes near them' and so on" (Luria, 1968: 47). Although Luria attributed S's exceptional memory to the vividness of his eidetic memory, subsequent researchers argue that S was using a variant of the ancient method of loci (Yates, 1966), where presented information, such as a text in a foreign language, is recoded into meaningful images (see preceding example), which in turn are associated to familiar locations, such as the concert hall and adjacent streets and buildings. Skilled memory experts (mnemonists) who use the method of loci have acquired long lists of journeys of locations, such as locations encountered with visiting one's own house – the mailbox, driveway, garage door, garage, door at main entrance, and so on. Most importantly, Luria (1968) found that S was able to recall matrices of digits without the need to retrieve meaningful associations and was able to commit a matrix of 50 digits to memory in only 3 min. Later, S was able to recall the digits in an arbitrary manner, in columns and zigzag patterns, which led Luria (1968) to infer that digits were directly available as a visual image. Other studies of exceptional individuals, such as the mathematics professor Rückle (Müller, 1911) and the Japanese mnemonist Isihara (Susukita, 1933), showed similar findings and found that mnemonic encoding methods played a central role in their superior performance. Scientists also examined the memories of individuals who were able to make mathematical calculations mentally (mental calculators), such as the Polish mental calculator Dr. Finkelstein (Bousfield and Barry, 1933) and the mathematics professor Aiken (Hunter, 1962, 1977), and were able to establish both calculation methods and exceptional memory performances for numbers.

These case studies of exceptional memory relied extensively on the individuals' introspective descriptions of their experiences during interviews and the characteristics of their images and, in particular, their vividness. Other contemporary researchers studied children with eidetic imagery. These children reported having detailed visual images of presented complex stimuli even after they had been removed from view. Many researchers, including Luria (1968), argued that individuals with exceptional memory must be relying on a similar basic capacity to form and maintain visual images. After decades of research on describing the reports of eidetic imagery, researchers started measuring the memory performance of eidetic and normal children. To everyone's surprise there was no difference in memory performance between children who reported seeing an image of the presented stimuli and other children (Haber, 1979). More recently, researchers have studied ratings of the reported vividness of memory for an experience and the level of accurate recall of presented pictures (Richardson, 1988; McKelvie, 1995). Most surprisingly, the amount of recall was not found to differ between people who rated their memory image as very vivid (almost as clear as still seeing the picture) and people who reported having little visual image of the stimulus at all. These findings supported the opinions of many experimental psychologists, who held that introspective judgments about experience were frequently misleading and sometimes even inconsistent with measures of performance.

A scientific analysis of exceptional memory would need to be based on reliably superior performance that could be repeatedly reproduced in the laboratory. Similarly, introspective descriptions by individuals are not acceptable as valid data and should be discarded in favor of concurrent verbal reports of participants' thinking (Ericsson and Simon, 1993). These reports can be analyzed and explained as are other types of data on cognitive processes (e.g., eye fixations, latencies, and recordings of brain activity).

The following sections of this chapter will discuss experimental studies of exceptional memory performance that assess its scope and structure, the development of exceptional memory ability, the structure of superior memory of domain experts, and some recent developments in study of the pattern of brain activation during exceptional memory performance.

## 2.42.3 Experimental Studies of Exceptional Memory: Generalizability and Mediating Mechanisms

When somebody demonstrates exceptional memory for a list of digits or a chess position, it is only natural that one would expect that superior memory would generalize to any aspect of memory. It is not possible to assess the generalizability of the exceptional memory simply by observing the individuals' behavior involved in committing particular types of information of the person's own choosing under everyday life conditions. It is necessary to get their consent to participate in experiments where possible to vary the presented types of materials and conditions of memory. Some of the early investigations of exceptional memory showed that the formation of memory was not instantaneous, and although much faster than required by regular adults, it took considerable time. Even more important, exceptional memory is primarily demonstrated for seemingly meaningless or arbitrary types of materials, such as list of digits, nonsense syllables, and texts in a foreign language. In fact, some of the early laboratory studies showed that the dramatically superior memory performance was often limited to lists of a certain types of materials, such as lists of digits and words. For example, the Japanese memory expert Isahara did not show exceptional memory for presented color patches (Susukita and Heindl, 1935). In his review of mental calculators, Smith (1983) found that their superior memory was invariably limited to numbers and digits. The most influential study demonstrating the domain-specific nature of mechanisms involved in exceptional memory was conducted by Bill Chase and Herb Simon (Chase and Simon, 1973) on chess players' memory for chess configurations in the 1970s.

## 2.42.4 The Role of Meaningful Associations in Superior Memory Performance

In their pioneering studies Chase and Simon (1973) replicated the superior memory for chess positions by chess experts found previously by Djakow et al. (1927) and de Groot (1946/1978). Chess players ranging from a beginner to an international master were shown a position from an actual chess game (such as the one illustrated in **Figure 1(a)**) for a brief time (normally 5 s) and then asked to recall the locations of all the chess pieces. The ability to recall increased as a function of chess skill. Beginners at chess were able to recall the correct location of about four pieces, whereas international-level players recalled virtually all of the more than 20 pieces.

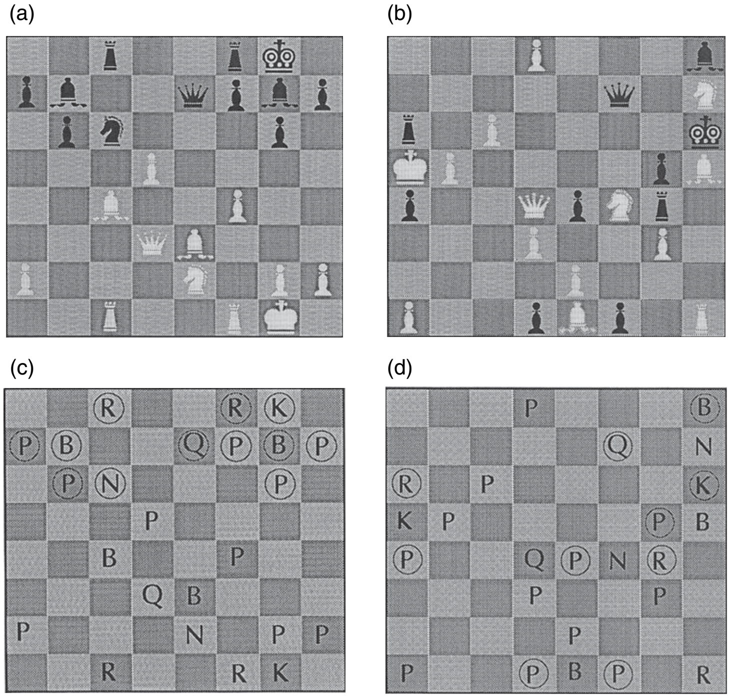

**Figure 1** Standard diagrams of an actual chess position (a) and a chessboard with randomly arranged pieces (b). Nonstandard representations of the same information using the first letter of the names of pieces are shown in (c) and (d).

To rule out that the superior memory of chess experts reflects a general superior ability to store any kind of visual information, Chase and Simon (1973) had chess players recall chessboards with randomly placed pieces (as illustrated in **Figure 1(b)**). With briefly presented random chessboards, players at all levels of skill had a similar poor recall performance and were able to recall the correct location of only about four pieces – a performance comparable with that of chess beginners for actual positions from chess games. Further, Chase and Simon (1973) showed that when an actual chess position was shown using an unfamiliar notation (see **Figure 1(c)** for an encoding of the meaningful positions and **Figure 1(d)** for the random positions), the chess expert was able to display a similar level of superior memory performance after a brief period of adjustment. These results imply that the superior memory of chess experts is not photographic and depends on seeing arrangements of chess pieces that can be encoded using associations to the experts' extensive knowledge of chess. Since Chase and Simon's classic study, investigators have replicated these findings for chess and found a slight yet reliable advantage of chess experts to recall more chess pieces even from random chess configurations (Gobet and Charness, 2006). Numerous other studies have also shown that level of expertise is related to superior memory performance for representative stimuli in the associated domain, such as computer programming, basketball, and dance, and that this superiority is mediated by increased knowledge and domain-specific skills (for a review, see Ericsson et al., 2000).

Unless one has the knowledge of the expert, it is difficult – indeed, impossible – to grasp the meaningful relations between chess pieces perceived by the expert in **Figure 1**(a) and **1(c)**. If, on the other hand, the availability of knowledge providing meaning to a stimulus is critical to superior memory, it should be possible to demonstrate the same effect in a domain where all adults are proficient, such as language. Human adults are able to recall verbatim meaningful sentences of 20 or more words after a brief presentation (Chase and Ericsson, 1982). An example of such a sentence would be: The woman in front of him was eating peanuts that smelled so good that he could barely contain his hunger. If the words of the sentence are randomly rearranged (analogous to Chase and Simon's procedure for generating random chessboards), accurate verbatim recall drops to around six words. An example of a random rearrangement of the preceding sentence would be: Was smelled front that his the peanuts he good hunger eating barely woman of so in could that him contain. For random lists of words, the recall of subjects is limited by the small number of words they can keep rehearsing, and once they stop rehearsal, the words are quickly forgotten. In contrast, once meaningful sentences are understood, their meaning is well retained in long-term memory. For example, during normal comprehension of a text the essential information in each sentence is efficiently stored in memory so it can be integrated with related information presented later in the text (Ericsson and Kintsch, 1995).

Stimuli from an unfamiliar domain of expertise, such as diagrams of chess positions and medical diagnoses, are often about as meaningless to most adults as random lists of words and digits. Studies described how people with exceptional memory for meaningless information actively sought out meaningful associations for the meaningless material, such as Subject S's encoding of the words of the Italian poem and remembering digits by noticing familiar dates, like 1945 – the year of the end of World War II. Individuals exhibiting truly exceptional memory performance for numbers, names, and pictures have been found to rely on some kind of mnemonics, relying on associations with previous knowledge, patterns, and acquired cognitive structures (Wilding and Valentine, 1997, 2006). There was always a question of whether individuals with exceptional memory were innately different and special or whether ordinary adults would be able to acquire exceptional memory through training.

## 2.42.5 Acquisition of Exceptional Memory through Practice and Training

The first study to trace the development of exceptional memory from average performance to the best memory performance in the world (in some memory tasks) was conducted in a training study by Chase and Ericsson (1981, 1982; Ericsson et al., 1980). We studied a college student (SF), whose initial immediate memory for rapidly presented digits was around 7, in correspondence with the typical average (Miller, 1956), but he eventually acquired exceptional performance for immediate memory and after 200 hours of practice was able to recall over 80 digits in the digit-span task. During this extended training period, we monitored any changes in SF's cognitive processes by having him give retrospective reports on his thought processes after most memory trials (this methodology is qualitatively different from the accounts given in interviews reported in the introduction of this article (cf. Ericsson and Simon, 1993). As his memory performance started to increase, he reported segmenting the presented lists into three-digit groups and whenever possible encoded them as running times for various races, because SF was an avid cross-country runner. For example, SF would encode 358 as a very fast mile time, 3 min and 58 s, just below the 4-min mile. The central question concerning any type of verbal reports is whether we can trust the validity of these reports and whether the ability to generate mnemonic running-time encodings influences memory.

To address that issue, we designed an experiment to test the effects of mnemonic encodings and presented SF with special types of lists of constrained digits. In addition to the list of random digits, we presented other lists that were constructed to contain only three-digit groups that could not be encoded as running times, such as 364 as 3 min and 64 s, in a list (364 895 481...). As predicted, his performance decreased reliably. In another experiment, we designed digit sequences where all three-digit groups could be encoded as running times (412 637 524 ...) with a reliable increase in his associated performance. In over a dozen specially designed experiments, it was possible to validate several aspects of SF's acquired memory skill (Chase and Ericsson, 1981, 1982; Ericsson, 1985). A similar methodology was applied to two other college students, who both attained exceptional memory after 50–200 h of training. In fact, one of the participants reached a digit span of over 100 digits (Richman et al., 1995). Other investigators, such as Wenger and Payne (1995), have also relied on protocol analysis and other process tracing data to assess the mechanisms of individuals who increased their memory performance dramatically with practice on a list learning task.

More generally, this method has been extended to any individual with exceptional memory performance. During the first step, the exceptional individuals are given memory tasks where they could exhibit their exceptional performance while giving concurrent and/or retrospective verbal reports. These reports are then analyzed to identify the mediating encoding and retrieval mechanisms of each exceptional individual. The validity of these accounts is then evaluated experimentally by presenting each individual with specially designed memory tasks that would predictably reduce that individuals' memory performance in a decisive manner (Ericsson, 1985; Wilding and Valentine, 1997). With this methodology, verbal reported mechanisms of superior performance have been validated with designed experiments in a wide range of domains, such as a waiter's superior memory for dinner orders (Ericsson and Polson, 1988), mental calculators (Chase and Ericsson, 1982), and other individuals with exceptional memory performance (Ericsson et al., 2004; Thompson et al., 1993). Several studies even demonstrated impressive memory improvements in large samples of participants after extended practice with instructions to use mnemonic encodings (Kliegl et al., 1987; Kliegl et al., 1989; Higbee, 1997).

## 2.42.6 Superior Memory of Experts and Their Superior Performance on Representative Tasks

Memory experts have been found to improve their memory performance by acquiring mnemonic techniques through extended practice. In contrast, chess experts and medical doctors attain superior memory for representative stimuli from the domain without training their memory deliberately. The primary goal for all experts is to excel at the representative tasks in their particular domain of expertise. For example, chess experts need to find the best moves to win chess matches, and medical experts have to diagnose sick patients to give them the best treatment. Their superior memory ability must thus be an indirect consequence of their improved performance on representative tasks (Vicente and Wang, 1998). Furthermore, experts appear to store task-relevant information in memory when they normally perform representative tasks in their domain, because if they are unexpectedly asked to recall information about a performed task, their memory is typically much superior to that of less-skilled individuals. In fact, experts' incidental memory of the relevant information is frequently so good that instructing them to intentionally memorize the information does not reliably improve their memory. For example, when chess experts analyze a position to find the best move, their memory of the position is just as good whether they were informed about an upcoming memory test or not. As part of performing the representative task of selecting the best move, the experts encode the important features of the presented information and store them in accessible form in memory. In contrast, when subjects, after training based on mnemonics and knowledge unrelated to chess, attain a recall performance comparable with that of the chess experts, they still lack the ability to extract the information important for selecting the best move. Hence, the remarkable characteristic of expert memory is not just the amount recalled, which can often be matched by training, but the rapid extraction and storage of important patterns and relevant information that allows the experts to perform better the representative task, such as selecting moves in chess (Ericsson, 2006a,b).

An analysis of expert performance shows that it is not sufficient to have merely stored the knowledge in memory; it is also critical that relevant knowledge is well organized and can be efficiently retrieved when it is relevant to the ongoing processes. In fact, the principal challenge of expertise is to acquire and organize the vast body of domain knowledge (Chi et al., 1981; Chi, 2006) such that all relevant prior knowledge can be immediately accessed to guide action in encountered situations. For example, with the superior organization of knowledge, a chess expert can rapidly perceive a promising move, or a medical expert can rapidly notice an inconsistency in a suggested diagnosis.

Efficient and reliable storage of relevant information in memory is especially important to experts when they engage in planning and complex reasoning that mediate their superior performance. During planning, experts have to mentally compare many alternative sequences of actions, which produces a great deal of information in working memory. Consequently, beginning chess players do not generate long plans, and it takes years of chess study before chess experts are able to plan long sequences of future moves reliably (Charness, 1989; Gobet and Charness, 2006). Chess masters eventually improve their memory skills for planning so much that they are even able to play chess without seeing the chessboard (blindfold chess), thus having to represent the locations of all the pieces on the board during the entire game in their mind. Analyses of the superior ability to plan suggest that experts acquire memory skills, which allow them to rely on long-term memory for storage of generated information (Ericsson and Kintsch, 1995). Recent research on expertise is making it increasingly clear that the vast knowledge of experts has to be well organized and supplemented with special memory skills so as to support memory-demanding planning, design, and reasoning.

Recent research has revealed the complex and intricate structure of expert performance and its associated memory skills. These skills are not attained automatically with experience but require the engagement in deliberate practice, typically designed by teachers. Even the most talented individuals have spent around 10 years of intense preparation before attaining an international level of performance in many domains, such as sports, chess, and arts (Ericsson, 2006b).

## 2.42.7 Research on Brain Structure and Activation Associated with Superior Memory Performance

Do the brains of people with exceptional memory differ in their anatomical features or their pattern of activation while exhibiting their superior memory performance? It is difficult to determine whether the brain of a single individual with exceptional memory differs from those of other people with similar gender, age, education, and ethnic background. Differences in the anatomical structure of brains exhibiting exceptional memory compared to a control sample have been found for taxi drivers in London, who have spent several years before they have successfully memorized the map of London with its massive number of streets, hotels, and significant landmarks (Maguire et al., 2003a). Most interestingly, the differences in the taxi drivers' hippocampus appear to be a consequence of the extended initial memorization of the London map as well as the daily work as a cab driver, rather than any innate differences.

More recently, Maguire et al. (2003b) examined the brains of ten of the world's foremost memory performers and compared them to control subjects with matched spatial ability and intelligence. They found no systematic anatomical differences between the two groups. This study also recorded the brain activity (functional magnetic resonance imaging) of both groups of participants while they were engaged in memorizing different types of stimuli for which the memory expert either exhibited clearly superior memory, namely three-digit numbers; intermediate superiority, namely faces; or no superior memory, namely snow crystals. After completing the memory tests, the participants gave detailed descriptions of their encoding strategies during the memorization. All of the memory performers reported using previously acquired techniques for generating associations, such as mnemonics, to make the presented information more memorable. All but one of the memory performers reported using the method of loci. In sharp contrast, none of the control group reported using any of the standard mnemonic techniques. These reported differences in strategies were sufficient to explain the regional differences in brain activation observed during memorization.

Recent brain-imaging studies of exceptional performers show that they activate brain regions that are different from those activated by control subjects. Consistent with accounts of memory experts, their differential brain activation is consistent with cognitive processes reflecting acquired memory skill. For example, exceptional mental calculators rely on storage in long-term memory (Presenti et al., 2001), and expert mental abacus calculators encode numbers in a manner qualitatively different from that of controls (Tanaka et al., 2002).

## 2.42.8 Conclusion and Future Directions

The emerging research on exceptional memory does not support the traditional views that only some uniquely gifted individuals endowed with an innately different memory system can attain exceptionally superior memory performance for particular types of information. Instead, the accumulated evidence supports the plasticity of the memory system in response to practice. The evidence supports the potential for ordinary healthy individuals to improve their memory performance with appropriate strategies and practice. However, future research is required to understand the specific processes of physiological adaptation of the brain and detailed modification of skills that occurs during extended skill acquisition. This research will need to combine cognitive and brain-imaging methods to study the process of skill acquisition and the changes required to reach exceptional levels of memory performance.

# 2.44 Eyewitness Identification

**J. S. Neuschatz**, The University of Alabama in Huntsville, Huntsville, AL, USA

**B. L. Cutler**, University of North Carolina at Charlotte, Charlotte, NC, USA

In the course of a criminal trial, eyewitness testimony can be very persuasive evidence (e.g., Wells et al., 1981; Fox and Walters, 1986; Cutler et al., 1990). Although the law makes no distinction between the relative weights juries should give to various types of evidence (United States v. Ramirez-Rodriguez, 1977), eyewitness evidence is most influential and salient to jurors even when paired with direct evidence that is inconsistent with the eyewitness identification (Fox and Walters, 1986; Cutler et al., 1990). Eyewitness identification of crime perpetrators is a common form of eyewitness testimony, forming the primary and sometimes the sole evidence in criminal cases. Eyewitness identification, however, is frequently inaccurate (Rattner, 1988; Wells, 1993; Wells and Bradfield, 1999; Wells et al., 1998).

Two independent phenomena combined in the late 1990s to create a perfect storm which resulted in a movement to reform the procedures by which eyewitness identifications are typically obtained, the lineup. First, research on eyewitness identification grew and matured throughout the 1980s and 1990s. By the late 1990s, effects of lineup instructions, filler selection, lineup presentation, and confidence assessment were fairly well understood based on a substantial body of research. Second, technical advances in DNA testing of identity and solid investigative work by the Innocence Project led to the growing realization that many innocent people had been convicted of serious felonies and had spent years in prison (Sheck et al., 2000). For example, the Innocence Project (groups of attorneys and law students operating out of law schools and legal clinics) has to date identified 200 cases of erroneous conviction. Mistaken identification is cited as the single leading cause of these erroneous convictions (Cutler and Penrod, 1995). Many of these erroneous conviction cases involve vivid, dramatic accounts of convicted felons who steadfastly maintained their innocence and traumatized and sincere eyewitnesses who with equal vehemence stood by their identifications (e.g., Junkin and Bloodsworth, 2004; Transcript of Penny Beernsten's speech, 2006; Transcript of Jennifer

Thompson Cannino's speech, 2006). Because eyewitness testimony is so prevalent and because such testimony can have dire consequences for the defendant, it has inspired volumes of research.

Given the voluminous research on eyewitness identification, an exhaustive review is untenable, even as a handbook chapter. Instead, we have adopted the following, more achievable objectives for this chapter. First, we provide an overview of the breadth of research on eyewitness memory. Second, we select two subsets of this research for more in-depth review: Estimator and system variables affecting eyewitness identification. Within each subset we review a sample of specific factors that have well-established effects on identification accuracy. For each of these variables, we provide a description of the effect on eyewitness identification accuracy and review a sample experiment to illustrate the science behind the research conclusions. We then summarize the state of knowledge regarding the factor, usually based on a published meta-analysis. We describe existing theory or at least speculation concerning the causes of the underlying effects of the factor. Following each subset of variables we discuss the practical implications of the knowledge gleaned from the research and how this knowledge influences actual policy and practices within the criminal justice system.

As mentioned, we divide this chapter into two subsets, estimator and system variables, a dichotomy that was developed nearly 30 years ago by Gary Wells (1978) and that continues to serve as a useful and oft-cited guiding principle today. Estimator variables are variables over which the police and criminal justice system exert no control. Many of these variables are those associated with the encoding stage of memory, such as the length of time the culprit is in view, whether the culprit wears a disguise or covers his face, whether the culprit has a gun, and the amount of stress experienced by the witness. They are called estimator variables because their main utility is to be used to estimate the reliability of an eyewitness's identification. System variables, by contrast, are under the control of the judicial system. These variables can therefore be used to enhance the likelihood of correct identification or minimize the likelihood of false identification. Examples of system variables include the instructions given to the eyewitness prior to a lineup, the selection of fillers for the lineup, and the manner in which the lineup is presented to the eyewitness. Research on estimator and system variables contributes to our understanding of the myriad of factors influencing identification accuracy, and both sets of variables have led to practical applications.

## 2.44.1 Breadth of Research on Eyewitness Memory

In addition to the distinction between estimator and system (independent) variables, the research on eyewitness identification can also be divided into two general categories, identifiable by the primary dependent variables: eyewitness recall and eyewitness identification. The estimator-system variable distinction applies to both categories of dependent variables. With respect to eyewitness recall, examples of estimator variable research programs include the impact of misleading postevent information on eyewitness memory, the suggestibility of child witnesses, the conditions under which people form false memories, and factors affecting peoples' abilities to describe perpetrators and crimes. System variable research on eyewitness recall has focused on such issues as the development of interview practices that increase the amount of accurate information recalled by eyewitnesses (e.g., the cognitive interview), and interviewing techniques for minimizing errors in children's recall.

A list of estimator and system variables examined in eyewitness recall and identification is presented in **Table 1** (column 1), followed by the percentage of experts in the field that agree that phenomenon is reliable (column 2), descriptions of their general effects (column 3), citations to sample studies (column 4), and citations to review papers – meta-analyses if available (column 5). As one can see, the number and range of variables examined are substantial. Column 2 of **Table 1** is an interesting index and requires some explanation. Kassin and colleagues (2001) authored an article describing a study of the general acceptance of factors affecting eyewitness identification. Kassin et al. surveyed 64 eyewitness researchers (mainly cognitive and social psychologists who had authored published research on eyewitness memory) for their opinions about the extent to which the factors listed (and some not listed) are reliable enough to testify about in court. The primary purpose of this study was to empirically address a concern that frequently arises in courts when expert witnesses are proffered. Our purpose in including this information is to provide another

**Table 1** List of system and estimator variables with representative and review studies

| *Variables* | *Expert agreement*[a] | *Major results* | *Representative study* | *Review study* |
|---|---|---|---|---|
| Weapon focus | 87% | Reduced ID and description accuracy when weapon is present | Loftus et al., 1987 | Steblay, 1992 |
| Disguise | | Reduced ID accuracy with disguises and physical transformations | Cutler et al., 1987a, b | Cutler, 2006 |
| Stress | 60% | Extreme stress impairs ID accuracy | Morgan et al., 2004 | Deffenbacher et al., 2004 |
| Own-race bias | | Reduced ID with other-race than same-race identifications | Platz and Hosch, 1988 | Meissner and Brigham, 2001a |
| Exposure time | 81% | Longer viewing times increase identification accuracy | Valentine et al., 2003 | Shapiro and Penrod, 1986 |
| Speed of identification | 40% | Faster identifications lead to more accurate identifications | Sporer et al., 1993 | Weber et al., 2004 |
| Unconscious transference | 81% | False identification of person who seems familiar because he/she was encountered near scene of crime | Read et al., 1990a | Ross et al., 1990 |
| Misleading postevent information | 94% | Reduces witness accuracy | Loftus et al., 1978 | Loftus, 1996 |
| Retention interval | 83% | Longer retention intervals (>1 week) lead to less accurate identifications | Shepherd, 1983 | Shapiro and Penrod, 1986 |
| Confidence malleability | 95% | Witness confidence is affected by social factors unrelated to accuracy | Bradfield and Wells, 2000 | Leippe, 2006 |
| Confidence accuracy | 87% | Relationship strong only when choosers are considered | Cutler et al., 1987a | Sporer et al., 1995 |
| Alcohol intoxication | 90% | Alcohol impairs witness identification | Morgan et al., 2004 | Birnbaum and Parker, 1977 |
| Hypnotic suggestibility | 91% | Increases false reports | Karlin and Orne, 1996 | Lynn et al., 1997 |
| Hypnotic accuracy | 45% | Small increases in witness accuracy | Geiselman and Machlovitz, 1987 | Scheflin et al., 1999 |
| Witness age: children | 94% | Increases likelihood of false IDs in young witnesses | Pozullo and Lindsay, 1998 | Dickenson et al., 2005 |
| Witness age: adults | 50% | Increases likelihood of false IDs in old witnesses | Memon and Gabbert, 2003 | Mueller-Johnson and Ceci, 2004 |
| Verbal overshadowing | | Reduces identification accuracy | Schooler and Engslter-Schooler, 1990 | Meissner and Brigham, 2001b |
| Distinctiveness of culprit | 32% | Increases accuracy with distinctive faces | Vokey and Read, 1992 | Shapiro and Penrod, 1986 |
| Lineup instructions | 98% | Unbiased instructions lower false identifications from TA lineup with lowering accuracy from TP lineups | Malpass and Devine, 1981a | Steblay, 1997 |
| Double-blind lineups | | Increase lineup identification accuracy | Haw and Fisher, 2004 | Russano et al., 2006 |
| Foil selection | 71% | Match-to-description strategies increase ID accuracy | Luus and Wells, 1991 | Wells and Olson, 2003 |
| Lineup presentations | 81% | Sequential lineups reduce false IDs | Malpass and Devine, 1981a | Steblay et al., 2001 |
| Showups | 81% | Increased risk of misidentification | Yarmey et al., 1996 | Steblay et al., 2003 |

(*Continued*)

**Table 1** (Continued)

| *Variables* | *Expert agreement*[a] | *Major results* | *Representative study* | *Review study* |
|---|---|---|---|---|
| Postidentification feedback | | Increases witness confidence without increasing accuracy | Wells and Bradfield, 1998 | Douglass and Steblay, 2006 |
| Suspicion inducement | | Reduces the inflation effect of postidentification feedback | Neuschatz et al., 2007 | Fein et al., 1990 |
| Mug shot exposure | 95% | Exposure to mug shots reduces identification accuracy | Gorenstein and Ellsworth, 1980 | Deffenbacher et al., 2006 |
| Cognitive interview | | Increases in witness accuracy without increases in inaccurate information | Fisher et al., 1989 | Powell et al., 2005 |

[a]This column represents the percentage of experts that agree that research on the variable is reliable. Those variables that do not have percentages in the testify and agreement columns were not included in the Kassin et al. (2001) survey.

index of the extent to which the findings are generally accepted in the scientific community.

Although this chapter focuses on estimator and system variables in eyewitness identification, note that these subsets of variables do not fully capture the breadth of research on eyewitness identification. Considerable research has also explored the effectiveness of safeguards designed to protect defendants from erroneous conviction resulting from mistaken eyewitness identification. This research has examined, for instance, the effectiveness of the presence of counsel at lineups, motions to suppress identification testimony, cross-examination, expert psychological testimony, and judges' instructions (see Van Wallendael et al., 2007, for a review). Underlying much of this research are assumptions concerning the extent to which laypeople (jurors) and legal practitioners (attorneys and judges) are sensitive to the factors that are known from the research to influence the accuracy of eyewitness identification, and the studies test these assumptions.

## 2.44.2 Estimator Variables Affecting Eyewitness Identification

### 2.44.2.1 Exposure Time

Witnesses typically identify suspects based on appearance, so it is reasonable to expect that longer and clearer viewing times lead to better memory and, therefore, enhanced identification accuracy. The literature on facial recognition certainly supports this assertion, as it has been consistently found that longer exposure leads to enhanced facial recognition (Ellis et al., 1975; Shapiro and Penrod, 1986; MacLin et al., 2001). To illustrate, Memon et al. (2003) exposed 64 young adults (ages 17–25) and older adults (ages 59–81) to a videotaped reconstruction of a robbery in which the perpetrator's face could be seen for either 12 s or 45 s. Each witness then attempted to identify the robber from a robber-present or robber-absent photoarray. Exposure duration had a significant impact on identification accuracy. Ninety-five percent of the young adults and 85% of the older adults made correct identifications from the robber-present photoarrays when the robber was exposed for 45 s, but only 29% of the young adults and 35% of the older adults made correct identifications when the robber was exposed for 12 s. Similarly, 41% of the younger adults and 50% of the older adults made false identifications from the robber-absent photoarrays when the target was exposed for 45 s, but 90% of the younger adults and 80% of the older adults made false identifications when the robber was exposed for only 12 s.

Shapiro and Penrod (1986) meta-analyzed 128 studies of face recognition and eyewitness identification involving over 17,000 participants. They examined the effects of exposure time in two different ways: They coded each study for exposure time and examined the impact of exposure time across studies (while controlling for other study characteristics), and they examined the average effects of exposure time within the subset of studies within which exposure time was directly manipulated. Both approaches revealed the expected relations between exposure time and identification accuracy. The respective hit rates for the long and short exposure time conditions were 69% and 57%. The respective false alarm rates were 34% and 38%. As exposure time increased there was a concomitant increase in the hit rate but no increase in false alarms.

Nevertheless, there are some qualifications to the effect of exposure time. Read et al. (1990b), for example, found that increased exposure time enhanced facial recognition when the face did not change from study to test. When slight variations in facial features occurred from study to testing, increased exposure did not improve recognition accuracy. They explained these findings by suggesting that increased exposure allows for encoding of more specific facial features, and the reliance on this information is only helpful at test if those features are still present in the target face at the time of retrieval. To the extent that features cue changes, more exposure time was found by Read et al. to be deleterious of facial recognition accuracy.

### 2.44.2.2 Changes of Appearance and Disguises

To what extent does a perpetrator's change in appearance from the time of the crime to the identification influence a witness's ability to identify him? The influence of changes in appearance on identification accuracy has been examined in several ways. The second author and his colleagues (Cutler et al., 1986, 1987a,b; Cutler and Penrod, 1988; O'Rourke et al., 1989) examined the effect of wearing a hood or baseball cap to cover the hairline of the culprit. In these studies, witnesses watched videotaped crimes and later attempted lineup identifications. In half of the videotaped crimes, the perpetrator wore a cap, while in the other half, his head was uncovered. In each of six studies the percent of correct identification decisions (including both target-present and target-absent lineups) was higher when the perpetrator's head was uncovered. The average performance levels across the six studies, which involved over 1300 eyewitness identifications, was 57% correct when uncovered versus 44% when a hat was worn (Cutler, 2006).

Whereas Cutler and colleagues examined deliberate attempts to disguise one's physical characteristics, Read (1995) examined the impact of more moderate and less invasive changes in appearance in a field study. In this study, two women, at separate times, approached a sales clerk. The first woman asked if her daughter had been in the store because they had arranged to meet at a specified time. The daughter entered the store 15 minutes later and asked the same store clerk if her mother had been in the store and asked for her. The daughter wore her glasses and had her hair pulled back from her face when she interacted with the clerk. Two days later the clerks were asked to identify the daughter from one of two lineups. In one lineup, the daughter's appearance was not changed, while in the other, her appearance was altered (no glasses, hair loose). It is important to note that even though the daughter's appearance was changed she still matched the general description given by the clerks. Consistent with the results reported by Cutler and colleagues, the changed appearance impaired subsequent lineup identification. Read found similar results in a subsequent study (Read et al., 1989)with a male confederate who changed his appearance by removing his facial hair between the crime and the lineup. In further support of these results, Hockley et al. (1999) found that presence or absence of glasses impaired facial recognition to the extent that there was a mismatch at study and test.

Appearance changes can occur naturally as a result of aging, for example, when a suspect is apprehended several months or years after a crime. Read et al. (1990b) examined the effect of such age changes on identification accuracy. Participants viewed black-and-white high school yearbook photos of students taken 2 years apart, in grades 10 and 12. Matched pictures were rated for appearance change by independent raters, and appearance change ratings were inversely associated with recognition accuracy. In Experiment 1, recognition accuracy was highest in the pairs of high similarity (54.5% correct) and lowest in the low-similarity pairs (32.6% correct). Furthermore, when two photos were highly similar, performance increased with exposure time.

Together, these results demonstrate that appearance changes resulting from deliberate attempts to mask features, modest changes in hairstyles and facial hair, and the natural processes of aging tend to impair identification accuracy. Conclusions from the studies of appearance change conform to the encoding specificity principle (Hunt and Ellis, 1974; Tulving, 1983). The encoding specificity principle states that the best memory performance occurs when the stimulus material at encoding matches the items at retrieval. When applied to appearance changes, we would predict, in accordance with this principle, that changes in appearance from the event (encoding) to the identification (retrieval) negatively impact identification accuracy.

### 2.44.2.3 Own-Race Bias

The own-race bias (ORB), also known as cross-race effect or other-race effect, refers to the conclusion that members of one's own race are more accurately recognized when compared to members of other races (Kassin et al., 1989). Though the majority of studies of the ORB have utilized White and Black participants, the consistency of this effect has been demonstrated across various racial and ethnic groups (Luce, 1974; Carroo, 1986). To illustrate, Platz and Hosch (1988) conducted a field study in which White, Black, and Hispanic customers visited convenience clerks and interacted with 90 White, Black, or Hispanic clerks. Within 2–3 h following each visit, an experimenter asked each clerk to identify the customers from photoarrays. Witnesses of each racial group demonstrated the ORB. White clerks were more likely to correctly recognize White customers (53.2%) than Black (40.4%) or Mexican (34%) customers. Black clerks were more likely to correctly recognize Black (63.6%) than White (54.6) or Hispanic (45.4%) customers. Hispanic clerks were more likely to correctly recognize Hispanic (53.6%) than White (35.7%) or Black (25%) customers.

The reliability of the ORB was examined by Meissner and Brigham (2001a), who meta-analyzed the results of 31 separate studies involving 91 separate experimental tests of own-race versus same-race identifications. The studies included over 5000 participants. Across all studies, eyewitnesses were 1.4 times more likely to correctly identify members of their own race than members of other races, and they were 1.56 times more likely to falsely identify members of other races than members of their own race. White participants demonstrated a significantly larger ORB when compared with Black participants but only with respect to false identifications. With respect to correct identifications, Whites and Blacks showed the same ORB. Exposure time moderated the ORB such that the magnitude of the ORB was inversely associated with exposure time.

Scholars with interests in the ORB have drawn upon various social-cognitive approaches (including racial attitudes, physiognomic homogeneity, interracial contact, schema theory, and perceptual learning theory) in their attempts to better understand its causal mechanisms. This research casts doubt on the underlying roles of racial prejudice and physiognomic homogeneity as explanations. Although racial attitudes may not have a direct influence on the ORB, several studies have found a correlation between racial attitudes and amount of interracial contact, a factor that, as noted later, does seem to influence the ORB effect (Brigham, 1993; Slone et al., 2000).

Considerable ORB research has examined the role interracial contact plays in reducing the ORB effect. Contact has been hypothesized to lessen the need to rely on stereotypical responses and to motivate people to accurately recognize members of other racial groups (Malpass, 1981b, 1990). The majority of the studies examining the contact hypothesis give some evidence in support of these predictions. For example, Cross et al. (1971) found that segregated neighborhood residents displayed a significantly greater degree of ORB than residents from desegregated neighborhoods. Further support for the contact hypothesis was obtained in the aforementioned meta-analysis (Meissner and Brigham, 2001a).

The contact hypothesis enlightens our understanding of certain social aspects that influence the ORB effect. Nevertheless, the contact hypothesis fails to account for the cognitive mechanisms by which it operates. To understand the cognitive mechanisms behind the ORB effect, researchers (e.g., Malpass, 1981a) have drawn upon Gibson's (1969) perceptual learning hypothesis. Perceptual learning and differentiation are acquired skills that enable an individual to efficiently extract pertinent information from the environment by experience and practice through focused attention toward invariant cues within certain stimulus sets (Gibson, 1969). Applied to the ORB, people are able to discriminate own-race faces more accurately because they can more efficiently extract invariant cues from own-race faces than other-race faces. Furthermore, these invariant cues are not necessarily predominant in other-race faces, resulting in decreased performance in recognition of other-race faces (Meissner and Brigham, 2001a).

#### 2.44.2.4 Stress Experienced by the Eyewitness

Witnessing a crime can be a highly stressful event, particularly if the witness is a victim or is in serious danger. Stress is commonly identified as a potentially influential factor affecting identification accuracy. Interestingly, lay opinion about the effect of stress is mixed. Many people think extreme duress improves identification accuracy, while others believe it impairs memory (Schmechel et al., 2006). This prevalence of conflicting lay opinions underscores the need for empirical research examining the impact of stress.

Stress is defined as the perception of the potential threat of injury or death to oneself or to another person (Thompson et al., 1998). Empirical examinations of the impact of extreme stress are made difficult for obvious reasons: A proposal to simulate extreme stress in the eyewitness laboratory would be risky business and would understandably meet with considerable resistance by university ethics review committees. Researchers have therefore had to rely on less evasive – and less ecologically valid – manipulations of stress. Some researchers have manipulated stress by exposing witnesses to violent versus nonviolent videotaped crimes (e.g., Clifford and Hollin, 1981). Others have conducted field research and examined actual witnesses to crime. Yuille and Cutshall (1986) interviewed witnesses to a murder and found that those who reported being under the greatest amount of stress were more accurate than those who reported experiencing less stress. Complementing this finding, Reisburg et al. (1988) and Wagenaar and Groeneweg (1990) interviewed participants about recently experienced ordinary events and traumatic events. When describing traumatic events, participants expressed more vivid memories, including the specifics of the event, than when describing ordinary events. Unfortunately, because the experimenter was not privy to the actual events described, the accuracy of these flashbulb memories could not be verified.

Morgan et al. (2004) investigated the impact of extreme versus mild stress on identification accuracy in a sample of 530 active-duty military personnel who participated in military survival school training. The training protocol required some participants to undergo a high-stress interrogation with real physical confrontation and a low-stress interrogation without real physical confrontation. Others experienced either high- or low-stress interrogations. At the end of training, all participants attempted to identify their interrogators from lineups which were either live (simultaneous presentation) or photographic (simultaneous or sequential presentation). Among eyewitnesses shown live, interrogator-present lineups, correct identification rates were much higher following low-stress interrogation (62%) than following the high-stress condition (27%). The same pattern held for simultaneously presented perpetrator-present photographic lineups (76% vs. 36%) and sequentially presented perpetrator-present photographic lineups (75% vs. 49%, respectively).

The effects of stress were further confirmed in a meta-analysis (Deffenbacher et al., 2004) that examined 27 separate tests of the impact of stress on identification accuracy and 36 tests on the impact of description accuracy. Across all studies of identification accuracy, stress inversely and significantly affected the likelihood of correct identification ($h = -0.52$, corresponding to correct identification rates of 0.19 in the high-stress conditions and 0.34 in the low-stress conditions). Stress had a negligible impact on performance in target-absent lineups ($h = 0.01$, corresponding to a 1% difference in false identification rates). Stress also impaired description accuracy across studies ($d = -0.31$).

Although the meta-analysis shows that extreme stress impairs eyewitness memory, the relation between stress and eyewitness memory is not thought to be linear. In one of the earliest reviews of the research on stress and eyewitness memory, Deffenbacher (1980) concluded that the research across 21 studies conformed to the Yerkes-Dodson law (Yerkes and Dodson, 1908). This law states that the effects of stress can be graphed as an inverted U so that with slightly increased levels of stress, there is improvement with memory. However, as stress increases, it reaches an apex and then begins to have a negative impact, resulting in poor encoding and recollection.

Easterbrook's cue-utilization theory has been posited as an explanation for the impact of stress on memory. According to this theory, as stress surpasses moderate levels, attention is diverted from the details of the event to the anxiety (Christianson, 1992; Easterbrook, 1959). It is further hypothesized that because less attention is available for a stressful event, there is a narrowing of focus so that the person allocates more attention to the most informative data (e.g., a weapon in a crime). This leads to the centralization of focus that occurs during highly arousing events. While there has been some debate as to the effects that stress has on the memory of an event, it is clear that information is encoded differently during a stressful event than during a nonstressful event, so that stressful events improve memory for certain aspects of the event while impairing memory for other aspects of the event.

### 2.44.2.5 Weapon Focus

The presence of a weapon is thought to lead an eyewitness to attend to the weapon, leaving less attention to deploy toward other information (Loftus et al., 1987; Mitchell et al., 1998; Pickel, 1998). Weapon focus, therefore, should impair the eyewitness's ability to identify the perpetrator. Put another way, the presence of a weapon is thought to create competition between the weapon and the assailant's face and physical characteristics. Does the presence of a weapon actually impair identification accuracy? In a study by O'Rourke et al. (1989), 120 community members (members of a church group, parents of a local Boy Scouts troop, and undergraduate summer school students) viewed a videotaped enactment of a crime. In half of the crimes, a handgun was visually present, and in the other half, the gun was hidden from view in the perpetrator's coat. One week later, each eyewitness attempted to identify the perpetrator from a lineup. Percent of correct decisions on the lineup test was 55% among witnesses who did not see the weapon but 37% for those who did see the weapon – a statistically significant difference. The weapon focus effect increased the likelihood of false identification and decreased the probability of correct identification.

Steblay (1992) meta-analyzed 19 empirical studies of the weapon focus effect. Of the 19 studies she examined, six demonstrated a significant weapon focus effect while 13 found null results. No study revealed enhanced memory for the presence of a weapon. When the results of these studies were combined, the weapon focus effect for identification accuracy was significant but relatively small in magnitude (corresponding to a difference of about 10% in identification accuracy rates). The effect was larger on description accuracy, however. The weapon focus effect was larger among studies that used more ecologically valid research designs.

The most direct support for the weapon focus effect comes from a study by Loftus et al. (1987). They employed a corneal reflection device which tracks both the direction and duration of eye movements. Participants watched slides that included a person approaching a restaurant counter with either a check or a weapon. They found that people looked at the weapon longer and more often than they looked at the check. In addition, participants' memories were significantly worse in the weapon condition compared to the check condition.

One of the more popular explanations for the weapon focus effect is that people focus their attention on information that is meaningful and not on the weapon *per se*. When a weapon is involved, it becomes the meaningful information (Loftus et al., 1987; Brown, 2003). Thus, the eyewitness focuses on the gun or the central details of the crime, while largely ignoring the peripheral information such as clothing or facial features of the perpetrator. Other researchers, in contrast, have theorized that the weapon focus effect occurs not because the weapon is stressful or highly arousing but rather because the weapon is unusual. To examine this hypothesis, Pickel (1998) had participants view a videotape in which a target was empty-handed or carrying something threatening or unusual. Her results indicated that it was the unusual object – not the dangerous object – that drew witnesses' attention. In other words, the appearance of a gun in a situation in which one would expect its presence, such as a hunting trip, would not lead to the traditional weapon focus effect. Pickel's explanation received further support in a study (Pickel, 1999) showing that the same weapon elicited a larger weapon focus effect when carried by a preacher (an unusual event) than when carried by a police officer (a typical event). Thus, Pickel's research supports the idea that unusualness of the object and situation, and not the mere presence of a weapon, are critical for obtaining the weapon focus effect.

### 2.44.2.6 Eyewitness Confidence

The confidence accuracy relationship (CA) is one of the most studied variables in eyewitness research. Common sense tells us that highly confident witnesses are more likely to be accurate than less confident witnesses (Schmechel et al., 2006). The courts have gone so far as to establish witness confidence as one of the indicators jurors should use to evaluate the accuracy of eyewitness identifications (Neil v. Biggers, 1972).

Does the relation between confidence and accuracy conform to common sense? Many studies of eyewitness identification have assessed witness confidence as a primary or secondary variable. Correlations between confidence and accuracy (or comparable indices of association) are reported in many studies. For example, in a study conducted by Cutler et al. (1987a), 165 students watched a videotaped enactment of a robbery and later attempted to identify the thief from videotaped lineups. Various aspects of the viewing conditions and lineup were manipulated. In all conditions, participants rated their confidence in the accuracy of their identifications immediately following their identification decisions. Across all conditions, the correlation between confidence and accuracy was significant but relatively weak ($r = 0.20$; $p < 0.05$) in magnitude.

The correlations between confidence and identification accuracy have been subjected to several meta-analyses over time (Deffenbacher, 1980; Wells and Murray, 1984; Shapiro and Penrod, 1986; Bothwell et al., 1987; Cutler and Penrod, 1989; Sporer et al., 1995). Sporer et al.'s (1995) was the most recent and comprehensive meta-analysis. Their analysis included 30 studies and over 4000 witnesses. The average correlation across studies was 0.29. The correlation was significantly higher among witnesses who made positive identifications than among witnesses who rejected their lineups ($r = 0.41$ vs. 0.12).

The oft-found modest correlation between confidence and accuracy begs explanation, as it is inconsistent with theoretical decision-making models (e.g., signal detection theory) that would predict a strong relation between confidence and accuracy (Brewer et al., 2005; Libuser and Ebbesen, unpublished data; Ebbesen and Wixted, unpublished data). The explanation, we believe, is that although eyewitnesses are somewhat sensitive to the accuracy of their identifications, their expressions of confidence are influenced by cognitive, personality, and social factors that are independent of identification accuracy. Any factor that influences confidence independent of accuracy should attenuate the relation between confidence and accuracy.

This very general explanation has received support in the eyewitness literature. For example, with respect to cognitive factors, Deffenbacher (1980) offered the optimality hypothesis as an explanation for the weak relation between confidence and accuracy he observed in his review. Optimal viewing conditions, according to this hypothesis, improve both accuracy and the relation between confidence and accuracy, for under optimal conditions, witnesses should give more accurate meta-cognitive judgments. The optimality hypothesis has received support in meta-analytic reviews (Deffenbacher, 1980; Shapiro and Penrod, 1986; Sporer et al., 1995), but support is not universal (Penrod and Cutler, 1995).

Kassin (1985) reasoned that the failure to find a relation between confidence and accuracy might reflect an inability to successfully employ the intrinsic and extrinsic cues that exist with memory traces. More specifically, witnesses may not be aware of the diagnosticity of the cues that exist in remembering and therefore cannot successfully apply those cues to gauge confidence estimates. For example, in their seminal article, Nisbett and Wilson (1977) have shown that people are poor at both identifying reasons for their behaviors and expressing their thought processes. Kassin (1985) believed that making participants aware of their meta-cognitive cues by showing them videos of their own identifications would in turn increase the confidence-accuracy relation. To this end, Kassin (1985) recorded participants during a lineup procedure and subsequently had participants report their confidence. Some of the participants watched a video of their identification before they made their confidence estimates, and others did not. The results indicated that those who watched the identification videos of themselves demonstrated a higher confidence-accuracy correlation.

#### 2.44.2.7 The Application of Estimator Variables: Expert Testimony

The primary application of estimator variable research is expert testimony about the psychology of eyewitness memory. With increasing frequency, psychologists are called upon to testify in criminal cases about the reliability of eyewitness identification. In the aforementioned survey of eyewitness experts (Kassin et al., 2001), the 64 experts surveyed reported being invited to testify on 3370 occasions. They agreed to testify in 1373 trials and actually testified in 960 trials. This activity represents a substantial increase over the results obtained in a previously published survey (Kassin et al., 1989). In this previous survey, experts reported being invited to testify in 1268 trials.

The typical content of expert testimony varies from jurisdiction to jurisdiction, and even from courtroom to courtroom within a jurisdiction, for judges have considerable discretion in determining what testimony will be allowed in a given trial. Generally speaking, experts discuss how memory works (e.g., the stages of memory, reconstructive processes), dispel myths about memory (e.g., memory does not work like a video recorder), and describe relevant estimator and system variables in the case that could influence memory. For example, an expert in a given case might discuss the influence of high stress, weapon focus, the ORB, and suggestive lineup instructions. Experts are not permitted to comment on the accuracy of the eyewitness.

Expert testimony about the psychology of eyewitness memory is in some respects controversial. Admissibility of the expert testimony varies considerably from state to state and within the federal court system. When expert testimony is not admitted, the single most common reason given is that the content of the testimony is merely a matter of common sense – a conclusion that is seriously challenged by empirical research (Schmechel et al., 2006). Some scholars (e.g., Konecni and Ebbesen, 1986; Elliott, 1993) have questioned the extent to which eyewitness studies, which are mainly conducted in the laboratory, generalize to actual crimes and therefore challenge the appropriateness of expert testimony. Such critics have found themselves in the role of opposing experts on occasion. Although the vast majority of cases in which experts testify are criminal cases, and the expert is almost always proffered by the defense (Kassin et al., 2001), occasionally the prosecution will offer an opposing eyewitness expert. The experts surveyed in Kassin et al.'s study reported that in the 960 trials in which they testified, an opposing expert testified in 76 cases (8%). In such cases, the opposing expert might challenge the generalizability of the research, question the extent of expert agreement about certain factors, or challenge the defense expert's conclusions based on the literature. Another concern about expert testimony is its actual effect on the jury. Empirical investigations of the impact of expert testimony on juror decisions show a range of effects, including making jurors more skeptical about eyewitness identification (Leippe, 1995), enhancing juror sensitivity to some of the factors that influence identification accuracy (Cutler et al., 1990), and no effect at all (Devenport and Cutler, 2004). In all probability, the effects of expert testimony are complex and qualified by other factors (e.g., Leippe et al., 2004).

Controversial issues notwithstanding, expert testimony is becoming an increasingly popular safeguard against erroneous conviction in cases in which eyewitness testimony figures prominently. The quality of testimony rests on the foundation of eyewitness memory research on estimator and system variables.

## 2.44.3 System Variables Affecting Eyewitness Identification

### 2.44.3.1 Lineup Instructions

Considerable attention has been devoted to understanding the impact of lineup instructions on identification accuracy. In their seminal article, Malpass and Devine (1981a) examined the effect of biased and unbiased lineup instructions on identifications from target-present and target-absent lineups. By not containing an explicit option to reject the lineup, biased instructions implied that participants were to choose someone from the lineup, whereas unbiased instructions provided a no-choice option. Malpass and Devine found that accurate identifications were not affected by instruction type when the target was in the lineup (75% vs. 83% accurate for biased and unbiased instructions, respectively). In contrast, false identifications from target-absent lineups were significantly higher in the biased-instructions condition (78%) than in the unbiased condition (33%). Thus, biased instructions increased the likelihood of false identification without influencing correct identification rates.

Steblay (1997) meta-analyzed the studies examining the effects of lineup instructions on identification accuracy. Employing 18 different studies in her analysis, she found a clear, consistent pattern that replicated the results of Malpass and Devine (1981a). That is, with target-absent lineups, unbiased instructions led to fewer false identifications (35%) than did biased lineup instructions (60%). The rates of correct identification from target-present lineups were virtually identical for unbiased (54%) and biased (53%) instruction conditions. While the impact of biased lineup instructions on false identifications is generally accepted (Kassin et al., 2001), the effect of biased lineup instructions on correct identifications is less clear, as noted by Clark (2005), who re-analyzed the studies examined by Steblay (1997) and reached a different conclusion.

### 2.44.3.2 Blind Administration of Lineups

According to Wells and Olson (2003), the person who typically conducts the lineup is the police officer assigned to the case. This officer usually constructs the lineup as well (i.e., chooses the fillers and the position of the suspect). Although having the investigator assigned to the case conduct the lineup test may seem perfectly reasonable from the perspective of efficiency and police administration, many years of psychological research on experimenter bias and expectancy effects call into question the value of this practice. Put succinctly, the investigator, who knows which lineup member is the suspect, can advertently or inadvertently convey the correct answer to the eyewitness and therefore influence her identification decision. When evaluating a positive identification under these circumstances, it is impossible to know whether the identification is the product of the witness's memory for the perpetrator, influence by the investigator, or some combination of the two. Given that the purpose of the lineup is to test the hypothesis that the suspect is the perpetrator, ruling out alternative explanations for positive identifications, such as influence by the investigator, is highly desirable. Thus, for the same reasons that we ensure that our experimenters are blind to the participant's experimental condition – or our physicians are blind to the assignment of patients to treatment versus placebo conditions in clinical trials – investigators would be well advised to ensure that lineups are conducted by investigators who do not know which lineup member is the suspect. This blind administration procedure allows the authorities to rule out investigator influence as an explanation for a witness's identification.

Although the need for blind lineups can be sufficiently established based on the vast literature on expectancy effects (Haw and Fisher, 2004), some eyewitness researchers have nevertheless empirically compared eyewitness identifications from blind versus nonblind procedures. In a study conducted by Garrioch and Brimacombe (2001), participants arrived in pairs and were assigned the roles of lineup administrator and witness to a crime. The lineup administrator was instructed on how to conduct the lineup, was told the position of the suspect, and was then instructed not to communicate this position to the witness. Unbeknownst to the lineup administrator, the lineups did not contain the perpetrator. Witnesses watched a videotaped crime and were reunited with their respective lineup administrators for the identification task. The results indicated that participants were more confident in their selection when they chose the target consistent with the administrators' expectations as compared to participants who chose an alternative lineup member. When asked if there was any outside influence that affected their decision, witnesses responded that there was none. Thus, even when lineup administrators were explicitly asked not to influence the witness, they were still able in some way to cue and influence the witness's identification decisions.

Phillips et al. (1999) compared blind versus nonblind administration in simultaneous and sequential lineups. Their study demonstrated the biasing influence of nonblind administration, but only for sequentially presented lineups. Haw and Fisher (2004) varied the amount of contact between the lineup administrator and the witness during the lineup test. They found that the witness was less likely to make a decision that was consistent with the lineup administrator's expectations if the amount of contact between the two parties was limited (the administrator was present but did not speak). This was true regardless of whether the lineup was simultaneous or sequential or whether the target was present or absent.

The use of blind administration raises some additional questions. For example, if a blind administrator shows a lineup to a witness and the witness makes a positive identification, is that investigator still blind? Should that investigator be allowed to show the lineup to another witness? There are often multiple eyewitnesses, so the impact of a positive identification on subsequent lineups is worthy of examination. Douglass et al. (2005) empirically examined this issue. They had participants, in the roles of lineup administrators, conduct the same target-absent lineup twice, once to a confederate witness and once to a participant witness. The authors were interested in determining if the lineup administrator's knowledge of the confederate selection would influence the selection of the second witness. Their results revealed that if the confederate witness selected a suspect with low confidence, then the lineup administrator influenced the participant witness to select the same person. Furthermore, even though the participant witness's selection was influenced, the influence was so subtle that independent observers could not detect it when watching the tainted identification procedure. Thus, it is clear that not only should lineup administrators be blind to the identity of the suspect, but they should also be replaced with another blind administrator after an identification is made, for then the administrator of the first lineup is no longer blind to the identity of the suspect.

In their recent review of both published and unpublished research on blind administration, Russano et al. (2006) concluded that the results are mixed, with some studies demonstrating the biasing effects of nonblind procedures and others failing to do so. Given the general acceptance of expectancy research, these mixed results are somewhat surprising. Russano et al. posit that the mixed results are in part due to the difficulty of effectively simulating investigations in the laboratory, the subtlety of the influence, the magnitude of the effect (which might be small), the use of students posing as lineup administrators (as opposed to more experienced police investigators), and, more generally, the dearth of research on the phenomenon.

### 2.44.3.3 Filler Selection

Fillers, which are sometimes referred to as foils or distractors, are innocent people included in the lineup with the suspect. Luus and Wells (1991) outlined some of the major functions of fillers in a well-constructed, fair lineup. Given that fillers, by definition, are known to be innocent, any selection of a filler is a known error, thereby giving the lineup administrator information regarding the accuracy of the eyewitness. The filler also serves as a control for guessing: the suspect should not be chosen more often than each of the fillers if the witness has no memory of the culprit. A witness with no memory of the culprit should choose the suspect at a rate of 1/N (where N is the total number of lineup members) if the lineup is not biased. Another function of the fillers is to ensure that the identification is made based on memory rather than on logical deduction (e.g., the culprit had a beard and only one person in the lineup has a beard so that must be him).

There are at least two strategies utilized in selecting fillers: match-to-similarity-of-suspect (MS) and match-to-description-of-culprit (MD) (Luus and Wells, 1991). The former involves selecting fillers who physically resemble the suspect. The latter involves selecting fillers based on their match to the witness's description of the perpetrator. How do the different strategies for choosing fillers achieve these aforementioned purposes of having fillers in the lineup? Wells (Luus and Wells, 1991) explains the benefits of the MD approach over the MS approach. The MD approach protects against the witness identifying the suspect based merely on her memory for her description of the perpetrator. For example, if the witness remembers some unique features of the perpetrator and the suspect is the only one in the lineup that possesses those features, the witness can deduce which one is the suspect. Deduction, like guessing, is not the preferred cause of a positive identification. By contrast, using the MD strategy, fillers are chosen because they possess those unique features, and the witness cannot identify the perpetrator merely on the basis of those features, and the witness is therefore required to rely on memory when making an identification (the preferred cause of a positive identification).

Using the MS strategy does not provide this same protection against mistaken identification. In theory, the MS strategy poses great risk to the innocent suspect who was arrested because he looks like the perpetrator. Consider a situation in which an innocent suspect becomes a suspect because he matched the description of the perpetrator. Of course, the suspect will not perfectly resemble the perpetrator. There will be some natural variation in their physical characteristics. Now suppose that fillers are selected because they match the suspect (i.e., the MS strategy). Because the suspect did not perfectly resemble the perpetrator and the fillers did not perfectly match the suspect, it is reasonable to infer that the fillers will on average look less like the perpetrator than does the suspect. If the witness seeks to identify the suspect who looks most like the perpetrator, it will usually be the innocent suspect. Clark and Tunnicliff (2001) refer to this ironic consequence of the MS strategy as the backfire effect.

According to Luus and Wells (1991), the MD strategy does not suffer from the backfire effect because fillers are matched on the relevant descriptors provided by the witness. In the target-absent lineup, all the relevant features (i.e., those mentioned in the description of the perpetrator) should appear in all members. Thus, the MD strategy leads to similar amounts of correct identifications when the target is present and fewer false identifications when the target is not present, as opposed to the MS strategy.

Beneficial effects of the MD strategy, however, are not universally obtained. Lindsay et al. (1994) noted that the MD strategy is less effective when the description of the culprit is incomplete. This study tested three types of lineups: MS, MD, and biased MD. In the biased condition, the fillers were chosen so that they matched the features mentioned in the witness description but were maximally different in appearance to the culprit. For example, if hair color was not mentioned as a feature by the witness, then the distracters could have a hair color that differed from that of the suspect. This biased condition produced more false identifications of the suspect than the other two conditions. Thus, it appears that the MD is the best strategy as long as the fillers selected match the description and also match the appearance of the culprit on some general overall characteristics such as race, hair color, or presence or absence of facial hair.

### 2.44.3.4 Lineup Presentation

Considerable research has been devoted to the examination of various methods for presenting lineups. The most commonly examined presentation methods are simultaneous and sequential. In simultaneous lineups the witness is shown all of the lineup members at the same time and is asked which one, if any, is the perpetrator. In the sequential lineup the witness views lineup members one at a time and makes an identification decision (yes/no) for each lineup member as he is presented. The witness is not told in advance how many lineup members are in the lineup.

Why should performance differ as a function of lineup presentation method? Wells (1984) hypothesized that the simultaneous method induces a cognitive process, known as relative judgment, in which the witness compares each of the lineup members in order to determine which one 'most' resembles his memory of the perpetrator. This process would lead a witness to compare each lineup member to the next using a process of elimination (e.g., "Number 2 looks more like the perpetrator than Number 1 does"). Given that one lineup member will inevitably better resemble the perpetrator than the other lineup members, the relative judgment strategy tends to produce positive identifications, whether the actual perpetrator is present or absent, thus increasing the likelihood of false identifications from target-absent lineups.

Recognizing the limitations of the relative judgment strategy, Lindsay and Wells (1985) developed the sequential method as a means of discouraging relative judgment processing and encouraging absolute judgment processing. In absolute judgment processing, the witness compared each lineup member in the sequence to his memory for the perpetrator and makes an identification decision on the basis of the memory-lineup member match. To test their hypotheses concerning simultaneous and sequential lineups, Lindsay and Wells (1985) staged thefts before 243 undergraduates and in the same sessions had eyewitnesses attempt identifications from thief-present or -absent photoarrays. Half were shown simultaneous and half were shown sequential photoarrays. When the thief was present, the percentage of correct identifications was comparable for simultaneous and sequential lineups (58% vs. 50%, respectively). When the thief was absent, simultaneous lineups produced more false identifications than did sequential lineups (43% vs. 17%).

To further test this theory, Lindsay (1991) compared each of the lineups and then asked people to report if they used a process of elimination (relative) or if the perpetrator popped out (absolute). He found that the accurate participants were more likely to indicate that they used absolute judgment in their decision process. In addition, some research has suggested that self-reported use of an absolute judgment process as opposed to a relative judgment process postdicts identification accuracy (Dunning and Stern, 1994).

How reliable is the effect of presentation method on identification accuracy? Steblay et al. (2001) addressed this question by conducting a meta-analysis of 23 studies comparing simultaneous and sequential presentation, nine of which were published and 14 of which were unpublished. In data from target-present lineups, participants were more likely to correctly choose the target (50% vs. 35%) and less likely to make a false rejection (26% vs. 46%) from simultaneous lineups. There were no differences between the two lineup presentation methods for filler choices. In target-absent lineups, sequential lineups garnered more correct rejections (72% vs. 49%) and fewer false identifications (28% vs. 51%). Overall, participants were more likely to positively identify a suspect from a simultaneously presented lineup than from a sequentially presented lineup (74% vs. 54%). Note that the effect of presentation was considerably larger on false identifications than on correct identifications. This means that, overall, sequential presentation produced identifications that were more diagnostic than did simultaneous presentation.

Although Steblay et al.'s (2001) meta-analysis reflects the state of the science concerning the effects of simultaneous and sequential presentation, the conclusion is not universally accepted. A critique of the meta-analysis by McQuiston-Surrett et al. (2006) identified some potentially important methodological issues that deserve consideration. Specifically, these authors observed that most of the significant results between the two procedures were produced in the same psychological laboratory. The inclusion of unpublished studies in the meta-analysis was also a concern for these authors. They call for greater attention to factors that may qualify the impact of sequential and simultaneous presentation.

The benefits of sequential lineups notwithstanding, not all researchers agree that the gains in lineup accuracy are due to relative versus absolute judgment processing, as originally proposed by Lindsay and Wells (1985). Clark and Davey's (2005) research found that identification decisions did not conform to predictions derived from relative- and absolute-judgment strategies. They included in the comparisons of simultaneous and sequential presentation conditions in which the targets were removed from the lineups without replacement. Clark and Davey reasoned that witnesses who adopt relative-judgment strategies would shift their identifications from the target to other fillers, whereas witnesses who adopt absolute-judgment strategies would shift their identifications from the target to lineup rejections. They found comparable degree of shifts from target identifications to filler identifications from simultaneously and sequentially presented lineups, thus casting doubt on the absolute-relative judgment explanations for the differences observed due to simultaneous and sequential lineups. By contrast, Meissner et al. (2005) demonstrated that the benefits of sequential lineup may be explained by a criterion shift. More specifically, sequential lineups induce the use of stricter criteria, which results in fewer false identifications without lowering correct identifications.

### 2.44.3.5 Showups

A showup is a one-to-one confrontation between the witness and the suspect in which the witness is asked if the suspect was the person who committed the crime. Psychologists have typically suggested that showups are suggestive and unreliable (Yarmey et al., 1994, 1996; Lindsay et al., 1997). In the aforementioned survey by Kassin et al. (2001) 74% of the eyewitness experts agreed with the statement "The use of a one-person showup instead of a full lineup increased the risk of misidentification" (see **Table 1**).

There are two theoretical arguments against using showup. First, a showup, by its very nature, provides only one option to the witness, making it difficult to distinguish identifications made from memory versus guessing, deduction, or social influence. A properly conducted photoarray provides better safeguards against these alternative explanations for positive identifications.

The second argument is that innocent fillers in the lineup that closely match the witnesses' description of the culprit improve lineup performance (Luus and Wells, 1991; Wells et al., 1994), as described earlier. It is thought that having fillers in the lineup that are reasonable alternatives forces the witness to closely scrutinize the lineup members and make more accurate decisions.

Do showups produce more false identifications than lineups? Gonzales et al. (1993) had a perpetrator enter the classroom and sit in the back row and steal the purse off of the instructor's desk. Participants were later shown either a live lineup or a live showup. In the showup condition, 30% correctly identified the perpetrator, where 67% correctly chose the perpetrator in the lineup condition. Furthermore, in the target-absent condition 92% in the showup condition correctly stated the perpetrator was not there, as compared to 38% in the lineup condition. Thus, the showups did not result in more mistaken identifications than lineups; however, Yarmey et al. (1994) have argued that when you take into account the guessing rate (15% vs. 16% showups and lineups, respectively), lineups produce more accurate lineup identifications with no differences in false identifications.

To further examine the difference in lineup versus showup performance, Steblay et al. (2003) meta-analyzed the existing 12 studies, which included 3013 participants. Overall, they found nonsignificant differences in identification performance between showups and photoarrays. Indeed, the rates of correct identifications from target-present lineups were nearly identical (47% and 45%, respectively). Contrary to expectation, there were significantly more correct rejections from showups than from lineups (85% and 57%, respectively). At least based on these data, therefore, the conclusion that showups produce more false identifications than lineups is not supported. Nevertheless, the first argument raised still holds: Showups provide poor safeguards against guessing, deduction, and social influence, all of which can explain positive identifications.

### 2.44.3.6 Postidentification Feedback

Postidentification feedback is any statement made to an eyewitness after he or she has selected a suspect from a lineup (Wells and Bradfield, 1998). For example, if Eileen Eyewitness picks out Scottie Suspect from a lineup, the administrator may say something like "Great, you got 'em." This comment may seem innocuous, but is it? Luus and Wells (1994) conducted one of the first studies that systematically investigated the effect of postevent feedback on retrospective certainty. Pairs of subjects watched a staged theft, made individual lineup identifications from a photo spread, and were subsequently given bogus postidentification feedback regarding their co-witnesses' alleged identification decisions. It is important to note that all of the witnesses who made positive identifications were incorrect, because they were all exposed to target-absent lineups. Although Luus and Wells gave nine different types of feedback, for the sake of brevity we will only address the confirmatory feedback (i.e., when the witness was told that they had selected the same person as the co-witness). Participants who were given confirmatory feedback expressed more confidence in their identification than witnesses given no feedback (8.77 vs. 6.90 on a nine-point scale) when later interviewed by confederates posing as police officers. It is important to note that this confidence inflation occurred even though participants were given no indication that the identification was correct. In the second experiment, participants role-playing jurors rated the (inaccurate) witnesses who received the confirmatory feedback as the most credible. Thus, confirmatory feedback increased witness confidence in their identifications and made their testimony seem more believable to jurors, and this occurred independently of the accuracy of the eyewitnesses.

In a related study, Wells and Bradfield (1998) examined the effects of postidentification feedback from a lineup administrator on retrospective eyewitness certainty. Their participants watched a clip from a security camera video and attempted to identify the target from a target-absent lineup. Following their identifications, some participants were told that they had selected the right person, while others were given no such feedback concerning their identifications. Participants who were given feedback reported that they paid more attention to the perpetrator, were more certain in their identification, and had a clearer view when compared to the subjects who were not given feedback.

The effects of postidentification feedback are robust and reliable. They have been demonstrated using a wide variety of dependent measures, as noted. The effects have been found to persist using a 1-week retention interval (Neuschatz et al., 2005) and have been observed in witnesses of varying ages (Hafstad et al., 2004).

Can the detrimental impact of postidentification feedback be mitigated? Wells and Bradfield (1998) suggested that eyewitnesses, at the time they make their identifications, do not make online judgments about how good of a view they had, how much attention they paid, or how certain they are in their identifications. When they are later asked about these issues, they base their responses on what is accessible in memory. Because participants do not make online judgments, they are forced to infer their confidence from the feedback that was given to them. To illustrate, an eyewitness might infer that if she was told that she was correct, she must have had a good view, paid attention, and been confident in her decision. Wells and Bradfield proposed that the postidentification feedback effect could be eliminated by forcing participants to think about their confidence, attention, and view at the time of the identification, thus giving them memory traces for these internal cues without having to rely on feedback from an external source.

To test this notion, Wells and Bradfield had participants give confidence ratings before and after the feedback manipulation. They argued that the confidence question would force participants to think about how certain they were and how good a view they had before they received the postidentification feedback. The results indicated that the feedback effect was mitigated in those participants who received the confidence question prior to the feedback. Wells and Bradfield referred to this as the confidence prophylactic effect. One problem with this effect is that, although it works if eyewitnesses are questioned immediately, its preventative effects seem to be short-lived. Neuschatz et al. (2007) found that the confidence prophylactic effect worked immediately but not after a 1-week retention interval. Given that the length of time between identification and trial is normally much longer than 1 week, the confidence prophylactic effect might not be an adequate safeguard against confidence inflation due to postidentification feedback.

Neuschatz et al. (2007) examined whether inducing suspicion about the postidentification feedback weakened its effect. Suspicion is the orientation in which the perceiver maintains the possibility that multiple causes may be influencing the actor's behavior and that the actor may be hiding something that might discredit the meaning of that action (Fein et al., 1990). Suspicion inducement has been found to reduce biases in studies examining the impact of prejudicial pretrial publicity and inadmissible evidence on jury decision making (Fein et al., 1997). In the experiment conducted by Neuschatz et al. (2007), participants viewed a video and were asked to identify a suspect from a target-absent photo lineup. Afterwards, some participants were informed that they selected the actual suspect, while others were given no information. Either immediately or after a 1-week retention interval, participants were led to another room by a different experimenter. Some participants who received feedback were given reasons to entertain suspicion regarding the motives of the lineup administrator. Subsequently, participants answered a questionnaire regarding their identification. The authors hypothesized that making the participant suspicious would lead the participant to question the validity of the feedback, thus adjusting their confidence in their witnessing experience. Neuschatz et al. found that suspicious perceivers did not demonstrate the confidence inflation effects typically associated with confirming feedback.

In summary, research converges on the conclusion that postidentification feedback influences eyewitness confidence and retrospective reports of the conditions under which they witnessed the event. Postidentification feedback, therefore, should serve to further attenuate the relation between eyewitness confidence and identification accuracy. Some research suggests that the postidentification feedback effect can be mitigated by assessments of confidence prior to postidentification feedback (at least when retention intervals are brief) and the inducement of suspicion concerning the source of the postidentification feedback.

### 2.44.3.7 The Application of System Variables: Lineup Reform

The aforementioned perfect storm resulted from, on the one hand, growing documentation of miscarriages of justice resulting from mistaken eyewitness identification and, on the other hand, a readiness on the part of eyewitness researchers to offer practical advice based on a large body of research on lineup techniques. What followed was a series of published recommendations, including the first white paper endorsed by the American Psychology-Law Society (Division 41, American Psychological Association) (Wells et al., 1998) and an influential United States Department of Justice report commissioned by Janet Reno, Attorney General at the time (Technical Working Group on Eyewitness Evidence, 1999). Following these published recommendations, the State of New Jersey was the first in the nation to adopt new guidelines for lineups. The guidelines adopted by the New Jersey Attorney General included such recommendations as (1) instructions that warn jurors that the perpetrator might not be in the lineup; (2) use of the match-to-description technique for selecting fillers; (3) sequential presentation of photoarrays; (4) the use of blind lineup administration; and (5) the assessment of eyewitness confidence immediately after the lineup and before witnesses are given confirming or disconfirming evidence about their identifications. These recommendations follow directly from the research literature. The State of North Carolina was the second state to develop and adopt new recommendations, and theirs were very similar to those adopted by New Jersey. Other states (Illinois, Minnesota) have experimented with these new techniques. Other states and cities (e.g., Virginia, Florida, Wisconsin, Boston, Seattle) are in the process of studying or implementing lineup reform.

Just as continuing research on estimator variables continues to inform expert witnesses and therefore lawyers, judges, and juries, research on eyewitness identification continues to inform psychologists who work with police and prosecutors to reform their identification procedures. Consider, for example, the influence of two recently published findings and the implications of these findings for practice. First, based on the research of Haw and Fisher (2004) described earlier, the amount of interaction between the lineup administrator and the witness should be held to a minimum. Second, the lineup administrator should not conduct the same lineup for witnesses tested in sequence. Being privy to the selection of one eyewitness can compromise the protection afforded by having administrators blind to the identity of the suspect, as the first identification may allow them to develop their own hypothesis as to the suspect's identity (Douglass et al., 2005).

## 2.44.4 General Conclusions

The foregoing review serves to illustrate how basic research on human memory can be applied to real-world phenomena, eyewitness memory in this case. Many years of research on eyewitness memory have positioned eyewitness researchers to offer practical advice in courtrooms and to police investigators charged with the responsibility of creating and administering lineups. The eyewitness research draws from traditional theories and methods of cognitive and social psychology and ultimately informs those disciplines in return.

Ideally, the next generation of eyewitness research will draw upon lessons learned in the field. The adoption of techniques developed and tested in the laboratory for use in the field should reveal new problems and questions that could not have been anticipated by laboratory researchers. For example, both authors of this chapter have served as expert witnesses in cases involving eyewitness identification. When providing these services, both authors have encountered new questions – potential variables – that can be brought back to the laboratory for further investigation. To illustrate, the first author recently worked a case in which the witness was given six simultaneous lineups, each with a different suspect, in order to identify two culprits. The witness chose four suspects out of the six lineups with varying degrees of confidence, even though there were only two culprits. This case raises many interesting questions. What effects do multiple lineups with multiple suspects have on the accuracy of the witness? How does the presence of two false identifications affect investigators', attorneys', and jurors' evaluations of the eyewitness? How 'should' these known false identifications affect evaluations of the eyewitness? Similarly, field studies and actual implementation of new lineup techniques can reveal questions and issues that have not been examined in the laboratory, thus suggesting new directions for laboratory research. With respect to the implications for justice, the application of eyewitness research to police practices and trials should serve to reduce identification errors and ultimately reduce the likelihood of erroneous conviction. Though much of the identification research seems to focus on one type of error (false identification), the research also has implications for improving the likelihood of correct identification and improving the extent to which positive identifications are diagnostic of guilt as well.

# 2.45 Prospective Memory: Processes, Lifespan Changes, and Neuroscience

**G. O. Einstein**, Furman University, Greenville, SC, USA

**M. A. McDaniel**, Washington University, St. Louis, MO, USA

**R. L. Marsh**, University of Georgia, Athens, GA, USA

**R. West**, Iowa State University, Ames, IA, USA

Prospective memory involves remembering to perform actions in the future. Thus, remembering to buy a loaf of bread on the way home, remembering to go to the dentist for an appointment, and remembering to actually attach an attachment to an email all are examples of prospective memory. Prospective memory has often been contrasted with retrospective memory (we explore this distinction in more detail in a subsequent section), which is what is typically studied in the laboratory. Remembering the plot of a movie that you saw 2 weeks ago and remembering a list of words presented in an experiment are examples of retrospective memory.

## 2.45.1 The Importance of Prospective Memory in Everyday Life

An interesting feature of prospective memory is that it is prevalent in everyday life and central to normal functioning, and yet it is an area that until recently has been neglected by memory researchers. In reflecting on the activities in our typical day, it is easy to realize the enormous number of prospective memory demands that permeate our lives. From remembering to take vitamins and medication in the morning to remembering meetings, appointments, and errands throughout the day, our lives are full of prospective memory demands. Consistent with this impression that prospective memory demands are ubiquitous, Crovitz and Daniel (1984), in a study in which they asked students to record in a diary all instances of forgetting over a 1-week period, found that about half of the reported instances of forgetting were prospective in nature.

Not only do prospective memory demands permeate our lives, but successful remembering is also critical to normal and efficient functioning. Consider that one-third of older adults take three or more medications on a regular basis (Morell et al., 1997). Problems in remembering to take these medications could have serious health consequences and could threaten independent living. Consider also that prospective memory demands are often the cause of mistakes and accidents at work (Reason, 1990). Indeed, Nowinski et al. (2003), in examining voluntary reports of cockpit incidents from pilots to the Aviation Safety Reporting System, found that 74 of the 75 memory failures in their sample were prospective in nature. From the other side of airline safety, imagine the consequences of prospective memory failure for a busy air traffic controller, who gets the thought to reroute an airplane but cannot do so immediately because she is engaged in another activity and therefore must hold on to the intention until she is free. As another example, despite the best intentions of conscientious surgical teams, roughly once a year in a large hospital, they accidentally leave foreign instruments such as sponges and clamps in a patient. The patient shown in **Figure 1** complained of abdominal pain and nausea 8 months after a hernia surgery. As you can see, a scan revealed that the surgical team had forgotten to remove a 16-cm clamp from his abdominal area.

More generally, Tulving (2004) theorizes that a forward-looking mind that is capable of imagining and anticipating the future is critical to human survival. He assumes that this subjective and conscious apprehension of the future is mediated by the episodic memory system, and he labels this ability proscopic chronesthesia. Moreover, he believes that this ability is unique to humans and that the evolution of this ability was necessary for the creation of human culture. Prospective memory is among the important functions of chronesthetic consciousness. The idea here is that basic survival as well as rich human-like social relationships benefit from those who are capable of appreciating the future, planning for it, and later remembering to perform planned actions.

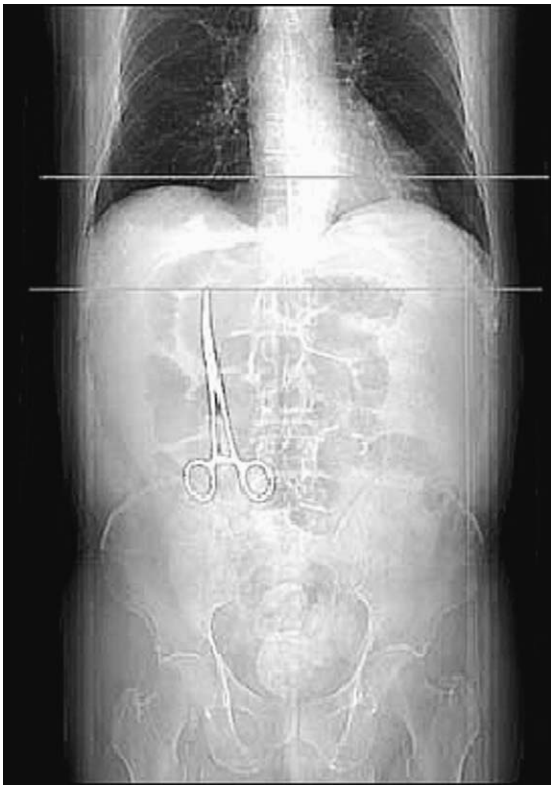

**Figure 1** Scan showing a 16-cm clamp left in the abdominal area of a patient. From Dembitzer A and Lai EJ (2003) Retained surgical instrument. *N. Engl. J. Med.* 348–228.

In the 1980s, a few researchers (e.g., Harris, 1984; Craik, 1986) started proposing that the retrospective memory literature had not addressed fundamental issues in prospective memory and, as such, alerted researchers to the gap in our understanding of prospective memory. As can be seen in **Figure 2**, the number of articles and chapters on prospective memory (collapsed over 2-year intervals) has risen dramatically since that time. The increased interest has been driven by a number of factors, including the realization that prospective remembering is critical to our everyday leisure and work lives, the growing awareness that important components of prospective memory tend not to be studied in the typical retrospective memory experiment or captured in conventional neuropsychological assessments of memory, the development of laboratory paradigms for studying prospective

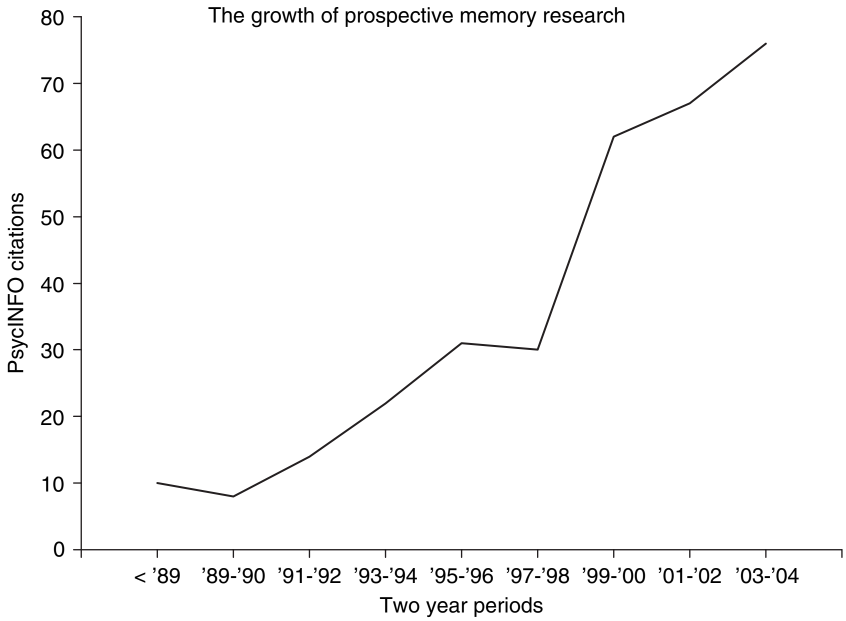

**Figure 2** References to prospective memory over recent years in the PsychINFO database. From Marsh RL, Cook GI, and Hicks JL (2006a) An analysis of prospective memory. In: Ross BH (ed.) *The Psychology of Learning and Motivation*, Vol. 46, pp. 115–153. San Diego: Academic Press.

memory, theoretical progress on the cognitive processes that support prospective memory as well as interest in how these processes change across the lifespan, and the development of imaging techniques for understanding the neural basis of prospective memory. We focus on these factors in this chapter.

## 2.45.2 Paradigms for Studying Prospective Memory

By and large, explicit retrospective memory tasks involve presenting people with materials to learn and then, at some later point, putting the participants in what Tulving (1983) calls a retrieval mode and directing them to search memory for the previously learned information. For example, in the standard cued recall task, participants might be asked to learn pairs of items (e.g., dog/grass, table/binder, etc.). After a delay, the experimenter presents the first member of the pair and explicitly asks the participants to search memory for the associated second member of each pair. On the surface, many prospective memory tasks resemble this cued-recall scenario. Consider, for example, remembering to give your friend Patty a message. It is likely that you form an association between Patty and the message (i.e., Patty/message), and then after a delay, when Patty occurs, you need to retrieve the message. A major difference between this and the retrospective cued recall task, however, is that in the prospective memory task no one puts the participant in a retrieval mode and asks her or him to search memory when the target cue occurs (i.e., Patty). Instead, upon seeing Patty, successful remembering requires that the participant remember to retrieve the intention on her or his own. It is this feature of prospective memory that led Craik (1986) to characterize prospective memory as being especially high in self-initiated retrieval. Thus, in designing a research paradigm for studying prospective memory, it is critical to include this self-initiated component of requiring subjects to remember on their own (see McDaniel and Einstein, 2007, Chapter 1, for additional defining features of prospective memory tasks).

### 2.45.2.1 Nonlaboratory Paradigms

The earliest methods for investigating prospective memory were conducted outside of the laboratory. For example, Meacham and Singer (1977) asked college students to return postcards on specified days and found, among other results, that stronger incentives led to better prospective memory. Other studies (West, 1988; Maylor, 1990) asked subjects to telephone the experimenter at particular times. Another approach is to examine the success with which people remember to carry out their own intentions. For example, Marsh et al. (1998b) asked subjects to list their planned activities for the next week (along with the importance of each). One week later, they asked them to indicate which intentions had been carried out and which had not (and to try to explain why these were not performed). In the medication adherence literature, researchers have asked people to adhere to their medication regimen and then put their pills in electronic medication bottles that record the date and time (over a 6-month period) every time the bottle cap is removed (see Park and Kidder, 1996, for a description). As reflected in these studies, nonlaboratory paradigms have the potential to examine prospective memory under highly naturalistic conditions.

One limitation of this approach, however, is that it is difficult to assess and/or control the strategies that subjects use in particular situations. For example, in the Meacham and Singer (1977) postcard study, some of the student subjects may have remembered using purely cognitive strategies, others may have used calendars, and still others may have given the post-cards to their parents to return for them. Thus, it is difficult to hone in on the mechanism by which incentives improve prospective remembering. Imagine also comparing older and younger adults and finding that the older adults remember more often than the younger adults (a typical finding in naturalistic studies; see Henry et al., 2004). This type of paradigm does not allow you to determine whether the better prospective memory for older adults was a result of more effective cognitive processes related to prospective memory, greater use of external aids, or both.

In recent years, researchers have been creative in elaborating nonlaboratory paradigms, and this has enabled them to begin exploring these processes. Kvavilashvili and Fisher (2007), for example, asked subjects to remember to call the experimenter 1 week later. They additionally asked them to record in a diary all thoughts related to the prospective memory intention over the 1-week period. Among other findings, Kvavilashvili and Fisher found that related cues (such as walking past a telephone pole) tended to spontaneously trigger thoughts of the intention. Sellen et al. (1997) gave their participants, all of whom were employees working in a single building, a prospective memory intention to perform for several days (e.g., to perform an action whenever they were in a particular room in the building). Moreover, the participants wore badges and were instructed to click their badge whenever they thought of the intention. There were sensors in the building that enabled the researchers to determine the location of the badge when it was clicked. Interestingly, participants were more likely to think of their intention when they were in transition (e.g., walking from one room to another) than when they were settled in a particular room (i.e., engaged by a task). Although these nonlaboratory paradigms have advantages over laboratory techniques in the sense that they tend to more closely approximate real-world prospective memory demands, ultimately they do not allow the precise control over independent and extraneous variables that is afforded by laboratory techniques. We now outline the basic laboratory paradigm that has been used.

### 2.45.2.2 Laboratory Paradigms

The essence of laboratory tests of prospective memory has been to busily engage participants in an ongoing task and to give them an intention to perform at some later time (see **Table 1** for the major

**Table 1** A typical laboratory paradigm for studying prospective memory

| | |
|---|---|
| 1 | Present participants with instructions and practice trials for an ongoing task (e.g., pleasantness rating). |
| 2 | Present participants with the prospective memory (PM) instructions (e.g., press a designated key whenever you see the word 'rake' in the context of the ongoing task). |
| 3 | A delay is introduced during which participants perform other activities (e.g., do other memory tasks and/or fill out demographics forms). |
| 4 | Reintroduce the ongoing task (pleasantness rating) without reminding participants of the PM task. |
| 5 | The PM target ('rake') occurs several times in the ongoing task, and PM performance is measured by the proportion of times participants remember to press the designated key when the target occurs. |
| 6 | To verify that forgetting was a result of PM failure rather than retrospective memory failure, participants are queried at the end of the experiment for their memory of the task demands. |

From Einstein GO and McDaniel MA (2005) Prospective memory: Multiple retrieval processes. *Curr. Dir. Psychol. Sci.* 14: 286–290.

phases of a typical experiment, and see Einstein and McDaniel, 1990, for a specific example). Successful prospective memory requires that one remembers to perform an intended action (the prospective component) and also the contents of the intention (i.e., that the target item is 'rake' and the particular response key to press; the retrospective component). In explicit retrospective memory tasks, experimenters challenge the retrospective component. That is, they present participants with a body of material and then test how much is retained. In prospective memory tasks, the retrospective content is usually kept simple, and the question is whether participants will remember to perform the action at the appropriate moment or time period. This is done so that one can be fairly certain that omissions are the result of prospective memory failures as opposed to forgetting the contents of the intention. Indeed, it is important to verify this by testing participants at the end of the experiment for their memory of the prospective memory task demands. Prospective memory failures occur when participants fail to perform the intended action and yet later show complete memory for the task demands (i.e., the retrospective component).

This basic paradigm seems to capture the processes that are involved in many everyday prospective memory demands. For example, consider the prospective memory task described earlier: the task of remembering to give your friend Patty a message. After forming the intention, there is a delay during which we become engaged by the demands of life (i.e., the ongoing task), and the interest is in whether we will remember to give the message when we later see Patty (i.e., the prospective memory target). Within this general paradigm, researchers have manipulated a number of variables, including the emphasis on the ongoing and prospective memory task (Marsh et al., 2005), whether the cue for initiating the action is an event, a time, or an activity (e.g., Einstein et al., 1995), the nature of the cue (e.g., whether the cue is distinctive; McDaniel and Einstein, 1993), the length of the delay (e.g., Hicks et al., 2000), and the demands on the participant while encoding the intention and at the point of retrieval (e.g., Einstein et al., 1997; Marsh and Hicks, 1998).

Despite the widespread use of some variation of this basic laboratory paradigm, it is important to realize that it does not capture all real-world prospective memory processes. For example, planning is minimized as the experimenter tells the subject when to perform the action. Also, Dismukes (2007) points out that many everyday prospective memory demands, unlike those in laboratory tasks, are embedded in well-learned and highly sequenced routines. For instance, a pilot's typical sequence of actions prior to take off may be to perform a checklist of actions, then set the flaps to take-off position, and then taxi to the runway. For an experienced pilot, this sequence has been performed thousands of times in just this order, and the completion of the checklist and the perceptual environment prior to taxiing are strong cues for setting the flaps to the take-off position. There has been little research examining this kind of heavily cued habitual prospective memory task or what happens on those rare occasions when the action must be performed out of sequence (e.g., when weather conditions require that the pilot delay the setting of the flaps until after taxiing, when the normal kinesthetic and perceptual cues are no longer present). In theory, however, these kinds of conditions can be created in the laboratory either through training or by taking advantage of long-standing habits. Thus, while it is clear that existing tasks have been and continue to be useful for understanding basic processes involved in the encoding, storage, and retrieval of prospective memories, we look forward to the development of other laboratory paradigms for examining prospective memory under a broader set of conditions.

## 2.45.3 Varieties of Prospective Memory Tasks and How They Are Measured

### 2.45.3.1 Event-Based Prospective Memory

Although there are some grey areas when defining prospective memory tasks (see McDaniel and Einstein, 2007, Chapter 1), the field seems to have focused the research on three main types of tasks. The lion's share of the research has examined event-based prospective memory in which the rememberer offloads the intention onto some external environmental cue or cues. An example of an event-based task is the one described in the previous section of pressing a key when the target word 'rake' is encountered while performing an ongoing task. A real-world example would be the task of stopping to buy stamps when driving by the post office. Usually performance on an event-based task is measured as the proportion of cues detected and responded to in the manner requested when the intention was formed. Cues can either be specific or general, such as responding to particular words and constructs or to more general categories of items such as fruits or U.S. presidents. The responses could be as simple as marking a response sheet in a particular way, pressing a special key on a keyboard, or rapping on the table when an item is detected.

#### 2.45.3.2 Time-Based Prospective Memory

Another form of prospective memory has been labeled time-based intentions because the intended actions relate to time in some way. The intention could be a relative measure, such as returning a phone call in 30 min, or it could be related to clock time, as in attending a meeting at 1.30 p.m. (note that if the target time were associated with an event or activity and one of these features triggered the intention rather than the monitoring of time, it would not be classified as a time-based task). Not much is known about the mechanisms underlying time-based prospective memory. Most of the work that has been done appeals to a test-wait-test-exit model (see Kvavilashvili and Fisher, 2007). Here the rememberer executes a time check, which is presumably on the first several occasions too early and thus necessitates a cyclical waiting period before another time check is made. As Kvavilashvili and Fisher have so eloquently stated, the problem with this model is that it does not specify what causes a person to engage in a time check in the first place. They conducted a diary study with a long-term time-based intention and found that many remindings were related to chance encounters with objects and language that were direct reminders of the time-based intention. They also found that many such retrievals of the time-based intention came to mind unbidden. We do know that the most successful individuals at time-based prospective memory tasks check the clock frequently in the period just prior to a required response (Einstein et al., 1995). However, that still does not specify what psychological process is responsible for the clock check in the first place, and this is especially true when a participant records in a diary that there was not an external or internal trigger of the time-based intention. Like event-based prospective memory, how many responses are successful is the usual dependent variable, although some metric of being early versus late is also a common variation. Of course, when measured, the distribution of clock checking can also be very informative as well.

#### 2.45.3.3 Activity-Based Prospective Memory

Finally, the third common form of prospective memory measures what is called activity-based prospective memory (e.g., Schaeffer et al., 1998). With this type of intention, people intend on doing one activity after finishing another one. For example, intending on walking the dog after the evening news would represent an activity-based intention. Although this might seem to be a habitual intention, whether something is novel or habitual depends on the frequency with which it is carried out, and this applies equally well to event-based and time-based tasks. There have not been many experimentally based studies on activity-based prospective memory, probably because there is some theoretical ambiguity about whether this is just a special form of an event-based task, with the conclusion of one task serving as the event that signals responding. However, this ambiguity highlights a very important point concerning prospective memory, namely, the rememberer can form an intention in any of these three different ways, and each will have varying success depending on tasks and conditions that prevail on that occasion. Take the simple intention of purchasing a birthday card. One could write oneself a note and hope that seeing the note was sufficient to accomplish the task (an event-based task). One could formulate the intention to run to the store right after lunch in order to carry out the purchase (an activity-based intention). Or, one could plan a specific deviation of one's day and commit to leaving the office at 5.00 p.m. to carry out the task (a time-based task). All three formulations are prospective memory tasks, but they will vary in the success rate depending on the individual and the conditions surrounding the performance interval (e.g., seeing the note but being late for work or for a class). The important point is that a desire to accomplish some goal can be linked to various future contexts in a variety of ways depending on whether the rememberer gives some serious consideration to what formulation will be best (for a more detailed treatment of prospective memory and contextual associations see Marsh et al., in press).

### 2.45.4 Retrieval of Prospective Memories: Retrieval Without an Explicit Request to Remember

A central problem in prospective memory is in understanding how we initiate an intended action at the appropriate moment. This is an interesting question because models of retrospective memory retrieval (e.g., recall and recognition) start with the assumption that people have been put in a retrieval mode and have been explicitly directed to search their memory for previously encoded information. As discussed earlier, prospective memory is different in the sense that we form an intention to perform an action at some later point and then get busily involved in other activities. How, then, do we remember to perform the action in response to that event? Because the majority of the research has investigated retrieval on event-based tasks, this is our focus in this section. Following, we consider two opposing theories that address this question and then present a compromise view. (For those interested in research and theorizing on retrieval of time-based prospective memories, we recommend the following sources: Harris and Wilkins, 1982; Harris, 1984; Ceci and Bronfenbrenner, 1985; Block and Zakay, 2006; Kvavilashvili and Fisher, 2007.).

### 2.45.4.1 Attentional Monitoring Theory

The attentional monitoring view assumes that some of our attentional and/or working memory resources need to be devoted to monitoring the environment for the target event in order for retrieval to occur. According to this view, successful prospective memory requires that an attentional system like Shallice and Burgess's (1991) supervisory attentional system monitors the environment in light of our prospective memory demands. When a target event is detected, this system interrupts the ongoing activity, evaluates whether the conditions for performing the action are appropriate, and if so initiates the appropriate actions.

The most thoroughly developed statement of this view is Smith and Bayen's (Smith, 2003; Smith and Bayen, 2004, 2006) preparatory attentional and memory (PAM) theory. According to this theory, when we form an intention, we initiate a capacity-consuming preparatory attentional process that monitors environmental events by initiating recognition checks to determine whether the events are instances of the prospective memory target. For example, consider the task presented in **Table 1**, in which the prospective memory task is to press the slash key when the target word 'rake' occurs while performing the ongoing pleasantness rating task. According to the PAM theory, preparatory processes involve initiating a recognition check for each item to determine whether it is an instance of the target event and could also include rehearsing the target event. According to this theory, forgetting occurs when people fail to maintain their attention on the intention and therefore fail to initiate recognition checks, or when there is a recognition failure (see Smith and Bayan 2004, 2006, for a multinomial model that measures these two parameters). Smith takes a strong position on the necessity of monitoring for successful prospective memory, arguing that "capacity must be devoted to the prospective memory task in the form of monitoring before a target event occurs if the target is to be recognized as a signal or an opportunity to perform the prospective memory action" (Smith, 2003, p. 359).

Because this view assumes that people are using attentional resources to monitor the environment for target events when they have a prospective memory intention, this view clearly predicts that adding a prospective memory task to an ongoing task should produce task interference (i.e., slowing on the ongoing task). Continuing with the example, the idea is that the pleasantness ratings for nontarget items will be slower because subjects are additionally monitoring these items for the prospective memory target event while they are performing the pleasantness ratings. Smith (2003, Experiment 1) provided strong support for this view when she found that participants were approximately 300 ms slower in performing a lexical decision task when they were also performing a prospective memory task compared with when they were performing the lexical decision task alone. Task interference to the ongoing task has been found repeatedly and with other types of ongoing tasks (Smith and Bayen, 2004) and in other labs (Marsh et al., 2003; Einstein et al., 2005). Moreover, Smith (2003) found that individuals who showed more task interference (i.e., more slowing on the ongoing task as a result of performing the prospective memory task) had higher prospective memory, thereby indicating that monitoring is important for prospective memory retrieval.

The monitoring view is also supported by research showing that dividing attention during retrieval lowers prospective memory (Einstein et al., 1997; Park et al., 1997; Marsh and Hicks, 1998). Marsh and Hicks have shown that divided attention tasks that required central executive resources, but not ones that increased the demands of articulatory suppression or visuospatial involvement, reduced prospective memory performance. A straightforward interpretation of these results is that dividing attention compromises monitoring processes that are needed to identify prospective memory targets.

### 2.45.4.2 Spontaneous Retrieval Theory

A different way to think about prospective memory retrieval is to assume that the occurrence of the target event can trigger remembering even when no resources are devoted to the intention at the time that the target event occurs (Einstein and McDaniel, 1996; McDaniel and Einstein, 2000; McDaniel et al., 2004; Einstein et al., 2005). Much like walking by a friend can reflexively trigger the recollection of an amusing past episode with the friend (when there was no prior intention to remember that episode prior to encountering the friend), according to the spontaneous view, it is the occurrence of the cue that triggers processes that lead to retrieval of the intended action. Within this view, then, monitoring or preparatory attentional processes are not necessary for successful retrieval.

In this section, we briefly review two theoretical mechanisms by which spontaneous retrieval can be accomplished. One theory, called the reflexive-associative theory (Einstein and McDaniel, 1996; McDaniel and Einstein, 2000; McDaniel et al., 2004), assumes that relatively automatic processes can underlie prospective memory retrieval. The idea is that during planning, people form an association between the target cue and the intended action (e.g., an association between the target word 'rake' and the action to press the slash key). Later, when the target event is processed in the context of the ongoing task, an automatic associative system (like the one proposed by Moscovitch [1994] and presumed to be mediated by the hippocampal system) retrieves the intended action and delivers it to consciousness. According to Moscovitch, the hippocampal system is an associative module that mediates associative encoding and associative retrieval. If we have formed a good association between the target cue and the intended action, and if the cue is fully processed at retrieval, then this associative module should rapidly, obligatorily, and with few cognitive resources deliver the intended action (press the slash key) to consciousness.

There are several results that are consistent with this theory. One comes from introspective reports of participants who often remark that the thought to perform the intended action appeared to pop into their mind while performing the ongoing task (Einstein and McDaniel, 1990). Also, Reese and Cherry (2002) found very little evidence that participants were monitoring while performing an ongoing task. They probed participants at various points during the ongoing task and asked them to indicate what they were thinking about. Both younger and older adults rarely indicated thinking about the prospective memory task (less than 5% of the time, compared with reporting thoughts of the ongoing task about 69% of the time). Even so, prospective memory performance was at a reasonable level (about 60%). Also consistent with the spontaneous retrieval theory is the finding that subjects who demonstrate no costs or task interference when performing an ongoing task (and are therefore unlikely to be monitoring) can still exhibit very high levels (93%) of prospective memory (Einstein et al., 2005, Experiment 4). We should also note that the previously described findings of negative effects of dividing attention on prospective memory do not unambiguously argue against spontaneous retrieval. At this point in our research, it is not clear exactly how dividing attention affects performance. For example, dividing attention may interfere with full processing of the target event, which may be essential for good spontaneous or associative retrieval (Moscovitch, 1994). Or, it may not interfere with retrieval of the intention but, instead, may increase working memory demands to such a degree that participants have difficulty selecting the retrieved intention and scheduling the intended action while it is still activated in working memory (Einstein et al., 1997).

The discrepancy plus attribution theory also explains how retrieval can occur spontaneously and in the absence of monitoring. It assumes that the processing of the target event leads to a feeling that there is something significant about the event, and this in turn leads to a search of memory for an explanation of its significance. Depending on how well the intention was encoded, this search at retrieval can lead to the realization that the event is a cue for an intended action. According to Whittlesea and Williams (2001a,b), people chronically evaluate the quality and coherence of their processing, and they are sometimes sensitive to the discrepancy between the actual quality of processing and the expected quality of processing in that context. This sense of discrepancy is alerting and begs for an explanation, which in the context of a recognition task could lead to the interpretation that the item has been seen before. McDaniel et al. (2004) proposed that these processes can also explain prospective memory retrieval. Specifically, the idea is that the target event, on the basis of its initial processing during the encoding of the intention, will, when it appears again in the context of the ongoing task, be processed more fluently (than other items in the ongoing task), and this discrepancy is likely to elicit a sense of significance. In turn, this noticing can lead to a search of memory for the source of the significance, and this can lead to the realization that the event is a cue for an intended action.

There has been recent support for this theory from research manipulating the prior exposure of the target item relative to the ongoing task items. McDaniel et al (2004) created a high-discrepancy condition by presenting the target words during the initial instruction and not preexposing the nontarget items. That is, none of the ongoing task items appeared in a preceding list-learning task, but the prospective memory target item appeared during the instructions for the prospective memory task items. In this condition, the target item should have been processed more fluently relative to the ongoing task items and thus should have produced discrepancy and a sense of significance. In the low-discrepancy condition, the ongoing task items were preexposed in a preceding list learning task. Thus, there should have been less discrepancy in the fluency of processing the target items relative to ongoing-task items. Consistent with the discrepancy attribution theory, prospective memory performance was better in the high-discrepancy condition than in the low-discrepancy condition.

Breneiser and McDaniel (2006) have recently provided additional support for this theory by showing that it is not simply greater familiarity for the target item but, rather, the discrepancy between the actual quality of processing and the expected quality of processing that is critical for determining a sense of significance. They found that preexposing ongoing task items four times each in a preceding list-learning task relative to one preexposure for the target items (high-discrepancy condition) led to better prospective memory performance than one preexposure of both the target and ongoing task items (low-discrepancy condition). Other evidence consistent with the general idea that discrepancy can stimulate a search for significance comes from research showing that manipulations that increase the noticing of the target event, such as making the target event distinctive (e.g., a target word presented in upper case letters with the ongoing task items in lower case letters), produced very high prospective memory performance (McDaniel and Einstein, 1993; Brandemonte and Passolunghi, 1994).

### 2.45.4.3 Multiprocess Theory

So, which processes do we rely on for prospective remembering? According to the multiprocess view (McDaniel and Einstein, 2000; see also Einstein and McDaniel, 2005; Einstein et al., 2005; McDaniel and Einstein, 2007: Chapter 4), there are many reasons to believe that the human cognitive system uses both monitoring and spontaneous retrieval processes for prospective remembering. First, given the prevalence and importance of prospective memory demands in the real world, it would be adaptive to have a system that relies on multiple processes for prospective memory retrieval and thus increases the chances that we will remember under a variety of conditions. Second, given that the delays between forming an intention and the opportunity to execute the intention are often substantial (on the order of several hours or more), it would seem maladaptive to have a system that relied exclusively on capacity consuming monitoring processes for successful retrieval. In Smith's (2003) research, for example, monitoring for target events slowed down lexical decision times by about 45% (Experiment 1). If we relied entirely on monitoring processes for successful prospective remembering, then the efficiency with which we performed the intervening ongoing activities in our lives would be severely compromised. Third, the view that participants sometimes (perhaps most often) rely on spontaneous retrieval processes fits with Bargh and Chartrand's (1999) theory that we have a limited capacity for conscious control over behavior and therefore much prefer to rely on automatic or unconscious processes. Consistent with this idea, several studies have shown that exerting conscious control over behavior in one phase of an experiment leads subjects to expend less conscious effort in a later phase (e.g., Baumeister et al., 1998). From this perspective, the cognitive system is limited in the extent to which it is able to maintain controlled monitoring of the environment for target events.

Fourth, the idea that we sometimes rely on spontaneous retrieval processes and sometimes augment these processes with capacity-consuming monitoring processes has the potential to explain some apparently inconsistent results. For example, although dividing attention often interferes with prospective memory, there are conditions under which dividing attention has no effect on performance (McDaniel et al., 2004). An explanation of this pattern of results is that dividing attention will interfere with prospective memory primarily in those conditions in which monitoring is useful for prospective memory retrieval but will have minimal effects under those conditions in which spontaneous retrieval processes are effective in producing retrieval.

There are three assumptions to the multiprocess view. One is that prospective remembering can be supported by several different kinds of processes ranging from strategic monitoring of the environment to spontaneous retrieval processes. A second assumption is that the process that people rely on in a particular situation and the effectiveness of that process for producing retrieval depend on a host of factors, including the nature of the prospective memory demand, the demands and characteristics of the ongoing task, and the characteristics of the individual. For example, if people can anticipate that they will later encounter a salient retrieval cue for prospective memory, they are more likely to rely on spontaneous retrieval processes. If, on the other hand, it would be catastrophic to forget the intended action and the delays are fairly brief, people may initiate and maintain an active monitoring strategy over the delay interval. A third assumption, and in line with the theory of Bargh and Chartrand (1999) noted above, the multiprocess theory assumes that people have a bias to rely on spontaneous retrieval processes.

As just noted, according to the multiprocess theory, certain conditions make it more likely that the presence of the target event spontaneously triggers retrieval of the intention (McDaniel and Einstein, 2000; see McDaniel and Einstein, 2007: Chapter 4, for further discussion of relevant variables). Assuming good encoding of the intention, an important variable, for example, is the extent to which the ongoing task encourages focal processing of the target event. This idea, which is an extension of the retrospective memory theory of transfer-appropriate processing (see more about this later, and see Morris et al., 1977), is that spontaneous retrieval is likely to occur to the extent that the ongoing task directs attention to the target event and encourages processing of those features that were processed at encoding or planning (see **Table 2** for examples of conditions McDaniel and Einstein believe do and do not encourage focal processing). On the other hand, with nonfocal cues, spontaneous retrieval is less likely, and successful retrieval is more dependent on monitoring for the target event.

The multiprocess theory assumes that subjects are generally sensitive to the conditions that lead to spontaneous retrieval (e.g., focal cues) and those that demand active monitoring for the target event (e.g., nonfocal cues). This idea is similar to that of Marsh et al. (2003; see also Marsh et al., 2006), who believe that subjects develop an allocation policy that is based on their perceived difficulty of performing the ongoing task and the prospective memory activities. For example, if subjects believe that the prospective memory task will be difficult, they will allocate attentional resources to monitoring for the

**Table 2** Representative examples of task conditions, some of which have been used in published research, that we assume are high and low in focal processing

| *Processing* | *Ongoing task* | *Prospective memory task* |
|---|---|---|
| Nonfocal | Words were presented in the center of a computer monitor and participants had to learn them for recall tests that occurred at unpredictable times. | Respond when you see a particular background pattern (background pattern changes every 3 s). |
| Focal | Participants had to keep track of the number of occurrences of each background screen pattern. | Respond when you see a particular background pattern (background pattern is changed every 3 s). |
| Nonfocal | Lexical decision task | Respond to items from the animal category. |
| Focal | Lexical decision task | Respond to the word ‘cat.’ |
| Nonfocal | Pairs of words were presented, and participants decided whether the word on the left was a member of the category on the right. | Respond to the syllable ‘tor.’ |
| Focal | Pairs of words were presented, and participants decided whether the word on the left was a member of the category on the right. | Respond to the word ‘tortoise.’ |
| Nonfocal | Pictures of famous faces were presented, and the task was to name the face. | Respond when you see a face with eyeglasses. |
| Focal | Pictures of famous faces were presented, and the task was to name the face. | Respond when you see a face with the first name of John. |

From Einstein GO and McDaniel MA (2005) Prospective memory: Multiple retrieval processes. *Curr. Dir. Psychol. Sci.* 14: 286–290.

target event. Marsh et al. believe that this allocation policy is dynamic and varies in response to subjects' changing perceptions of the difficulty of prospective memory and ongoing tasks change.

## 2.45.5 Storage of Prospective Memories: Do They Enjoy a Privileged Status in Memory?

Because prospective memories are formed with the goal of later retrieving them in the appropriate context, some researchers have suggested that they may have special storage properties. Indeed, Goschke and Kuhl's (1993) seminal work suggests that intentions may hold privileged status in memory. In their work, participants were asked to learn pairs of scripted actions for, say, clearing a messy desk or setting a table (e.g., actions might be: distribute the cutlery, polish the glass, light the candle, etc.). After learning, participants were told that one script in the pair would have to be performed later. In an immediate recognition test, latencies were faster to words coming from the to-be-performed script as opposed to the neutral script about which there was no prospective intention. Marsh et al. (1998a) replicated this decreased latency effect using a lexical decision task but also discovered that if the assessment of activation came after performing the script, then latencies were slower to the already-performed script as compared with the neutral script. Applying the standard interpretation that faster latencies are associated with information being more accessible in memory, Goschke and Kuhl concluded that prospective memories enjoy a privileged status in memory, whereas Marsh et al. concluded additionally that a prospective memory, once completed, goes into a state of being temporarily inhibited, which could be ecologically adaptive in planning what activities one has to do next.

There are converging reports to suggest that prospective memories reside in a privileged state. For example, Maylor et al. (2000) asked younger and older adults to list their plans for the coming week and also to list what they completed in the previous week. The conditions under which they did so were speeded, and participants were asked to write two or three words to describe each future intention or each completed intention. Consistent with the intention superiority effect (ISE), younger adults listed more future plans than they did completed activities, ostensibly because the future plans were more available in memory. In contrast, the older adults did not. Lebiere and Lee (2002) modeled Marsh et al.'s (1998) data using the ACT-R assumptions (Anderson and Lebiere, 1998) that prospective memories represent a goal node in that model. According to ACT-R, goal nodes receive constant sources of activation, and this facet of the model would account for their higher accessibility in memory. In measuring cue interference, Marsh et al. (2002b) found that prospective memory cues that were missed (i.e., that were not detected and that had received no prospective memory response) in a lexical decision task were responded to more quickly than control-matched items. Because they used a categorical intention to respond to animals, Marsh et al. assumed that they had found a more specific version of the ISE. That is, because intention-related material has privileged accessibility, it is processed more quickly even when the cue does not elicit a prospective memory response (but see West et al., 2005).

Marsh et al. (2008) have recently reported a related, very provocative finding. In this study, participants were asked to pay attention to a visual stream of words and actively ignore the information presented in an auditory channel. The participants were also given the prospective memory task of responding to a categorical intention (e.g., vegetables) when an exemplar appeared in the visual channel of information. Participants were then tested on their memory for only information presented in the to-be-ignored auditory channel. Recognition of intention-related material in the to-be-ignored channel was significantly better than control-matched material in the same channel. Marsh et al. interpreted these results as consistent with the ISE, in which intention-related material gains more obligatory access to consciousness than comparable material about which there is no intentionality.

As an alternative to the ACT-R account, if one assumes a network model of memory, then whenever plans and intentions are considered or otherwise brought into consciousness, some small amount of activation might accrue to other plans and intentions, and this process could keep them in a higher baseline resting state. Combined with a view that prospective memories are revisited from time to time, whereas retrospective memories probably receive fewer such rehearsals, then perhaps some confluence of these different explanations is what actually confers a special status on prospective memories. Of course, this general perspective is not without its opponents. In their original report, Marsh et al. (1998; see also

Marsh et al., 1999) were somewhat skeptical that a critic would necessarily adopt the notion that prospective memories were stored in a more accessible fashion. They argued that an alternative conception of the ISE is that prospective memories reside as declarative representations with the same level of baseline activation in their resting state as do retrospective memories. As such, prospective memories may be able to be revived faster because they are more elaborately encoded or because they are related to one's self schema. Also, Freeman and Ellis (2003) report boundary conditions on the ISE. In their report, they used subject-performed tasks (e.g., clap your hands), and they found an ISE only with verbal encoding and not if people learned the tasks motorically. Consequently, the ISE may be a verbal learning phenomenon. If so, this finding may not really constrain the generality of the effect because most of our everyday intentions are self-generated from thoughts.

There are no published reports contravening the ISE other than Maylor et al.'s (2000) failure to find the effect in older adults and Freeman and Ellis's (2003) failure to find it with motoric encoding. Unfortunately, this does not mean that the ISE is not a major contributor to the file drawer problem. After the Marsh et al. (1998) article appeared, Richard Marsh was contacted by many people for stimulus materials expressing an interest in testing older adult populations in order to assess whether older adults fail to inhibit after completing a prospective memory task. Because none of these reports have appeared in the last decade, one cannot help but wonder just how robust the ISE truly is. Of the many effects found in prospective memory, the ISE stands alone because it is a tantalizing proposition that the human memory system would have evolved to single out our ancestors' intentions as privileged material. Of course, from an evolutionary perspective, it would be advantageous if our ancestors who were proactive about finding food, water, shelter, and a mate survived and thrived more readily as opposed to being reactive toward these basic needs. The ISE is one of those phenomena in the realm of prospective memory that needs to be scrutinized more carefully than it has been in the scientific record to date. Only a handful of reports have been published on the effect, but any theoretical influence the ISE has on clock checking or the probability of an event-based cue being recognized needs to be based on a deeper understanding of the basic phenomenon and why it occurs.

## 2.45.6 Encoding of Prospective Memories

The work on encoding has reflected two general orientations: (1) the influence on prospective memory performance of instructions or experimental conditions that guide encoding of the intention to perform an action in the future (including encoding of the target event that signals the appropriateness of performing the intention) and (2) the nature of planning processes that people display in the absence of instructions directing specific encodings. Most of the research has centered on the first topic, and accordingly our review concentrates on that research.

### 2.45.6.1 Associative Encoding

A primary finding is that instructions or conditions that foster associative encoding of the target cue and the intended action tend to improve prospective memory performance. This finding resonates well with the reflexive associative theory presented earlier. Several aspects of this finding merit amplification. First, as is elaborated later, associative-encoding manipulations do not always produce improvements in prospective memory, and this may be because of the nature of laboratory tasks. In laboratory prospective memory tasks, where the participants are instructed to perform an intended action in the presence of a particular cue event, it is especially likely that people are spontaneously encoding a target cue–intended action association. Consequently, instructions specifically designed to augment such associative encoding could be redundant with the encoding already engaged by participants.

A second key pattern is that prospective memory effects of at least one type of associative-encoding manipulation may be accompanied by signatures of spontaneous retrieval. This pattern is consistent with the reflexive-associative theory described earlier that assumes that retrieval of an encoded target cue–intention association can be mediated by an automatic associative memory system.

One general technique to stimulate associative encoding that people can be instructed to use is an implementation intention (Gollwitzer, 1999). An implementation intention specifies situational cues for initiating an intended action and a technique to link these specific cues to the intention by using a condition-action statement such as: If situation *x* arises, I will perform *y*. However, in the experimental work on prospective memory, laboratory instantiations of an implementation intention have varied. Cohen and Gollwitzer's (2007) implementation intention required subjects to write down three times the implementation intention (e.g., "If I see the word *window* at any point in the task [lexical decision], I will say *wrapper* as fast as possible!"). The implementation intention produced a significant advantage in prospective memory over a standard prospective memory instruction that simply told participants to say a response word upon seeing the cue word (but without repetitive writing of the instruction), even though the standard instruction group displayed relatively high prospective memory performance.

In other experiments, the implementation intention involved both saying aloud the condition–action statement and a period of encoding (typically 30 s) during which subjects imagined themselves performing the intended action upon seeing the target cue (Chasteen et al., 2001). Prospective memory performance improved under these conditions relative to a control not given implementation intention instructions for both younger adults (Howard et al., 2006) and older adults (Chasteen et al., 2001). Furthermore, it appears that the imagery encoding alone is not sufficient to produce the benefits (Einstein et al., 2003, Experiment 3; Howard et al., 2006, Experiment 2), even though imagery encoding would presumably be fostering associative linkages between the target event and the behavior (McDaniel and Pressley, 1987). Thus, based on current evidence, it seems that the full implementation intention procedure (imagery plus the if … then statement) is most likely to create positive effects of this kind of associative-encoding instruction.

It is important to note, however, that the full implementation intention procedure does not always yield improvements in prospective memory (Kardiasmenos et al., 2004; Bennett et al., 2005; see also Chasteen et al., 2001; Howard et al., 2006, for other instances of null effects with implementation intentions). These findings dovetail with the first point made above. Participants under standard prospective memory instructions may at least sometimes spontaneously form good associative encodings of the target cue–intention action, thereby rendering experimenter-instructed associative encoding procedures unnecessary.

Another possibility is that even when implementation intentions do not affect levels of prospective memory, the processes underlying prospective memory retrieval may be altered. Under standard prospective memory instructions, attention-demanding retrieval processes (e.g., monitoring) might be recruited (processes that in some cases support relatively high levels of prospective memory; McDaniel et al., 2006; Cohen and Gollwitzer, 2007), whereas with an implementation intention, encoding relatively automatic retrieval processes may prevail (see section 2.45.4 for details of these processes). The limited evidence is consistent with this possibility. For instance, in Cohen and Gollwitzer (2007), response times to the ongoing activity (lexical decision) did not differ between the implementation intention condition and a control for which there was no prospective memory task (implicating relatively spontaneous retrieval processes), yet in the standard prospective memory condition, the response times were significantly longer relative to the no-prospective memory control (this cost implicating a demanding process for prospective memory). Further, Howard et al. (2006, Experiment 2) substantially increased the demands of the ongoing activity (by requiring random number generation as a secondary task). Prospective memory performance significantly declined relative to a condition without the demanding ongoing activity (random number generation was not required) with standard prospective memory instructions but not with implementation intention instructions.

The benefits of focusing encoding on the association between the target cue and the intended action are underscored by another type of finding. In one paradigm, after encoding the prospective memory intention, participants were interrupted several times during the ongoing task and re-presented with aspects of the prospective memory instructions (Guynn et al., 1998, Experiment 3). Some participants were presented with only the target cues, others were presented with the intention, and still others were presented with the target cues and the associated intended action. In all cases, participants were instructed to think only about the information presented. Thus, these conditions reflect additional encoding of target cues, the intention, or both. The differences in prospective memory performance as a function of the type of additional encoding were pronounced. Additional encoding of target cues alone and intention alone produced relatively low performance (36% and 56% prospective memory responding, respectively), whereas additional encoding of the target cue–intention pairs promoted high prospective remembering (82%).

### 2.45.6.2 Target Cue Encoding

An interesting aspect of the above results is that repeated encoding of target cues produced no increases in prospective remembering relative to a single-encoding control condition. Ample evidence indicates, however, that the quality of the target-cue encoding plays a role in successful prospective remembering. Paralleling the retrospective memory literature, semantic encoding of the target cue tends to improve prospective memory performance relative to nonsemantic encoding (McDaniel et al., 1998, Experiment 3), generating the target cue at encoding improves prospective remembering relative to reading the target cue (Matthews, 1992; Robinson-Riegler, 1994, Experiment 1), and presenting the referent of the target cue as a picture at encoding produces better prospective memory performance than presenting the cue as a word (even when the presentation of the cue during retrieval is in a different modality than at encoding; McDaniel et al., 1998, Experiment 2). Similarly, dividing attention during encoding of the target-cue significantly attenuates prospective remembering (Einstein et al., 1997).

Further, elaboration of the target-cue prior to its specification as a prospective memory target event appears to enhance prospective remembering. In one study, prior to the prospective memory instructions, some participants repeatedly generated the target cue (from word fragments or anagrams). These participants evidenced high levels of prospective memory under both standard and demanding ongoing task demands. In contrast, participants who generated words that were not subsequently used as targets displayed a significant reduction in prospective memory when ongoing task demands became more challenging (Guynn and McDaniel, in press; see Mantyla, 1994, for a similar finding).

It is worth noting that the positive effects of elaborative encoding of the target cue are entirely compatible with the theories of prospective memory retrieval reviewed in the preceding section. Such encoding would be expected to lead to better recognition of the cue during the retrieval period (assuming the PAM theory) or to create more discrepancy between subsequent processing of the target cue and nontarget events (assuming the discrepancy-attribution processes), thereby facilitating noticing of the target cue in the retrieval context. Even the reflexive-associative approach assumes that interaction of the cue with a memory trace (e.g., the intended action) is facilitated by initial encodings that are more semantic or distinctive (Moscovitch, 1994).

## 2.45.7 Similarities and Differences Between Prospective and Retrospective Memory

Given the formal distinction between prospective and retrospective memory, it may be tempting to focus on their differences and perhaps even to appeal to different memory systems; however, this approach would overlook many similarities as well as undercut our exploration of how our rich conceptualization of retrospective memory can help us understand prospective memory (see Marsh et al., 2006, for a more detailed treatment of the similarities and differences between retrospective and prospective memory). As a fundamental starting point, consider that prospective memories share three basic stage-like histories with retrospective memories, namely, encoding, retrieval, and any changes that occur over a retention interval (as reflected in the content of the previous sections; cf. Ellis, 1996). Intentions occur as a function of direct requests from others, or they are self-initiated. No work to date has experimentally examined the fate of these two basic types of intentions. However, even a cursory analysis or Gedanken experiment would suggest that the former type should go unfulfilled more frequently than the latter (with notable exceptions arising such as not breaking social contracts). The reason for this is twofold. First, self-generated information may undergo more rehearsals because it is self-referential in nature. Second, prospective memories that are self-referential may be more elaborately encoded and better linked to present and future contexts. More generally, for both of the same reasons that self-defined intentions may be completed more often than requests from others, prospective memories may be more durable than retrospective memories as a consequence of the manner in which they are encoded and/or rehearsed (see West and Krompinger, 2005, for an empirical approach designed to maximize similarities in order to identify fundamental differences).

To elaborate, when an intention is formed, a host of self-referential information is stored, such as why we want to complete the task, the costs and benefits of doing (or not doing) so, the current context, and the future context we might be in at the time of completion. Because material that is related to one's self is better remembered (e.g., Klein and Kihlstrom, 1986), prospective memories may be more durable than otherwise equivalent retrospective memories. More elaborated intentions that are stored more durably in memory also should have a higher probability of coming to mind during the retention interval. Just like a retrospective memory, the more frequently a memory is rehearsed, the better it will be recalled on a subsequent occasion (called retrieval sensitivity by Mäntylä, 1994). So, based on the properties of encoding, one cannot make a blanket statement that all prospective memories will be remembered more faithfully than retrospective memories, only that on average, the amount of effort expended in creating a prospective memory could be greater than in creating a simple, everyday retrospective memory. In addition, the contextual details surrounding retrospective memories are usually lost quite quickly (e.g., Bornstein and LeCompte, 1995), whereas they often form the core of a prospective memory. For example, we often plan to fulfill a prospective memory in a particular context, and therefore, a prospective memory will have linked with it at least two contexts (the environment during formation and the one in which we expect to do it). These can serve as important retrieval cues to fulfilling intentions, and when contexts mismatch our expectations, then the consequences can be very grave indeed for intention completion (Cook et al., 2005).

As we said earlier, retrieving intentions is usually a self-initiated act, whereas many times retrieving retrospective memories is not. Of course, exceptions to this rule exist, such as when a third party queries you about your intentions (e.g., "Got plans for this weekend?"). Nevertheless, when we rely on retrieval cues, many of the principles of prospective memory appear to mimic what has been found with retrospective memory. For example, if one has the intention to respond to a word such as 'bat' (as in baseball), then receiving the cue as bat (as in mammal) leads to much worse prospective memory (McDaniel et al., 1998). A form of transfer-appropriate processing is also found in what is known as task-appropriate processing (Marsh et al., 2000; West and Craik, 2001; Maylor et al., 2002). If the features of the ongoing task focus one on the correct aspects of the prospective memory cue, intention retrieval is more successful. As such, a semantic intention to respond to words denoting animals is more successful if the ongoing task encourages semantic, as opposed to orthographic, processing of the items. Also, resource sharing during retrieval appears to have similar effects on prospective and retrospective memories. Dividing attention during either encoding or retrieval generally reduces retrospective memory (Baddeley et al., 1984; Craik et al., 1996) and prospective memory (e.g., Einstein et al., 1997, 1998; McDaniel et al., 2004). One possible difference is that some forms of event-based prospective memory require difficult, centrally mediated divided attention tasks to observe lower rates of responding to prospective memory tasks (Marsh and Hicks, 1998).

Finally, prospective and retrospective memories both share the property that they will change over the course of a retention interval. Obviously, an unrehearsed memory will grow weaker over time and eventually be forgotten. However, most people review their intentions periodically as a part of their daily mental life. Alternatively, cues in the environment can remind us of intentions, such as the sight of one's vehicle serving as a reminder to have the oil changed. These periodic reminders of intentions only serve to strengthen their representation, as we argued earlier. Most retrospective memories do not enjoy such periodic revisitation and more likely fall into desuetude, thereby requiring increasingly stronger retrieval cues over time to recover that information.

## 2.45.8 Development and Prospective Memory

Although there has been much interest in examining prospective memory from developmental perspectives, most of it has been conducted with older adults. This focus on older adults is probably a result of the obvious practical importance of understanding how aging affects prospective memory (e.g., to help inform health care issues related to prospective memory such as medication adherence), but also in response to compelling theoretical issues. We briefly review first the literature with children and then the research with older adults. As might be expected, the research generally shows that older children outperform younger children and younger adults outperform older adults on prospective memory tasks. However, it is also clear that the age differences vary greatly across prospective memory tasks and that there are some tasks on which no age differences are found. Thus, an interesting theoretical and applied challenge for prospective memory researchers is to understand those conditions that are and are not especially difficult for younger children and older adults.

Before reviewing this literature, we briefly raise a methodological issue that is important to consider when examining developmental trends in prospective memory. Given that prospective memory tasks are embedded in ongoing tasks and that demanding ongoing tasks have been shown to interfere with prospective memory (Marsh and Hicks, 1998), it is important to control the demands of the ongoing task across age groups. Otherwise, differences in prospective memory could stem from the ongoing task being functionally more demanding for younger children or for older adults (see Einstein et al., 1997; Kvavilashvili and Fisher, 2007, for discussion of this issue).

### 2.45.8.1 Prospective Memory in Children

Even though there is not a plethora of existing research on prospective memory in children, several interesting results have emerged, and these seem to be stimulating increasing interest (e.g., see Kliegel et al., in press; Kvavilashvili et al., in press). Recent studies examining event-based prospective memory in 5- and 7-year old children generally suggest that age differences are larger on tasks that require more controlled or strategic processes. All of these studies used a variation of Kvavilashvili et al.'s (2001) prospective memory task of asking children to name pictures from stacks of pictures for Morris the Mole because he does not see very well (the ongoing task). The prospective memory task was to hide any picture of animals from Morris because he was scared of them. Kvavilashvili et al. varied whether the animal pictures appeared in the middle or the end of the stack. Five- and 7-year old children both remembered about 75% of the time when the target was at the end of the stack, but the older children did much better than the younger children when the target was in the middle. Thus, the older children were better able to inhibit the ongoing activity in order to perform the intended action. When inhibition was not needed, however, the younger children were as capable of remembering as the older children.

To directly study strategic processes, Stokes et al. (2007) manipulated whether the target event was focal or nonfocal. Children in their study were presented with cards (with four pictures on each card) and asked to name the circled picture on each card (the ongoing task). The prospective memory task was to hide the card if there was an animal on it. In the focal condition, animals always appeared as the circled picture, and thus the ongoing task requirement to name the picture forced processing of the target pictures, which in turn could trigger spontaneous retrieval. In the nonfocal condition, the target picture always occurred in a noncircled location, and thus subjects had to remember to monitor the other locations for the target picture. Whereas the prospective memory performance of the older children was nearly perfect regardless of the cuing condition (around 95%), prospective memory was much higher for the younger children in the focal condition (68%) than in the nonfocal condition (20%). Consistent with this pattern, McGann et al. (2005) found high performance and no differences between 5- and 7-year old children with salient target pictures (when the pictures were larger than others) but higher performance for the older children (relative to the younger children) with nonsalient target pictures. All of these studies suggest that some prospective memory conditions are more difficult for younger children than others. Consistent with the general developmental trend showing that younger children have more limited attentional and working memory resources (e.g., Guttentag, 1984) and with the multiprocess theory (McDaniel and Einstein, 2000), younger children seem to have greater difficulty with prospective memory tasks that require active monitoring of the environment and inhibiting the demands of the ongoing task.

Very little research has examined time-based prospective memory in children. An interesting question with this kind of task is whether children can develop and maintain a clock checking strategy in the absence of a cue to trigger remembering. Ceci and Bronfenbrenner (1985) asked 10- and 14-year-old children either to remember to remove cupcakes from the oven or to remove cables from a battery charger exactly 30 min later. The children performed these tasks either at home or in the laboratory. During the 30-min interval, they were engaged in an entertaining video game, and there was a wall clock at their back. This arrangement allowed the researchers to record monitoring of the clock. Interestingly, most children developed a monitoring strategy, but the strategy varied across the laboratory and home contexts. In the lab, the children monitored the time increasingly more often as the target time approached. In the home setting, children tended to adopt what Ceci and Bronfenbrenner described as a more adaptive U-shaped monitoring pattern. That is, they monitored frequently initially (presumably to calibrate the passage of time) and then very little after that except for the last 5 min before the target time (at which point they monitored frequently). This strategy is adaptive in the sense that it frees up resources for the ongoing video task. Although the large majority of both 10- and 14-year-olds remembered on time, late responding was associated with less strategic monitoring. In light of the surprising finding that very young children (2 years old) can show very good prospective memory for tasks that they consider important (e.g., buying candy at the store; Sommerville et al., 1983), it would be interesting to explore the conditions and age at which strategic monitoring develops.

### 2.45.8.2 Prospective Memory in Older Adults

As noted earlier, the majority of the developmental research has focused on aging issues (for recent papers, see Henry et al., 2004; McDaniel and Einstein, 2007: Chapter 7; McDaniel et al., in press; Phillips et al., 2007; Wilson and Park, 2007). This interest was motivated by both practical and theoretical considerations. The applied concerns included that good prospective memory may be especially important for older adults who often have health-related prospective memory needs like remembering to take medication. Craik's (1986) theory, suggesting that prospective memory should be very difficult for older adults, provided the theoretical thrust. Noting that aging affects some retrospective memory tasks more than others, Craik proposed that aging disrupts self-initiated retrieval processes, and therefore that older adults need greater environmental support or external cuing for accomplishing retrieval. This theory helps explain why age differences are often larger with free recall than recognition tasks. Because prospective memory is not accompanied by an external request to remember (i.e., subjects are not put in a retrieval mode), Craik theorized that prospective memory should be especially demanding in terms of self-initiated retrieval and thus particularly difficult for older adults.

The findings remind us that prospective memory is not a unitary concept and that age differences vary as a function of the nature of the task demands and the contexts in which they are performed. One pattern is what Phillips et al. (2007) describe as the age prospective memory paradox, which is the finding that older adults generally perform more poorly on prospective memory tasks in the lab but perform as well as or better than younger adults in naturalistic settings (e.g., remembering to mail postcards or to call the experimenter on designated days). Indeed, Wilson and Park (2007) discuss the high medication adherence of older adults in the face of declining cognitive functioning as another paradox (but see Insel et al., 2006, for evidence of modest levels of medication adherence by older adults). It is not currently clear what produces this reversal of performance across naturalistic and laboratory settings, but Phillips et al. and others (e.g., Kvavilashvili and Fisher, 2007) have suggested several possible explanations including age differences in conscientiousness, views regarding the importance of punctuality, busyness and structure of lifestyle, perceptions of task importance, and use of reminders (see also Wilson and Park, 2007). Another possible explanation is that older adults have greater control over the pacing of their ongoing activities in natural settings (McDaniel et al., in press).

Even in laboratory settings, however, there is a large range of age effects. Many studies show large age-related deficits in prospective memory (e.g., Maylor et al., 1999), whereas some show modest or no age-related declines in prospective memory (e.g., Einstein and McDaniel, 1990; Cherry and LeCompte, 1999). Henry et al.'s (2004) meta-analysis revealed an interesting pattern that prospective memory tasks that required greater degrees of controlled or strategic processing (i.e., ones with less external support, and thus ones that required greater monitoring) were associated with larger age effects than those that could be accomplished by relatively automatic retrieval processes (i.e., those with good external cues that could support spontaneous retrieval processes). From a cursory interpretation of Craik's (1986) theory, this should not happen; all prospective memory tasks should be difficult for older adults. From a deeper analysis, however, if one considers prospective memory to be a general label for a variety of specific tasks that differ in the extent to which they are cued by environmental events, the data may be consistent with the theory. The data also appear consistent with the multiprocess theory, which assumes that, depending on the conditions, people rely on monitoring versus spontaneous retrieval processes to different degrees in different kinds of prospective memory tasks. This is important as it relates to aging because working memory and attentional resources that are assumed to be needed for monitoring are thought to decline with age (Craik, 1986), whereas relatively automatic retrieval processes may remain relatively intact with age (McDaniel et al., in press).

To evaluate this interpretation, Reese (2004) tested younger and older adults and varied whether the prospective memory cues were focal or nonfocal (see **Table 2**; recall that focal cues are thought to stimulate spontaneous retrieval processes, whereas nonfocal cues are thought to require monitoring for successful retrieval). The ongoing task involved remembering short lists of words, and as every new word appeared, the background pattern of the screen changed. In the focal condition, subjects were asked to press a designated key whenever they saw a particular word, whereas in the nonfocal condition subjects were asked to press a designated key whenever a particular background pattern occurred. Consistent with the multiprocess theory prediction, Reese found that the size of the age difference depended on the type of prospective memory cue such that the age difference was smaller with the focal cue (80% for younger vs. 49% for older) than for the nonfocal cue (80% younger vs. 17% older). Sometimes there is no age difference with focal cues (e.g., Einstein and McDaniel, 1990; Cherry and LeCompte, 1999; McDaniel et al., in press) and sometimes, as in this particular experiment, the age difference is reduced but not eliminated (see also Rendell et al., 2007, Experiment 1). Possible explanations for the existence of age differences in some experiments even with a focal cue conclude that younger adults may be more likely to engage in monitoring and thereby increase the chances of retrieval, and that spontaneous retrieval processes may not be entirely spared with age.

In addition to tasks with nonfocal cues, prospective memory tasks that seem to pose special problems for older adults seem to be time-based tasks (Henry et al., 2004), habitual prospective memory tasks (ones in which the intended action is performed repeatedly; Einstein et al., 1998), and those in which the retrieved intention cannot be performed immediately and must be delayed (as when a person remembers to take her/his medication in the bathroom but then needs to maintain the intention until she/he gets to the kitchen; see McDaniel et al., 2003). In closing this section, we note again the striking finding that the magnitude of the age differences varies greatly across studies. We suspect that we will better understand this pattern as we examine the processes that are recruited for different prospective memory tasks and how aging affects these processes.

## 2.45.9 Cognitive Neuroscience of Prospective Memory

Building upon the considerable advances that have been made in our understanding of the cognitive processes underlying the realization of delayed intentions, significant progress has been made in identifying the functional neuroanatomy of prospective memory. The neural basis of prospective memory has been investigated using complimentary methodologies within the neuropsychological, functional neuroimaging, and electrophysiological traditions. Study in these domains has revealed a number of neurological and psychiatric conditions that are associated with impaired prospective memory as well as illuminating the temporal dynamics of the functional neuroanatomy of prospective memory.

### 2.45.9.1 Neuropsychology

Studies using the neuropsychological approach reveal that impairments of prospective memory are observed in a variety of neurological and psychiatric disorders including traumatic brain injury (TBI; Shum et al., 1999), stroke (Cockburn, 1995), epilepsy (Palmer and McDonald, 2000), multiple sclerosis (Bravin et al., 2000), Parkinson's disease (Kliegel et al., 2005), schizophrenia (Shum et al., 2004), and substance abuse (Hefferman et al., 2001). Additionally, other evidence has revealed individual differences in prospective memory associated with genetic expression (Driscoll et al., 2005; Singer et al., 2006). Together, work in the area of neuropsychology converges with several themes that arise from the cognitive psychological literature. A number of studies reveal that damage to or disruption of neural networks involving the prefrontal cortex results in impaired prospective memory (Cockburn, 1995; Burgess et al., 2000). This finding is consistent with evidence revealing that prospective memory covaries with the efficiency of executive functions (typically thought to be dependent on the functional integrity of the prefrontal cortex) and the availability of working memory capacity (Marsh and Hicks, 1998). Also, disruption of the medial temporal lobe memory network results in impaired prospective memory (Palmer and McDonald, 2000). This finding is consistent with theoretical models of prospective memory wherein similar processes are thought to support prospective memory and explicit episodic memory (Einstein and McDaniel, 1996; Guynn et al., 2001).

The effects of mild to severe TBI on prospective memory have been considered in a number of studies. This research reveals negative effects of TBI on measures of time-, event-, and activity-based prospective memory (Shum et al., 1999) that increase with the severity of the injury (McCauley and Levin, 2004). TBI has an adverse effect on multiple phases of prospective memory including intention formation, re-instantiation, and execution, and it may have a lesser effect on intention retention (Kliegel et al., 2004). Consistent with this finding, individuals with TBI can benefit from reminders that are inserted in the middle of task performance (McCauley and Levin, 2004). The magnitude of the effect of TBI on prospective memory is equivalent when focal and nonfocal prospective cues are used (Schmitter-Edgecombe and Wright, 2004), possibly indicating that patients do not benefit from spontaneous processes underlying the recognition of prospective cues (Einstein et al., 2005). There is also some evidence that indices of monitoring for prospective cues may be relatively intact in patients with TBI (Shum et al., 1999; McCauley and Levin, 2004). Studies examining the effects of TBI on prospective memory have revealed a mixed neuropsychological profile, with some, but not other, groups of patients demonstrating impairments of episodic or declarative memory, processing speed, and executive functions (Kliegel et al., 2004; Schmitter-Edgecombe and Wright, 2004; Mathias and Mansfield, 2005), making it difficult to ascertain whether there is a core deficit underlying the effects of TBI on prospective memory.

There is growing evidence that disruption of the frontostriatal dopamine system leads to impaired prospective memory. At least two studies reveal that schizophrenia can produce deficits of time-, event-, and activity-based prospective memory (Shum et al., 2004; Kumar et al., 2005). The effect of schizophrenia may result from a disruption of the representation of intentions as the intention superiority effect is reduced or absent in patients with this disorder (Kondel, 2002), or from a reduction in the efficiency of strategic monitoring processes (Elvevag et al., 2003; Shum et al., 2004). There is also some evidence that prospective memory is disrupted in Parkinson's disease (PD; Katai et al., 2003). Furthermore, the effect of PD on prospective memory may result from a reduction in the efficiency of processes supporting the formation and realization of intentions rather than processes supporting the representation of an intention in memory (Katai et al., 2003; Kliegel et al., 2005). Finally, data from two studies indicate that the recreational abuse of MDMA, or Ecstasy – which is known to be toxic to dopaminergic and serotonergic neurons (Ricaurte et al., 2002) – results in both self-reported (Heffernan et al., 2001) and laboratory-based (Zakzanis et al., 2003) prospective memory deficits.

### 2.45.9.2 Functional Neuroimaging

Data from studies using functional neuroimaging methods generally converge with those from the neuropsychological literature. Specifically, PET and fMRI studies reveal activation of a broadly distributed neural network during the performance of prospective memory tasks that includes the rostral and lateral frontal cortex, structures within the medial temporal lobe, parietal cortex, and the thalamus (Okuda et al., 1998; Burgess et al., 2001; Simons et al., 2006). Functional neuroimaging techniques also reveal neural correlates of processes that may distinguish prospective memory from working memory, vigilance, and divided attention (Reynolds et al., 2003; De Bruycker et al., 2005).

Evidence from one line of research reveals that the recruitment of rostral frontal cortex is important for the realization of delayed intentions (**Figure 3**;

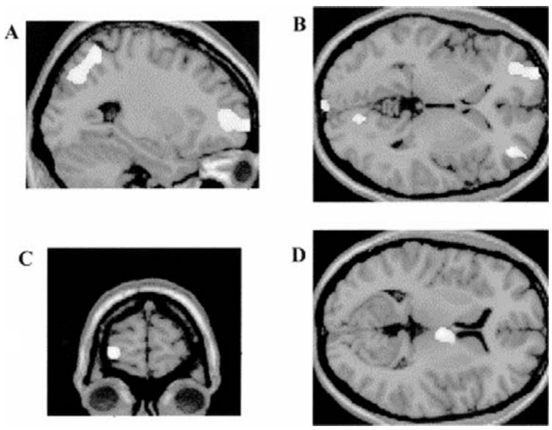

**Figure 3** Functional activation differentiating (execution + expectation) – ongoing alone (a–c) and execution – expectation (d) conditions. Parts (a) and (b) portray activation within lateral rostral PFC, (c) portrays activation in right lateral prefrontal cortex, and (d) portrays thalamic activation. Adapted from Burgess PW, Quayle A, and Frith CD (2001) Brain regions involved in prospective memory as determined by positron emission tomography. *Neuropsychologia* 39: 545–555.

Burgess et al., 2001, 2003). In tasks requiring event-based prospective memory, the lateral rostral frontal cortex is consistently activated, while the medial rostral frontal cortex is often deactivated (Burgess et al., 2003). In contrast, in tasks requiring time-based prospective memory, this pattern may be reversed, revealing activation of medial rostral frontal cortex and deactivation of lateral rostral frontal cortex (Okuda et al., 2001). Variation in the respective roles of the lateral and medial rostral frontal cortex across a variety of tasks has served as the impetus for the development of the Gateway hypothesis, wherein rostral frontal cortex is believed to play a role in switching the focus of one's attention between stimulus-dependent and stimulus-independent aspects of information processing that may be critical for the realization of delayed intentions (Burgess et al., 2005). For instance, as applied to the typical prospective memory paradigm, the rostral frontal cortex may support the ability to switch from a focus on attributes of a stimulus that are relevant to performance of the ongoing activity to a focus on attributes of a stimulus that are internally represented, such as the cue-intention association.

Using PET, Burgess et al. (2001, 2003) sought to determine whether the rostral frontal cortex was involved in the maintenance or realization of delayed intentions. In the baseline condition of these studies, individuals simply performed one of three ongoing activities; in the expectation condition, individuals anticipated the presentation of prospective cues, but cues were never presented; in the execution condition, individuals anticipated prospective cues – and cues were in fact presented. A comparison of neural recruitment in the expectation + execution conditions versus the baseline condition revealed bilateral recruitment in lateral rostral frontal cortex, right parietal cortex, and the precuneus region, while a comparison of neural recruitment in the expectation and execution conditions did not reveal activation in these regions. This finding led to the suggestion that rostral frontal cortex was associated with cognitive processes that support the maintenance of an intention during the delay period (e.g., preparatory processing, Smith, 2003), rather than processes related to the realization of an intention once the prospective cue was detected (Burgess et al., 2001).

fMRI has also been used to examine item-level or event-related neural recruitment associated with processes underlying prospective memory. Evidence from one study reveals what may reflect a neural correlate of item checking described in the strategic monitoring account of prospective memory (Guynn, 2003; Smith, 2003). De Bruycker et al. (2005) compared neural activity for ongoing activity stimuli when the ongoing activity was performed in isolation or when it was performed in the context of a prospective memory task. This comparison revealed increased activation in the medial and lateral extrastriate cortex for ongoing activity stimuli presented during the prospective memory condition relative to the ongoing activity condition. This basic finding was replicated by Reynolds et al. (2003), who observed decreased activation for prospective cues that were presented in a prospective memory condition relative to a simple vigilance condition. The decrease in activation for prospective memory cues from the prospective memory condition to the vigilance condition is consistent with the idea that the addition of a prospective memory component to a task may require the reallocation of processing resources between the prospective and ongoing components of the task (Smith, 2003; Marsh et al., 2006b).

### 2.45.9.3 Electrophysiology

Studies incorporating the event-related potential (ERP) methodology have sought to address three fundamental issues related to the neural basis of event-based prospective memory. First, work in this area has sought to identify the temporal dynamics of the neural correlates of prospective memory. Second, investigations in this area have sought to determine whether the neural correlates of prospective memory can be distinguished from other modulations of the ERPs related to target processing. Third, other investigations have sought to link the neural correlates of prospective memory to cognitive processes described in theories of prospective memory.

Work examining the temporal dynamics of the neural correlates of prospective memory has consistently revealed three modulations of the ERPs that are associated with the realization of delayed intentions (**Figure 4**; N300, parietal old–new effect, and prospective positivity; West et al., 2001; West and Krompinger, 2005). The N300 reflects a phasic negativity over the occipital-parietal region of the scalp that typically emerges between 300 and 400 ms after onset of the prospective cue and is often accompanied by a positivity over the midline frontal region of the scalp (West et al., 2001; West and Ross-Munroe, 2002). The amplitude of the N300 is greater for prospective hits than for prospective misses, leading to the suggestion that it is associated with processes

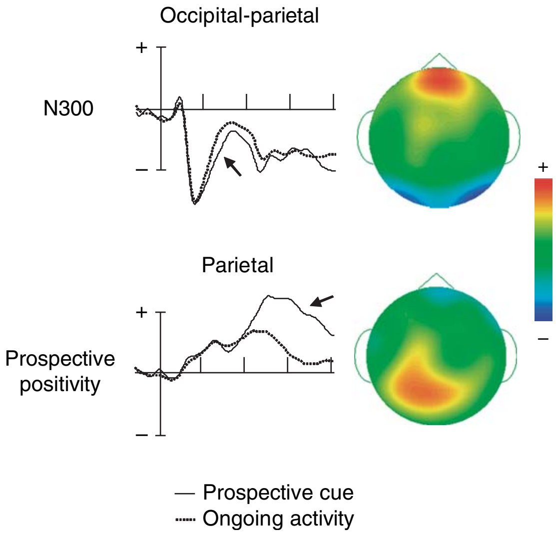

**Figure 4** Grand average ERPs and scalp topography maps as viewed from above, demonstrating the time course and topography of the N300 and prospective positivity. Adapted from West and Wymbs (2004) and West and Covell (2001).

supporting the detection of prospective cues (West and Ross-Monroe, 2002). The N300 is elicited by prospective cues that are defined by letter case, color, and word identity, indicating that it reflects a relatively generic process that is associated with prospective memory (West et al., 2001; West et al., 2003; West and Krompinger, 2005). The parietal old–new effect and prospective positivity reflect enhanced positivity over the parietal region of the scalp between 400 and 1000 ms after stimulus onset (West et al., 2001; West and Krompinger, 2005). The parietal old–new effect reflects a relatively general process that is associated with item recognition in recognition memory (Rugg, 2004) and prospective memory paradigms; the prospective positivity is more specific to prospective memory and may reflect processes that serve to coordinate the prospective and ongoing components of the task once the prospective cue is detected and the intention is retrieved from memory (West and Krompinger, 2005).

An example of research addressing the second issue is portrayed in a study comparing the prospective positivity and the P3 component. Given similarities between the time course and topography of the prospective positivity and P3 component, one might wonder whether the prospective positivity reflects a general index of target categorization in prospective memory paradigms (West et al., 2003). To examine this question, West et al. (2006) examined the effects of working memory load on the amplitude of the prospective positivity and the P3 component. The logic of the study was this: If the prospective positivity and P3 arise from the activity of similar processes, then both should be sensitive to working memory load (Gevins et al., 1996); in contrast, if the prospective positivity and P3 reflect distinct processes, then there may be differential effects of working memory load on these two modulations of the ERPs. The data from this study support the latter hypothesis, as the amplitude of the P3 for target stimuli decreased with increasing working memory load (**Figure 5**), while the amplitude of the prospective positivity was unaffected by increasing working memory load (West and Bowry, 2005; West et al., 2006). These data demonstrate that that the neural correlates of prospective memory, in this case the prospective positivity, can be dissociated from processes that are more generally related to target categorization or selection.

Following from work examining the temporal dynamics of processes underlying prospective

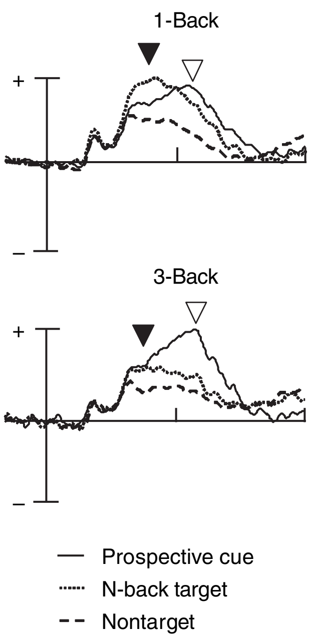

**Figure 5** Grand average ERPs for prospective cue, N-back target, and nontarget trials at electrode, Pz demonstrating the effect of N-back load on the P3, but not the prospective positivity. The filled arrow marks the P3, and the unfilled arrow marks the prospective positivity. Adapted from West R, Bowry R, and Krompinger J (2006) The effects of working memory demands on the neural correlates of prospective memory. *Neuropsychologia* 44: 197–207.

memory, other investigations have sought to determine whether modulations of the ERPs associated with the realization of delayed intentions possess the characteristics of cognitive processes described in theories of prospective memory. Two such studies have examined the influence of the working memory demands of the ongoing activity and strategic monitoring on the N300 (West et al., 2006; West, in press a). Based on strategic monitoring accounts of prospective memory, the amplitude of the N300 was expected to decrease as the working memory demands of the ongoing activity increased; in contrast, based on the discrepancy plus search account, the N300 was not expected to be sensitive to working memory load. The application of partial least squares analysis (McIntosh et al., 1996) – which allows one to decompose the effects of different experimental manipulations on the ERPs into a set of orthogonal latent variables – revealed that the N300 was expressed by two latent variables (West et al., 2006): one that was sensitive to N-back load and expressed the N300, but not the prospective positivity, and one that was insensitive to N-back load and expressed the N300 and prospective positivity. The results of this study reveal two important findings. First, consistent with the multiprocess view of prospective memory, these data reveal that both relatively automatic and more resource demands processes contribute to the detection of prospective cues. Second, these data reveal that the N300 and prospective positivity may be coupled to one another, a finding that is consistent with the general architecture of the discrepancy plus search theory (West, in press b).

## 2.45.10 Summary

Although ignored for many years, and indeed characterized as a forgotten topic 25 years ago (Harris, 1984, p. 71), research since that time has proven prospective memory to be an experimentally tractable and theoretically exciting area. Laboratory and nonlaboratory paradigms have been developed to examine prospective remembering under a variety of situations, and theoretical issues are stimulating rich understanding of the cognitive processes and neural mechanisms underlying prospective memory. Because the memory literature has focused on memory tasks in which experimenters initiate retrieval by putting subjects in a retrieval mode, it has ignored the important capability of humans to plan for future events and then later perform them in the appropriate circumstance. It appears that this self-initiated characteristic of prospective memory has important implications for considering optimal encoding, storage, and retrieval processes (see Ellis, 1996; Dobbs and Reeves, 1996). As our understanding of prospective memory has developed, and consistent with contextualistic views of memory (Jenkins, 1979), it also appears that prospective memory is not a unitary concept and, instead, that different processes are involved in different prospective memory tasks. We believe that it will be important, for both theoretical and applied concerns, to carefully examine these processes and the extent to which they are prominent in different prospective memory tasks.

# 2.46 Autobiographical Memory

**M. A. Conway and H. L. Williams**, University of Leeds, Leeds, UK

## 2.46.1 Introduction

The term autobiographical memory refers to our memory for specific episodes, episodic memory, and to our conceptual, generic, and schematic knowledge of our lives, autobiographical knowledge. Typically these two types of long-term memory representation are brought together in an act of remembering where they form a specific memory. Consider the following example:

> My earliest memories relate to a time in my childhood when we were living in Malta. I was about four years old. We lived in the most glorious Italian house on the sea which had a great big flagstone hall and shutters looking out to the sea and a sweeping staircase that led up to the first floor and, I think this is true, but it seems wrong somehow because my parents were very kind to me. I remember having to stand looking at the wall halfway up the stairs because I couldn't remember the days of the week and I was taught them with reference to the gods, you know, Thor's day, Woden's day and so forth, and that I remember very vividly. One lunchtime I was asked to repeat them and I couldn't remember them and my father told me to go and stand halfway up this great big sweeping staircase and just look at the wall. (Taken from the BBC Radio 4 Memory Survey, July 2006, which collected 11,000 memories from the general public.)

There are various segments of autobiographical knowledge in this memory, e.g., when we lived in Malta, my parents were kind to me, some generic visual imagery, e.g., how various features of the house looked, and some highly specific knowledge of time, locations, and actions. Autobiographical memories very frequently come to mind as these compilations of different types of knowledge are configured into a memory in a specific act of remembering. As such they clearly illustrate the highly constructive nature of autobiographical remembering. We will return to memory construction in a later section, but now that we have some idea of what is meant by the term autobiographical memory, we might ask about how it has been studied. After all, autobiographical memories are personally important memory representations. They are the content of the self and define who we are, who we have been, and, importantly, who we can yet become. They enable us to have a past, present, and future in which we exist as individuals. They are, therefore, one of our most important bodies of knowledge and because of that would have been, it might be thought, the focus of memory research for many decades.

## 2.46.2 A Brief Biography of Autobiographical Memory Research

Remarkably, however, the study of autobiographical memory has mainly taken place over the last 2 decades, whereas as the formal scientific study of memory itself is at least over a century old, dating, arguably, to the seminal work of Herman Ebbinghaus (1885). Ebbinghaus famously studied memory for relatively meaningless items, such as short lists of constant-vowel-constant (CVC) letter strings. Less well known is that he also studied memory for meaningful materials such as passages of prose, poetry, etc. Ebbinghaus concluded that memory for these latter materials was influenced by too many factors beyond the experimenter's control and because of this the scientific or experimental study of memory would be more surely advanced using materials that the experimenter had powerful control over, such as CVC strings. Ebbinghaus's view held sway and the experimental study of memory in the laboratory has generally used to-be-remembered materials generated and controlled by the experimenter. Almost by definition this excludes autobiographical memories, as these are formed outside the laboratory in our everyday lives in response to complicated meaningful experiences – experiences over which the experimenter has no control.

Given the dominance of experimental studies of memory, it is perhaps not so surprising that it is only in relatively recent times that autobiographical memory has received any attention at all. According to one view, science moves from the simple to the complex and perhaps it was the case that some understanding of memory, deriving from experimental studies, had to be attained before the field could grapple with the complexities of autobiographical memory and the inevitable role in memory of mysterious entities such as the self, goals, and emotion. There is no doubt some truth in this but, as with all history including personal history, the story is more complicated. So, for instance, at the time Ebbinghaus was writing his field-defining book, another great nineteenth-century scientist, Sir Francis Galton (1883), was reporting his seminal work into memory. One aspect of this research focused on the recall of autobiographical memories. Galton was interested in how many memories we have and developed a technique that 100 years later became known as the cue word technique. In this procedure, Galton revealed to himself, one at a time, words he had previously arranged into an alphabetical list. In response to each word, he noted what thoughts passed through his mind. So when reading abasement, abhorrence, etc. (remember this was Victorian England), he would write out his thoughts. He carried out this procedure for the fairly long list of words on several separate occasions. There were a wide range of findings but one striking outcome was that many of his thoughts were (autobiographical) memories and they often came to mind in the form of visual mental images. Galton was rather disappointed to discover that there was not an endless variety in his thoughts or memories and that he often recalled the same thoughts/memories on subsequent occasions of testing. He concluded that we probably have far fewer memories than we imagine we have – about 6500 according to one researcher who tried to recall all her memories (Smith, 1952).

An obvious problem with Galton's method is that once a subject has recalled a memory, then that memory became associated with the cue word and as such was much more likely to be recalled on subsequent occasions. If so, then Galton may well have underestimated the extent of his autobiographical memories. Nonetheless, the cue word method has proved especially useful in more contemporary studies of autobiographical memory and Galton's original work remains a rewarding read for memory researchers, as does Ebbinghaus's important book.

Another book from this period that remains significant is Theodore Ribot's (1882) classic case studies of memory distortions and malfunction following brain injury. This work also contains one of the first theories of autobiographical memory and is worth consulting for that alone. Other memory researchers from the late nineteenth century also studied autobiographical memory (see Conway, 1990, 2004, for reviews), and among them Henri and Henri (1896, 1898) conducted the first autobiographical memory survey. However, psychology came to be dominated by behaviorism, at the heart of which was the belief that all psychological theory should be built upon that which was observable. As memories are internal mental states, they cannot be studied by direct observation but can only be inferred by their effects upon behavior, i.e., upon what can be recalled in an experiment where the conditions of learning, retention, and remembering are highly controlled. This approach became known as verbal learning. Indeed, the dominant journal in the area was called the *Journal of Verbal Learning and Verbal Behavior* (renamed in the 1980s the *Journal of Memory and Language*). For many decades, verbal learning dominated memory research and in many respects still does. A lone voice during this period was the British researcher Sir Fredrick Bartlett, whose famous book *Remembering: A Study in Experimental and Social Psychology* (1932) is generally credited with having created and maintained a different tradition in memory research. In this tradition, the concept of a schema (some sort of general representation of similar experiences, narrative, and cultural conventions) was central and social interactions and culture played important roles in remembering. Bartlett was, however, largely uninterested in detailed memories of specific experiences – what we now call episodic memories. Because of this, his work did not reinvigorate the study of autobiographical memory.

Instead the reemergence of the study of autobiographical memory after 100 years of silence (Cohen, 1989) started to take place in the 1970s and gathered pace in the 1980s. **Figure 1** shows the cumulative frequency of papers, by year since 1970, that have used the phrase autobiographical memory. This admittedly is a crude index of research activity into the topic, but as crude as it is, it nonetheless depicts very strikingly how autobiographical memory research has rapidly increased and developed in the last 35 years. So what happened to end the century of silence? There were, arguably, two main forces that led to renewed interest in this important aspect of memory. The first was the gradual emergence of neuropsychology as a distinct research area and within it the study of malfunctions of human memory following brain damage. One of the striking symptoms of patients with memory impairments caused by brain damage is that they virtually always have disrupted autobiographical memory. In a particularly important paper Crovitz and Schiffman (1974) reintroduced the Galton cue word method as a way of eliciting autobiographical memories in normal populations and later in patients with closed head injuries suffering from various degrees of amnesia, thus simultaneously rediscovering both Galton and Ribot. The second force was the developing interest within cognitive science in how to model and represent stories and memories. An important paper here that demonstrated how autobiographical memory might be studied under laboratory conditions was that of Robinson (1976), who also used the cue word method to investigate differences between memories with different types of affect. Add to this Brown and Kulik's (1977) original survey of flashbulb memories, a rather timely reminder from Neisser (1978) about the narrowness of memory research in the 1970s and preceding decades, and the highly significant volume edited by Neisser (1982), *Memory Observed*, which reprinted many of the papers of earlier researchers on autobiographical memory and other then-neglected areas of memory, and a strong impetus was in place to rejuvenate research into autobiographical memory. It is, perhaps, important to note that the renewed interest, reflected in **Figure 1**, had its roots in a rediscovery of the original work of Galton, Ribot, and others (see too Rapaport, 1950, for an especially interesting review of emotion and memory). It might be noted that the methods used by these early researchers – studying one's own memory, investigating malfunctions and distortions of memories, and surveying memories – also re-emerged in the contemporary study of autobiographical memory, and it is to the findings of these more recent studies we now turn.

## 2.46.3 The Representation of Autobiographical Knowledge in Long-Term Memory

This section reviews current thinking about the nature of autobiographical knowledge. It is important

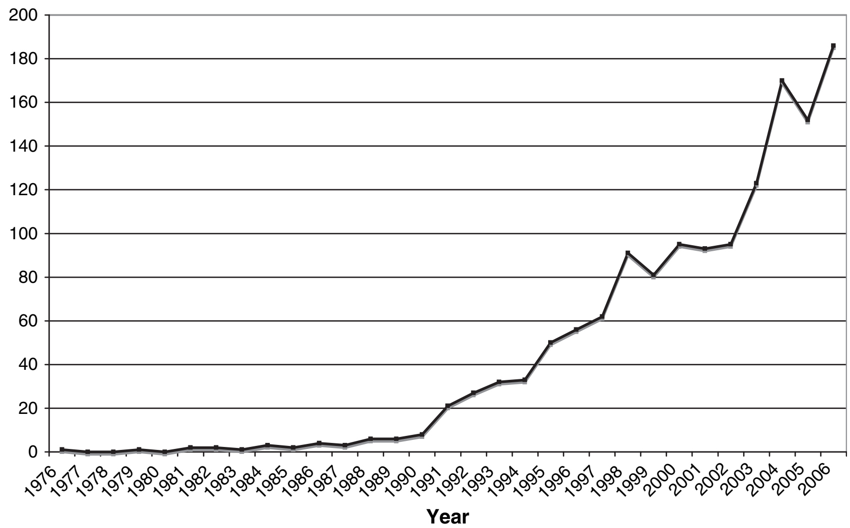

**Figure 1** Frequency of articles or research reviews published using the term autobiographical memory in the article title, abstract, or key words from 1970 to 2006. Data obtained from ISI Web of Knowledge, January 2007.

to note that a full review of findings is not undertaken here and instead only main findings and their implications are considered. One current model proposes that autobiographical memories are generated in the self-memory system or SMS (Conway and Pleydell-Pearce, 2000). Very briefly, the SMS is considered to be a virtual memory system consisting of a temporary interaction between control or executive processing systems with a complex multilayered long-term memory knowledge base. Another way to conceive of this is as an interaction between currently active, dynamic, or fluid aspects of the self with more permanent, long-term, or crystallized representations of the self and attributes of the self. The dynamic or executive aspect of the self is termed the working self. The working self consists of a complex hierarchy of currently active goals (Conway and Pleydell-Pearce, 2000) through which memories are encoded and retrieved. The working self also contains what Conway et al. (2004) termed the conceptual self, which in turn consists of beliefs, evaluations, and currently active self-images of what the self has been in the past, currently is considered to be, and what it may become in the future.

The working self regulates the construction of new memories in the SMS, at both encoding and during retrieval, by controlling access to the autobiographical memory knowledge base. **Figure 2** illustrates this relation between the working self and the knowledge base. The working self modulates memory by controlling the cues that are used to activate knowledge in the knowledge base. This is achieved by shaping cues so that particular types of information are activated. For example, a person asked to recall a memory of childhood might recall their earliest memory. Thus, elaborating the cue from 'recall a memory from childhood' into the cue 'recall my earliest memory.' This elaboration may take place several times as a cue is fine-tuned to access the information sought. An idea central to the SMS model is that specific autobiographical memories are formed when stable patterns of activation exist over interconnected representations of autobiographical knowledge and associated episodic memories. Thus, when conceptual and generic knowledge of the attributes of a house one lived in as a child, the relationship one had with one's parents, and a specific (episodic) memory of a moment in time are all activated together and interlinked, then the rememberer has the experience of remembering and their consciousness is dominated by a specific memory – as in the example we started with. It is these different types of autobiographical knowledge and their organization in long-term memory that we are concerned with next and we return to considering the process of constructing memories in a subsequent section.

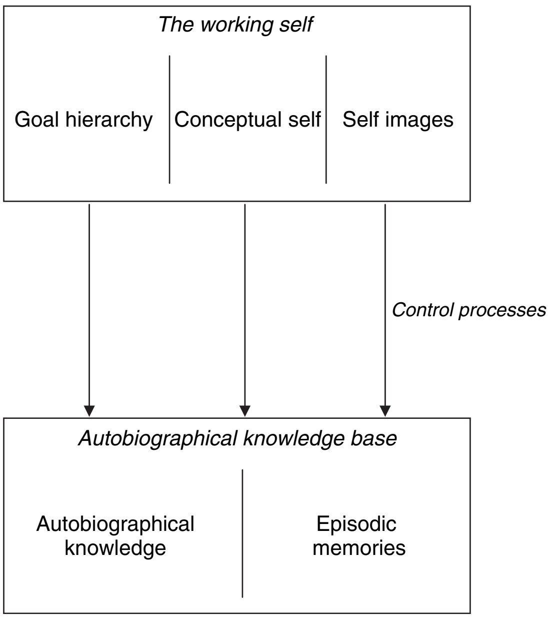

**Figure 2** The relationship between the working self and the autobiographical knowledge base.

According to the SMS model, long-term memory contains two distinct types of autobiographical representation: autobiographical knowledge and episodic memories. Autobiographical knowledge is organized in partonomic hierarchical knowledge structures (Conway and Bekerian, 1987; Barsalou, 1988; Conway, 1993, 1996; Lancaster and Barsalou, 1997; Burt et al. 2003) that range from highly abstract and conceptual knowledge (such as that contained in the conceptual self) to conceptual knowledge that is event-specific and experience-near. Autobiographical memory knowledge structures terminate in episodic memories, the second type of autobiographical representation contained in the autobiographical knowledge base. **Figure 3** illustrates how these complex autobiographical memory knowledge structures might be represented in long-term memory.

The upper part of **Figure 3** focuses on autobiographical knowledge and specifically on the life story, lifetime periods, and general events (Conway, 2005). These divisions of autobiographical knowledge are on a dimension of specificity, and at the most abstract level is a structure termed the life story

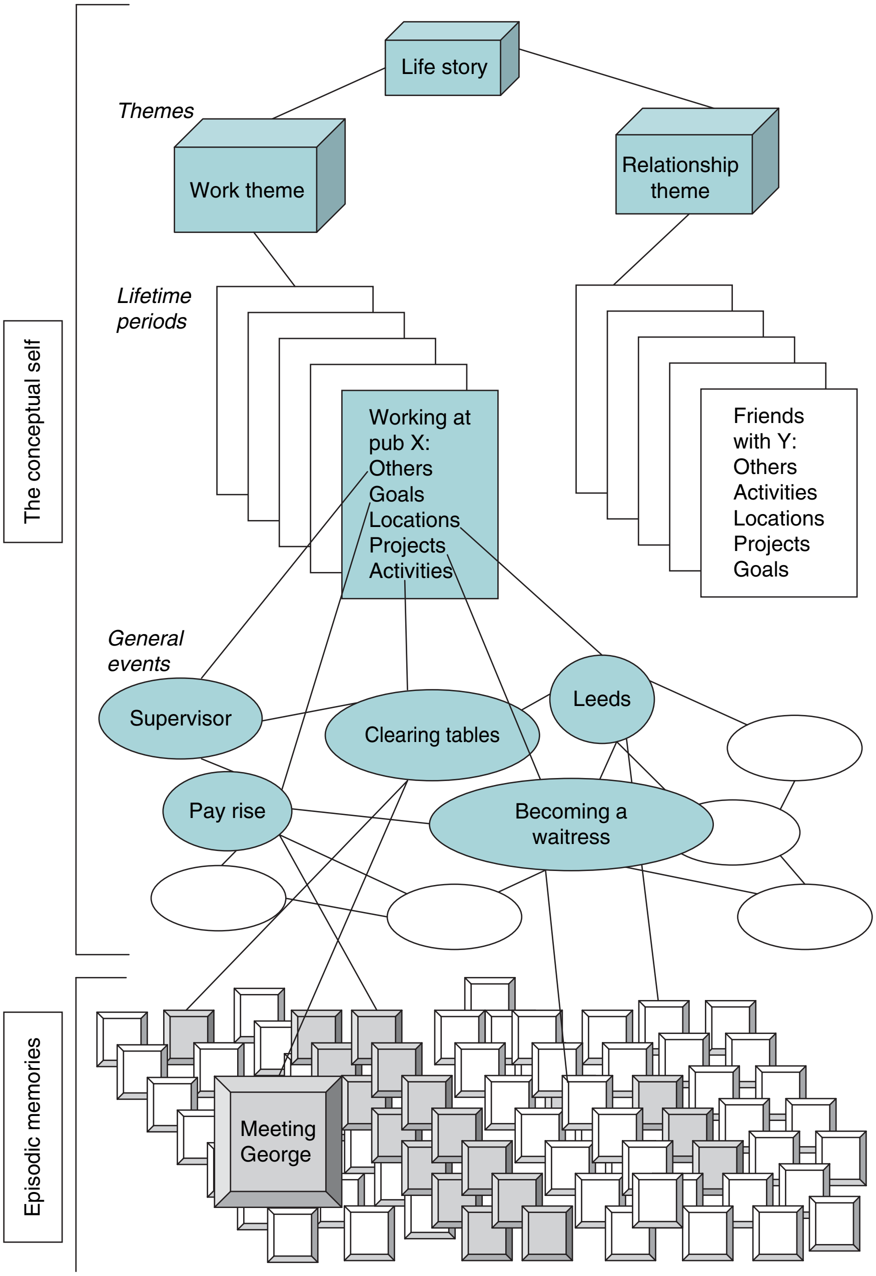

**Figure 3** Knowledge structures in autobiographical memory. Adapted from Conway MA (2005) Memory and the self. *J. Mem. Lang.* 53(4): 594–628.

(Pillemer, 1998; Bluck and Habermas, 2001; Bluck, 2003). The life story contains general factual and evaluative knowledge about the individual. It may also contain self-images that divide and separate the self into several different selves. It is represented in more or less coherent sets of themes that characterize, identify, and give meaning to a whole life (Bluck and Habermas, 2000, 2001). Divisions in the life story may be supported by the way in which different self-images contain cues that differentially access other knowledge in the autobiographical knowledge base. For example, a self that accesses a particular lifetime period (see **Figure 3**) will have cues that are channeled by knowledge represented as part of the lifetime period, which in turn can be used to access particular sets of general events that contain cues to specific episodic memories. It in this way that a memory can be gradually formed or constructed.

Lifetime periods contain representations of locations, people, activities, feelings, and goals common to the period they represent. They effectively encapsulate a period in memory and in so doing provide further ways in which access to autobiographical knowledge is channeled, or directed. Lifetime periods have been found to contain evaluative knowledge, negative and positive, of progress in goal attainment (Beike and Landoll, 2000), and lifetime periods may play an important role in the life story. For instance, lifetime periods may provide autobiographical knowledge that can be used to form life story schema and thus support the generation of themes. Lifetime periods may be particularly appropriate for this because of the goal-evaluative information they contain. For example, a lifetime period such as 'when I was at university,' will consist of representations of people, locations, activities, feelings, and goals common to the period but will also contain some general evaluation of the period, i.e., this was an anxious time for me, living away from home was difficult, I was lonely, I found the work too difficult, etc. (see Cantor and Kihlstrom, 1985).

The life story and lifetime periods are part of the conceptual self where they represent a summary account of the self and its history, and where they can be used to initiate and focus searches of the autobiographical knowledge base. General events, on the other hand, are more clearly part of the knowledge base itself and have been found to play important roles in organizing personal knowledge. General events are more strongly event-specific than lifetime periods but not as event-specific as sensory-perceptual episodic memories, which are directly derived from actual experience (Conway, 2001, 2005). General events refer to a variety of autobiographical knowledge structures such as single events, e.g., the day we went to London; repeated events, e.g., work meetings; and extended events, e.g., our holiday in Spain (Barsalou, 1988). General events are organized in several different ways. For example, they can take the form of mini-histories structured around detailed and sometimes vivid episodic memories of goal attainment in developing skills, knowledge, and personal relationships (Robinson, 1992). Some general events may be of experiences of particular significance for the self and act as reference points for other associated general events (Singer and Salovey, 1993; Pillemer, 1998). Yet other general events may be grouped together because of their emotional similarity (McAdams et al., 2001), and it is likely that there are yet other forms of organization at this level which await investigation(see for example, Brown and Schopflocher, 1998). However, the research currently available indicates that organization of autobiographical knowledge at the level of general events is extensive and it appears to virtually always refer to progress in the attainment of highly self-relevant goals. General event knowledge then represents information highly relevant to the goal hierarchy of the working self.

In one study of this type of knowledge, Robinson (1992) examined people's memories for the acquisition of skills, e.g., riding a bicycle, driving a car, and for aspects of personal relationships. These general events were found to be organized around sets of vivid memories relating to goal attainment. Consider two examples from Robinson's study:

> Ever agreeable, and eager to do anything that would get me out of the doldrums of inferiority, my father rented a bike and undertook to help me to learn to ride it. I shall always remember those first few glorious seconds when I realized I was riding on my own... (Quinn, 1990, cited in Robinson, 1992: 224.)

> The first time I flew an airplane was one of the best firsts. It marked a sense of accomplishment for myself, and it also started me on the career path I have always wanted to follow. The day was warm and hazy, much as summer days in Louisville are. My nervousness didn't help the situation, as I perspired profusely. But as we took off from runway 6 the feeling of total euphoria took over, and I was no longer nervous or afraid. We cruised at 2500 feet and I worked on some basic manoeuvres for approximately 45 minutes. We then returned to the airport, where I realized that this will soon be a career. (Robinson, 1992: 226.)

These first-time memories cue other related memories and the whole general event carries powerful self-defining evaluations that persist over long periods of time.

Relatively recent experiences, particularly those occurring during the current lifetime period, that give rise to sets of multiply related general events and associated episodic memories must be represented in terms of the currently active goals of the working self that dominate at the time. Burt et al. (2003) investigated this for several extended events, e.g., Christmas shopping. In these studies, events were sorted into groups by participants, and from these groupings currently active themes were identified. **Figure 4** shows the organization of a series of episodic memories associated

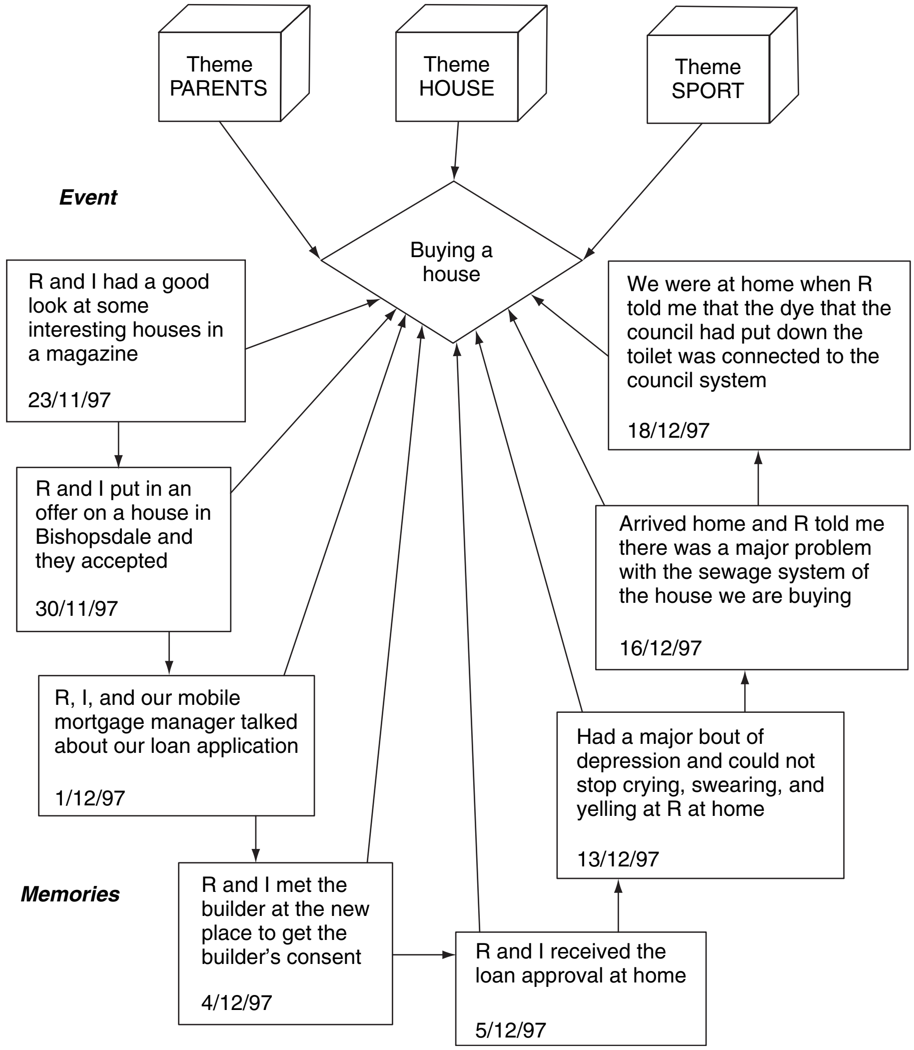

**Figure 4** Episodic memories associated with the general event of buying a house. From Burt CDB, Kemp S, and Conway MA (2003) Themes, events, and episodes in autobiographical memory. *Mem. Cogn.* 31: 317–325.

with the general event of buying a house (Burt et al., 2003). The themes shown in **Figure 4** are all associated with other memories as well and with lifetime periods in which the themes were present. The findings of Burt et al. (2003) demonstrate that general events typically access groups of episodic memories that connect the general event to unique and specific moments in time. One important property of this organization is that when goals change and new themes and lifetime periods become central to the working self, a record of the past concerns of an older version of the working self exists in the form of general events and the colonies of episodic memories they access. Thus, even if no goal information is explicitly encoded, it can, to at least some extent, be inferred from the groupings of general events and the associated episodic memories. Indeed, Robinson found that many memories featured goal-related evaluative knowledge or self-defining memories (Singer and Salovey, 1993) along with more general knowledge and specific episodic memories. General events provide, then, records of complicated and extended goal-related activities. These have powerful implications for the self, especially the conceptual self, and how a person evaluates their self.

## 2.46.4 Episodic Memory

So far we have been concerned with autobiographical knowledge, but specific autobiographical memories

**Table 1** Eight characteristics of episodic memory

| | |
|---|---|
| I | They retain summary records of sensory-perceptual-conceptual-affective processing derived from working memory. |
| II | They are predominantly represented in the form of (visual) images. |
| III | They represent short time slices, determined by changes in goal processing. |
| IV | They are only retained in a durable form if they become linked to conceptual autobiographical knowledge. Otherwise they are rapidly forgotten. |
| V | Their main function is to provide a short-term record of progress in current goal processing. |
| VI | They are recollectively experienced when accessed. |
| VII | When included as part of an autobiographical memory construction, they provide specificity. |
| VIII | Neuroanatomically they may be represented in brain regions separate from other (conceptual) autobiographical knowledge networks. |

consist of autobiographical knowledge and episodic memories. Episodic memories are, however, rather different types of representations. **Table 1** lists eight characteristics of episodic memories (from Conway, 2005, Table 4), and each of these is now considered in turn. The first three characteristics of episodic memories (numbered I, II, and III) in **Table 1** concern properties of episodic memories. First, the content of episodic memories is highly event-related and consists of detailed records of sensory-perceptual and conceptual-affective processing that was prominent during the original experience. Note that these are summary rather than literal representations, although they may occasionally contain some exact representations of processing that occurred during an experience (see the last paragraph of this section). Second, although they can, and indeed do, contain information from all the sensory modalities, they have been found to be predominantly visual in nature (see Brewer, 1988, for an interesting early study of the content of episodic memories). Finally they represent short time-slices of experience highly related to the moment-by-moment segmentation of experience into events (Williams et al., 2007b; Zacks et al., 2007).

Clearly, many episodic memories will be formed every day and simply casting one's mind back over the events of the day will bring to mind many highly detailed and specific episodic memories of events which occurred earlier in the day (see Williams et al., 2007b). In subsequent days, however, as the retention interval lengthens, many of these episodic memories, which are often of rather low self-relevance, routine events, become inaccessible. Even those that are retained over longer retention intervals are often not as detailed as they were close to the point of their formation. It has been suggested that only those episodic memories that are linked in some way to currently active goals become integrated with autobiographical knowledge in long-term memory. Episodic memories that become integrated in this way are retained over long retention intervals measured in months, years, decades, and even a lifetime (point IV in **Table 1**). Relatedly, the SMS model posits that one of the main functions of episodic memories is to provide a record of recent goal-processing episodes. Episodic memories provide a way in which to rapidly and effectively check that goal-related actions have been executed. They let the rememberer know that they did, for instance, lock the door, post the letter, have a coffee, and so on. If one of these routine events mapped onto an important goal or set of goals, then the episodic memory might become integrated with other knowledge in the autobiographical knowledge base and so become an enduring episodic memory. The study of self-defining experiences, the experience of trauma, and vivid memories generally provide many examples of how episodic memories become important parts of the autobiographical knowledge base, where they endure for many years (see Pillemer, 1998; Ehlers and Clark, 2000; Singer, 2005).

Points VI and VII in **Table 1** focus on another important aspect of episodic memories – that they are very highly associated with the experience of remembering. This is often referred to as recollective experience, and this and other forms of memory awareness have been the focus of many contemporary memory studies (see Tulving, 1985; Gardiner and Richardson-Klavehn, 2000, for reviews). Memory awareness in autobiographical remembering appears to be triggered or activated when an episodic memory enters conscious awareness (Conway, 2001, 2005), although it can also occur in other ways (cf. Moulin et al., 2005). Episodic memories, when they enter the construction of an autobiographical memory, cause the experience of remembering and also provided the constructed memory with specificity. As we will see, the specificity of the memory is important and is a quality that can be lost when memory malfunctions in, for example, psychological illness. Specificity provides a link to the experience of the world, and episodic memories are experience-near representations and stand in contrast to autobiographical and other conceptual knowledge which is experience-distant. Thus, the experience of remembering and memory specificity are important qualities of episodic memories. Finally, in **Table 1** (see VII), it is suggested that episodic memories might be represented in a separate brain region from more autobiographical conceptual knowledge (this is elaborated in Conway, 2005). We will return to this issue in the closing section of this chapter, but we might note here one general and intriguing finding that seems to support it: patients who suffer brain damage which has led to amnesia for much of their preinjury life, and especially amnesia for preinjury episodic memories, have nonetheless been found to retain often extensive autobiographical knowledge (Conway and Fthenaki, 2000).

## 2.46.5 Self-Defining Memories

The autobiographical knowledge base is complex and represents the personal history of an individual in different ways, i.e., as knowledge and as specific memories. Because of this complexity, the knowledge base is highly organized and some parts are more accessible than other parts. Generally, those autobiographical knowledge structures that are strongly associated with current goals and current images of the self are in a more accessible state than knowledge structures that are currently less self-relevant. In this section, we consider how the relation to the self can shape and organize autobiographical memory.

One important type of personal knowledge that appears to be highly accessible to the self is that of self-defining memories (SDMs). An SDM is a specific type of autobiographical memory that has the following attributes: affective intensity, vividness, high levels of rehearsal, linkage to similar memories, and connection to an enduring concern or unresolved conflict (Singer and Moffitt, 1991/1992; Singer and Salovey, 1993; Singer, 2005). Self-defining memories can be distinguished from other types of vivid memories. For example, flashbulb memories, as originally defined by Brown and Kulik (1977), are a particularly vivid and affective form of personal event memory (Pillemer, 1998), often about important public events. They have been found to be associated with four interrelated variables: surprise, consequentiality, importance, and emotion (Conway, 1995). Having these qualities does not necessarily indicate, however, that the memory is central to enduring goals of the self, and it is certainly possible to have highly vivid memories of events that are low in self-relevance (Conway et al., 2004). Importantly then, the two distinguishing criteria for self-defining memories that differentiate them from other vivid memories are, first, their linkage to other memories within the individual that share similar personal themes and, second, their relevance to the individual's enduring concerns or unresolved conflicts.

Both of these features – linkage of similar memories and relevance to concerns and conflicts – have been investigated in research into individuals' motivations and goals. For example, Thorne et al. (1998) looked at young adults' important relationship memories generated in two interviews over a 6-month period of time. Participants had freedom to describe similar or different relationship episodes in the second interview. Thorne et al. scored the memories for social motives for the memories that varied from time 1 to time 2, as well as the points of emphasis in the twice-told memories. For both unique memories and repeated memories, the authors found "moderate thematic consistency" (Thorne et al., 1998: 258), indicating that these memories, even when varying in content, reflected similar motivational themes and narrative structures. In a related study, Demorest and Alexander (1992) had raters code individuals' significant personal memories for overarching interpersonal scripts. A month later, these same individuals generated a set of fictional scenarios. Raters coded the themes of these scenarios and found striking overlap in terms of thematic continuity between the original memories and the imaginary stories. These results, along with those of Thorne et al. (1998), suggest that individuals link remembered and imagined experiences through personally significant themes. These themes originate, according to the SMS model, from the goals of the working self, but later can also serve to influence its ongoing goal processing.

Further evidence of the relationship of self-defining memories to individuals' enduring conflicts and concerns comes from the work of Singer and colleagues (Singer, 1990; Moffitt and Singer, 1994; Singer, 2005). These researchers found the affective quality of self-defining memories to be a function of the relevance of the memories to the attainment of a person's most desired goals. Moreover, this was found to be the case not only for memories relevant to the attainment of approach goals (desired goals), but also for memories about active efforts to avoid the consequences of undesired outcomes (Moffitt and Singer, 1994). Singer et al. (2002) additionally reported that the more personal growth students attributed to memories that grew out of community service experiences, the more likely these students were to place an overall emphasis on generative goal pursuits in their lives (see also de St. Aubin and McAdams, 1995). Similarly, in examining the relationship of turning-point and other significant personal memories to overall themes of the personality, McAdams (McAdams, 1982; McAdams et al., 1996) has consistently found power-oriented memories to be linked to agentic or individualistic motives, while intimacy-oriented memories reflected communal, social, and relationship motives. Jardine (1999) found that women counselors who experienced life transitions during their clinical training associated themes from their self-defining memories with their set of possible selves (Markus and Nurius, 1986). In a series of clinical case studies involving both individual and couples in psychotherapy, Singer found self-defining memories to be linked to critical relationship themes which were expressed in both clients' intimate relationships and in the transference dynamics of the therapy (Singer and Singer, 1992, 1994; Singer and Salovey, 1996; Singer, 2001; Singer and Blagov, 2004).

In addition to their linkage to goals, SDMs also can play directive and mood regulatory functions for the self (Pillemer, 1998, 2003; Bluck, 2003). For example, SDMs have been found to play a role in providing life lessons or integrative meanings that help individuals in optimal adjustment and personal growth. This is what Bluck (2003) termed the directive function of autobiographical memories. Blagov and Singer (2004) demonstrated that individuals with larger numbers of SDMs that contained reflective themes or messages, as reliably coded by three raters (see Singer and Blagov (2000) for an SDM coding manual), displayed optimal levels of self-restraint and emotional expression, as measured by the Weinberger Adjustment Inventory Short Form (Weinberger, 1997, 1998). Thorne et al. (2004) found that, compared to other types of personal memories, individuals were more likely to rely on SDMs involving tension or goal conflict to provide insights and life lessons.

SDMs provide information that can guide and direct the individual in everyday life. One specific form of directive function is the regulation of mood. Josephson et al. (1996) found that nondepressed individuals enlisted positive memories to repair negative moods, while mildly depressed individuals were less likely to recruit positive memories after a negative mood had been induced. Similarly, Moffitt et al. (1994) found that depressed individuals were less likely to recall SDMs when asked to retrieve a positive memory, while they did not differ in memory specificity for negative memories. Williams (1996), though not specifically addressing SDMs, has argued that a lack of memory specificity in depressed and suicidal individuals reflects a cognitive deficit generalized from a learned defense against encoding and retrieving affectively threatening self-relevant experiences. In summary, the findings from a broad range of studies converge on the view that SDMs are central to goals and conflicts within the individual (see Singer, 2005); they provide important integrative lessons, insights, or directives for the working self (see especially Pillemer, 1998); and they may regulate mood in important ways.

## 2.46.6 Self-Images

Conway et al. (2004) describe what they termed the conceptual self. One important knowledge structure in the conceptual self are self-images. It is proposed that self-images are knowledge structures that summarize complex sets of interlinked autobiographical knowledge and episodic memories that cumulatively support a particular view or version of the self. (Note that self-images can be permanent stable representations or more transitory, fleeting mental representations.) Conway (2005) proposes that these summary representations may often be experienced as images and hence the term self-images. A question of some interest here is how self-images are related to selective sets of memories. Rathbone et al. (2006; described in Conway, 2005) studied this by having a group of middle-aged participants complete a short questionnaire in which they completed six 'I am…' statements (Kuhn and McPartland, 1954). An 'I am…' could be anything, for example, I am bad, I am sociable, I am a banker, I am a mother, etc. Later each person recalled specific autobiographical memories to each of their 'I am…' statements. The dates of the memories, expressed in age at encoding, and the dates of the emergence of the 'I am…' statement were then compared; **Figure 5** shows the distribution of age at encoding of the memories relative to age of emergence of the 'I ams…'. **Figure 5** strikingly shows that age at encoding clusters around the date of emergence of the 'I ams…,' strongly

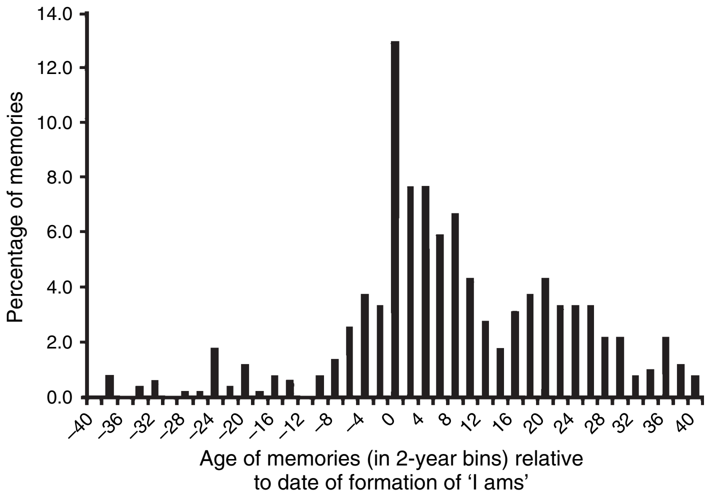

**Figure 5** Distribution of memories recalled to "I ams…" (Rathbone et al., 2006).

suggesting that 'I ams…' or self-images are grounded in sets of memories of formative experiences.

Further work found that the 'I ams…' could be categorized into two broad classes: roles and traits, e.g., I am a student versus I am charming. However, both types of 'I ams…,' role and trait, gave rise to the same distribution as that shown for 'I ams…' overall in **Figure 5**. Both role and trait 'I ams…' seem then to be marked in memory by highly accessible specific memories that come first to mind when the 'I am…' is processed. This may reflect the grounding of these aspects of the conceptual self, self-images, in subsets of memories and knowledge that define and provide the content for that self-image. This differentiation of the self, supported by the organization of autobiographical memory into self-images, might be particularly important in the development of the self – a point we return to after considering the distribution of memories over the life span and the significance of this for the self.

## 2.46.7 The Life Span Distribution of Autobiographical Memories

Important periods of development of the self are reflected in the life span retrieval curve which is observed when older adults (about 35 years and older) recall autobiographical memories in free recall or in a variety of cued recall conditions (Franklin and Holding, 1977; Fitzgerald and Lawrence, 1984; Rubin et al., 1986, 1998). Memories are plotted in terms of age at encoding of the remembered experiences, and the resulting life span retrieval curve typically takes a form similar to that shown in **Figure 6** (this is an

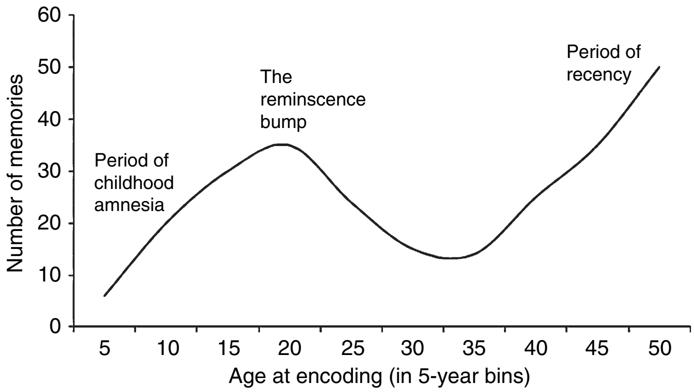

**Figure 6** Idealized representation of the life span retrieval curve. From Conway MA (2005) Memory and the self. *J. Mem. Lang.* 53(4): 594–628.

idealized representation derived from many studies and not based on specific data).

As **Figure 6** shows, the life span retrieval curve consists of three components: the period of childhood amnesia (from birth to approximately 5 years of age), the period of the reminiscence bump (from 10 to 30 years), and the period of recency (from the present declining back to the period of the reminiscence bump). The pattern of the life span retrieval curve is extremely robust and has been observed in many studies – to such an extent that it led Rubin to conclude that it was one of the most reliable phenomena of contemporary memory research (Conway and Rubin, 1993). This reliability is remarkably striking. In a recent study, Conway et al. (2005) sampled groups from five different countries: the United States, the United Kingdom, Bangladesh, Japan, and China. **Figure 7** shows the life span retrieval curves for each of these countries. (Note that participants were instructed not to recall events from the previous year to eliminate the recency portion of the curve.)

It can be seen from **Figure 7** that there were highly similar periods of childhood amnesia and reminiscence bump across countries. This further demonstrates the robustness of the life span retrieval curve and perhaps its universality. If the data for the five countries are collapsed together and an overall life span retrieval curve plotted, then the remarkably consistent distribution shown in the idealized curve of **Figure 6** is observed.

There are many theoretical explanations of the period of childhood amnesia (see Pillemer and White 1989; Wang, 2003, for reviews), but most flounder on the fact that children below the age of 5 years have a wide range of specific and detailed autosbiographical memories (Fivush et al., 1996; Bauer, 1997). Explanations that postulate childhood amnesia to be related to general developmental changes in intellect, language, emotion, etc., fail simply because apparently normal autobiographical memories were in fact accessible when the individual was in the period of childhood amnesia. It seems unlikely that an increase in general functioning would make unavailable previously accessible memories. From the SMS perspective, this period is seen as reflecting changes in the working self goal hierarchy, the idea being that the goals of the infant and young child, through which experience is encoded into memory, are so different, so disjunct, from those of the adult that the adult working self is unable to access those memories (see also Howe and Courage, 1997, for a particularly interesting account of childhood amnesia in terms of development of the self). Other accounts emphasize mother/child interactions, the role of language development, and emergence of narrative abilities (Fivush and Nelson, 2004).

Socialization and culture must play some role in the development of memory, although it seems that the infant/child capacity to actually have episodic memories may predate these developments (Rovee-Collier, 1997). If this is the case, then presumably the effects of socialization, culture, and language are largely on the organization of memory and perhaps on memory content as well, rather than on the processes that mediate the actual formation of episodic memories. For instance, the finding of Conway et al. (2005) that U.S. participants retrieved earlier earliest memories than all other groups might relate to the

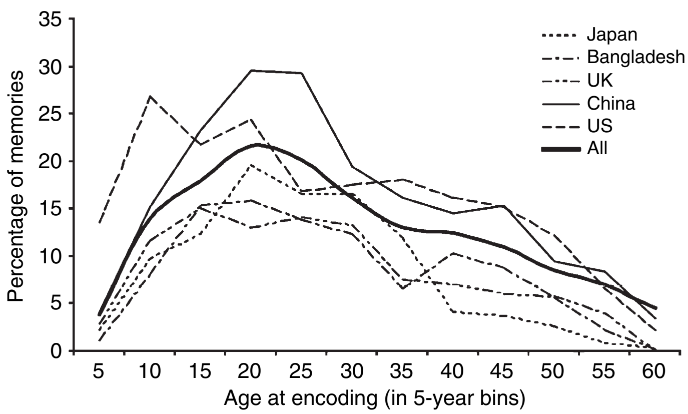

**Figure 7** Life span retrieval curves from five countries. From Conway MA (2005) Memory and the self. *J. Mem. Lang.* 53(4): 594–628.

observation that U.S. mothers undertake more memory talk with their children than mothers from other countries. Moreover, Wang and her colleagues (e.g. Wang, 2001) have found powerful cross-cultural differences in the focus and content of memories. Childhood memories from people in cultures with interdependent self-focus (Markus and Kitayama, 1991) such as China tend to be less oriented to the individual, less emotional, and more socially oriented than the childhood memories of people from cultures with independent self-focus, for example, Northern European or North American cultures (see Wang, 2001). Thus, socialization experiences and the self-focus that predominates in a culture may influence the accessibility of earliest memories and their content.

The second component of the life span retrieval curve is the period when rememberers were aged 10 to 30 years, known as the reminiscence bump (Rubin et al., 1986). The reminiscence bump is distinguished by an increase in recall of memories relative to the periods that precede and follow it. The reminiscence bump is present not just in the recall of specific autobiographical memories but also emerges in a range of different types of autobiographical knowledge. For example, the reminiscence bump has been observed in the recall of films (Sehulster, 1996), music (cf. Rubin et al., 1998), books (Larsen, 1998), and public events (Schuman et al., 1997; Holmes and Conway, 1999). Memories recalled from the period of the reminiscence bump are more accurate (Rubin et al., 1998), are judged more important than memories from other time periods, and are rated as highly likely to be included in one's autobiography (Fitzgerald, 1988; Fromholt and Larsen, 1991, 1992; Fitzgerald, 1996; Rubin and Schulkind, 1997). The reminiscence bump is only observed in people over the age of about 35 years and some recent findings suggest that it might only be present, or is much more prominent, in memories of positive experiences (Rubin and Bernsten, 2003).

Many of the more obvious explanations of the reminiscence bump have been rejected, e.g., that the memories are of first-time experiences and that is why they are memorable, as in fact it has been found that less than 20% are typically of first-time experiences (Fitzgerald, 1988). Rubin et al. (1998) reviewed a series of potential explanations and argued in favor of an explanation in terms of novelty. According to this view, the period when people are aged 10–30 years, and especially 15–25 years, is distinguished by novel experiences, occurring during a period of rapid change that gives way to a period of stability. It is assumed that memories from the period of rapid change are more distinct than those from the period of stability and this is why they are comparatively more frequently accessed. By this account, a period of rapid change taking place at some other point in the life cycle should also lead to raised accessibility of memories from that period relative to more stable periods, and there is some evidence that this is the case (Conway and Haque, 1999). However, periods of (goal) change and experiences of novelty always involve the self and a related but alternative explanation is that the high accessibility of memories from this period (and other periods as well) may be related to their enduring relation to the self (Conway and Pleydell-Pearce, 2000). Possibly, many memories from the period of the reminiscence bump are memories of self-defining experiences (see Fitzgerald, 1988) and have a powerful effect in cohering the working self into a particular form. The novelty of reminiscence bump experiences lies in their newness and uniqueness for the self and they may play a crucial role in the final formation of a stable self system and identity formation during late adolescence and early adulthood. The raised accessibility of these memories might then serve processes relating to the coherence of self through time.

Thus, the period of the reminiscence bump might be a period in which a sole 'I am...,' or self-image, develops into multiple 'I ams...,' e.g., I am a son, I am a student, I am a boyfriend, etc. Also, at this point multiple 'I will becomes...' may be formed, supported by the differentiation of 'I ams...' and the final emergence of a complete working self goal hierarchy and conceptual self grounded in autobiographical knowledge and memories (the SMS). Finally it might be noted that older patients with schizophrenia have been found to show an early and disorganized reminiscence bump, with an impairment of conscious recollection associated with memories highly relevant to personal identity (Cuevo-Lombard et al., 2007). This suggests that a developmental failure present in schizophrenia is the consolidation of personal identity in late adolescence/early adulthood. Possibly, one of the features of the abnormal SMS associated with this is a failure or weakening of the grounding of conceptual autobiographical knowledge in episodic memories of formative experiences, further demonstrating the importance of an integrated self with self-images strongly embedded in sets of defining episodic memories.

## 2.46.8 Closing Section: Why Do We Have Autobiographical Memory?

In many respects this may seem a pointless or rhetorical question; after all, if we did not have autobiographical memory there would be little in the way of individuality, personality, culture, society, literature, etc. Much that differentiates humanity from other species would be absent (see Tulving, 1983). At the level of the individual, disruption to or loss of autobiographical memory leads to people who typically cannot function in society. For example, clinically depressed patients often have severely impaired autobiographical memories in which they can no longer generate specific memories, their memories lack detail, they are overly general (Williams, 1996). Such patients cannot operate in the social world and, moreover, have unspecific futures in which they cannot visualize specific plans and goals (Williams et al., 2007a). Similarly, with amnesic patients whose memory disorders arise from organic brain damage, having multiple self-images in a specific future in which goals and plans originating from memories of the past are realized is no longer possible. Thus, one good reason to have an intact and functioning autobiographical memory is that it allows the individual to have a future in which a continuous self operates.

But what does this mean? The future is, of course, a time where new experiences, some anticipated, will take place. But we cannot know we have arrived at the future without a memory – that is, without knowledge of a past. The concept of future makes no sense, conceptually or psychologically, without a past. One way to think about this is to conceive of the future as a place where new goal processing will take place and the past as some sort of record of previous episodes of goal processing. To achieve future goals it is essential to have a record of how one has progressed with the same or related goals in the past. Consider very recent goals. In order to know that one locked the car after parking it this morning, we simply remember that episode. The events of the current day can typically be recalled (on that day) at length and in highly specific detail. Thus, checking on progress with goals, locking the car, making a call, mailing a paper, etc., can be verified. However, within a few days, access to these sorts of detailed memories is lost. No doubt this is useful as retaining a highly detailed record of every action would lead to an overloaded and unworkable memory. Nonetheless, keeping a detailed record in the short term is highly adaptive and prevents the repetition of actions and the adoption of courses of actions that have a high probability of failing.

Conway (2005) argues that episodic memory is the memory system that keeps a record of very recent goal-related activities. It is a system that has evolved highly specific memory representations that facilitate the type of short-term goal processing that can keep goals focused and environmentally relevant. It is suggested that this is a species-wide adaptation and, consequently, episodic memory is common to many species. As such it is probably a phylogenetically older memory system and may be represented in neural networks located toward the middle and posterior of the brain (a temporal-occipital network; see Conway, 2005). In contrast, humans have developed conceptual knowledge that forms complex knowledge structures that endure over long periods of time, even over a lifetime. This, it is suggested, is a more recent evolutionary development and is mediated by neural networks toward the front of the brain: fronto-temporal regions. The conceptual memory system supports long-term goal processing, for example, relationships, work projects, etc. Episodic memories that are retained become attached to conceptual knowledge and provide highly specific instances of goal processing related to the more general or generic goals of the conceptual self and self-images. Autobiographical memory then allows us to have both short- and long-term goals and to integrate these in coherent ways that facilitate goal processing in the future.

# 2.47 Social Memory Processes

**M. Ross, C. W. Blatz, and E. Schryer**, University of Waterloo, Waterloo, Ontario, Canada

In 1932, Bartlett published a classic book on memory in which he rebelled against the prevailing Ebbinghaus tradition that focused on people's ability to reproduce lists of words or nonsense syllables. Bartlett argued for the importance of studying memory of more complex and meaningful material. He also opposed the idea, still common today (e.g., Kandel, 2006), that remembering is analogous to mental time travel. This analogy implies that people can go back in time and recapture their original experiences. The invalidity of this assumption is perhaps evident to most people with memory for emotionally tinged events. The negative emotions associated with adverse events fade markedly with time. Similar fading of emotional intensity occurs for positive events, but at a much slower rate (Walker et al., 2003).

Bartlett emphasized that memory of more complex information often involves active reconstruction, in addition to the reactivation of lasting traces in nerve cells in the brain. He suggested that remembering is guided by present knowledge and goals, with the result being that a reconstruction can differ from the original experience. Bartlett also noted that remembering can be a collaborative as well as an individual activity, and that people develop particular memory skills in response to the demands of their social, cultural, and physical environments. Bartlett highlighted the importance of social factors by entitling his book *Remembering: A Study in Experimental and Social Psychology*.

Today, most psychologists studying memory focus on the cognitive and neurological factors underlying individual recall. It is social psychologists who have picked up Bartlett's themes regarding the social aspects of remembering. Social psychologists study topics such as self-conceptions, attitude formation, relationships, conformity, and conflict. They do not typically study memory *per se*. Nevertheless, memory, and especially autobiographical memory, plays an active role in many phenomena of interest to social psychologists. Autobiographical memories and self-conceptions are closely related (James, 1950; Singer and Salovey, 1993; Pillemer, 1998; Conway and Pleydell-Pearce, 2000; McAdams, 2001; Bluck, 2003; Ross and Wilson, 2003). People can use their memories to assess their beliefs, traits, self-worth, and social acceptance, as well as to guide their actions and decisions.

According to Bartlett (1932) and Neisser (1967), people often remember only a few elements of an episode; they then use their current knowledge and beliefs to fill in gaps and resolve ambiguities in their memories. Rememberers reconstruct what should (or must) have happened and confuse their reconstruction with recollection: They suppose that what should have happened did happen (Bartlett, 1932; Mead, 1964; Neisser, 1967; Ross, 1989). Although people are better than Bartlett proposed at distinguishing their suppositions from their recall (Roediger et al., 2001), his analysis provides a useful conceptual tool for examining when and how the present affects recollections.

The reconstructive aspect of memory has perhaps been overemphasized relative to another important characteristic of memory: its selectivity. In remembering and reconstructing the past, people focus on some episodes and not others (e.g., memory of a particular wedding), and on some aspects of episodes rather than others (Rogers et al., 1977; Bellezza, 1984; Symons and Johnson, 1997). People's current goals and motives can influence both the selection of past episodes and their reconstruction. Past experiences are often sufficiently numerous, contradictory, and ambiguous that people can use selection, reconstruction, or both to remember what they need or prefer to recall. A man motivated to recall happy times in his marriage will typically remember at least some pleasant memories involving his partner. When motivated to recall unhappy times, the same man would probably remember some unpleasant memories. As we shall see, however, there are constraints on memory: Remembering is not just wish fulfillment.

In the present chapter, we discuss research on the effects of present knowledge, goals, and motivation on individual recall. Because people often remember as pairs or groups in real life, we also review research on two important forms of joint remembering. People collaborate to recall dates, names, and past events. We examine research on the effects of collaboration on accuracy of recall. Also, people often exchange memories with other individuals. Indeed, much of people's knowledge of events comes from others, including friends, family, teachers, and the media. We examine how memories change as they are transmitted from one person to another, as well as how these changes affect people's beliefs and attitudes.

## 2.47.1 The Effects of the Present on Recall

In everyday life, the hindsight bias, or the I-knew-it-all-along effect, is perhaps the most widely recognized example of the influence of the present on recall. According to a popular cliché, hindsight is 20-20. In research on the hindsight bias, psychologists compare hindsight judgments made with knowledge of an outcome (e.g., the winner of an obscure military battle) to foresight judgments made without such knowledge. Participants in the hindsight condition typically regard the actual outcome as more likely than do those in the foresight condition (Fischhoff and Beyth, 1975; Slovic and Fischhoff, 1977; Hoffrage et al., 2000). For example, Fischhoff and Beyth (1975) asked university students to predict the likelihood of various events before President Nixon's visits to Beijing and Moscow. After Nixon's trips, these students remembered assigning higher probabilities than they originally did to events that actually occurred. Presumably participants had a difficult time recalling the exact probabilities that they had assigned. In reconstructing their predictions, they used their present knowledge to estimate their prior probabilities (Hoffrage et al., 2000).

The hindsight bias has potentially important implications for people's assessments of behavior and individuals. When people evaluate past performances, they often know the outcomes (e.g., whether a medical diagnosis was valid or a military tactic was successful). The hindsight bias can inappropriately lead people to criticize individuals who fail and admire those who succeed. For example, physicians informed of both a patient's symptoms and autopsy results indicating the cause of death are surprised that other physicians could have made an incorrect diagnosis prior to the autopsy. Physicians told of the symptoms but not of the autopsy results are less certain of the diagnosis (Dawson et al., 1988). Alternatively, when events turn out well, successful people are sometimes credited with too much foresight. In *War and Peace*, Tolstoy accuses Russian historians of making this error in judgment (cited in Hoffrage et al., 2000). Historians wrote that the Russian army defeated Napoleon by tricking him into marching toward Moscow. However, the Russian victory was probably more attributable to luck than to foresight.

Researchers have extended investigations of hindsight by examining how people's current knowledge and beliefs influence their recall of their earlier attitudes, feelings, and behaviors. While recalling the past, people are often very aware of the present (Ross, 1989). For example, people know how they currently feel about a politician but may be less certain how they felt years earlier. Unless they have a compelling reason to think that they have changed, they often presume personal consistency, supposing that their earlier opinions resemble their current beliefs (Ross, 1989). The perception of consistency helps people to sustain a sense of personal identity: They are the same individuals that they were yesterday or last year (Erikson, 1968; Epstein, 1973; James, 1950). When people assume stability in the face of actual change, they exaggerate the similarity of the past to the present and evidence a consistency bias in recall.

## 2.47.2 A Consistency Bias in Recall

Much of the research demonstrating a consistency bias in recall examines people's memories of their earlier attitudes and feelings. Goethals and Reckman (1973) studied the effect of an experimentally induced change in attitudes on recall of earlier opinions. At an initial session, high school students completed a questionnaire indicating their attitudes on a variety of issues, including bussing students to achieve racial integration in the schools. At a second session 4–14 days later, the students received information that led them to change their views on bussing. They were then asked to recall their attitude responses on the initial questionnaire. They remembered responding more in harmony with their new position on bussing than they actually had. Following a change in attitudes, individuals tend to underestimate the degree to which they have altered their opinions.

Several researchers have examined this same phenomenon in the context of naturally occurring changes in evaluations. McFarland and Ross (1987) asked undergraduates to evaluate their dating partners at an initial session on a series of rating scales and then again months later. At the second session, participants also attempted to recall their earlier ratings. Presumably they could not easily remember precisely where they placed their x on the rating scales. As a result, they had to reconstruct their earlier evaluations. Apparently, participants based their reconstructions, in part, on their current impressions of their partners. Participants who became more favorable over time recalled more positive evaluations than they had provided originally; those who became less favorable recalled more negative evaluations.

Levine (1997) studied changes in feelings reported by supporters of Ross Perot, an independent candidate for the US presidency. Perot withdrew from the presidential race in July 1992 and then re-entered in October 1992. Levine polled Perot supporters immediately following his withdrawal and again following the election in November of the same year. After the election, supporters recalled the emotional reactions they had reported immediately following Perot's withdrawal 5 months earlier. Respondents' recall of their emotions following the withdrawal was consistent with their current political ideology. Those who continued to support Perot recalled feeling less anger and more hope than they had reported earlier.

Taking the consistency bias in recall one step further, Ross et al. (1981) examined how people's current attitudes affect their recall of their own past actions. To show a cause and effect relation between attitudes and behavioral recall, Ross et al. (1981) provided participants with communications that challenged their beliefs concerning certain health issues. For example, some participants learned of scientific evidence that frequent tooth brushing is potentially harmful to gums and tooth enamel. Shortly after reading the communication designed to change their attitudes toward tooth brushing, participants completed a questionnaire that assessed their frequency of engaging in various health-related behaviors in the previous 2 weeks. As anticipated, those who now believed that frequent tooth brushing was harmful recalled brushing less often than did participants not exposed to the anti–tooth brushing message.

If people recall behavioral histories that are consistent with their new beliefs, then the act of remembering past behavior could increase people's commitment to their new beliefs. On looking back, people 'discover' that they have behaved consistently with their new beliefs; this memory should support the validity of these beliefs. To test whether behavioral recall increases support for new attitudes, Ross et al. (1983) induced participants to change their attitudes. Some participants were then asked to recall past behavior relevant to the attitude domain in question. Their recall was not constrained. They were free to recall behaviors congruent or incongruent with their new opinions. Other participants did not engage in behavioral recall. Participants in the behavioral recall condition seemed to be more committed to their new attitudes. They were more likely to report intentions to act consistently with their new attitudes and more resistant to a message attacking their new attitudes than were participants who were not prompted to recall past behaviors. These findings suggest a reverberating circuit in which new attitudes affect behavioral recall, which in turn affects commitment to the new attitudes.

Studies of memory reconstruction point to the dangers of assuming the validity of people's recall. Recent research in cross-cultural psychology supports this concern. There is an extensive literature on cultural differences in the experience and determinants of emotion (e.g., Kitayama and Markus, 1994; Oishi, 2002). Much of this research on emotion is retrospective. For example, people are asked how frequently they felt various emotions in the last month (e.g., Eid and Diener, 2001). Researchers typically find that American and Canadians of European heritage recall experiencing many more positive (e.g., happy) than negative (e.g., sad) emotions in their everyday lives. In contrast, Americans and Canadians of East Asian heritage as well as respondents living in Japan report experiencing about the same number of positive and negative emotions (Markus and Kitayama, 1994; Oishi, 2002; Ross et al., 2002), and fewer positive emotions than European Americans and Canadians.

These research findings can be interpreted as indicating that Westerners are happier on a daily basis than are their East Asian counterparts. Alternatively, perhaps Western and East Asian individuals experience about the same number of pleasant and unpleasant episodes, but Westerners recall a greater number of their pleasant experiences. Such a recall bias in Western cultures could reflect a Western cultural schema that happiness is important and common, a cultural schema that is less evident among Eastern cultures (Oishi, 2002). Conceivably, Westerners and East Asians recruit memories that support their differing beliefs, with the result that Westerners recall more happy experiences.

Oishi (2002) compared retrospective accounts to daily diary and online reports of emotional experiences. European and Asian Americans did not differ in daily diary reports of the quality of their day, or in online reports of current positive and negative moods. Interestingly, cultural differences clearly emerged at the end of the week when participants were asked how good or bad the week was, or how often they had experienced positive and negative moods. European Americans retrospectively reported greater satisfaction with the week and a higher frequency of positive moods compared to Asian Americans.

Are East Asians less happy than their Western counterparts? The answer depends on whether the focus is on current or retrospective reports. As Oishi observed, "retrospective judgments seem to be as important as actual experiences in understanding subjective experiences of well-being . . . online and global reports capture different but equally important aspects of well-being" (Oishi, 2002: p. 1405).

Oishi's study is unlikely to be the final word on cultural differences in emotional experience. Researchers using other samples and procedures might find evidence of online differences. From the present perspective, the Oishi study is important for two reasons. First, it reminds us that recall should never be assumed to be an exact replica of earlier experience. Second, as Oishi notes, retrospective reports can be psychologically significant, even when they do not mirror online reports.

## 2.47.3 Motivated Recall

In presenting research on the effects of current beliefs on recall, we depicted the recall process as a rather dispassionate cognitive exercise. A new belief can be more than a recall cue, however; it can also motivate biased recall (Greenwald, 1980; Kunda, 1990). For example, in the tooth brushing study reported by Ross et al. (1981), people presumably preferred to believe that they had been behaving in a way that would not cause their teeth to rot or their gums to fall apart. Researchers examining the relation between motives and recall have studied both chronic motives and experimentally induced motives. The research evidence indicates that the content of autobiographical recall reflects people's persistent motives (e.g., McAdams, 1982; McAdams et al., 1996; Woike et al., 2003; Gramzow and Willard, 2006; Sahdra and Ross, 2007). For example, Sahdra and Ross (2007) examined how degree of identification with a religious group influenced people's recall of harms committed by members of that group. High identifiers (who are motivated to view their group favorably) were less likely than low identifiers to recall episodes in which members of their group acted violently toward members of a different religious group.

Other researchers have altered people's beliefs about the desirability of specific traits or behaviors and then assessed people's memories of their past actions. In studies conducted by Sanitioso and his associates, individuals were led to believe that a particular trait such as extraversion was or was not related to success in life. Participants who believed that extraversion is desirable were able to recall their own extraverted behaviors more quickly and easily than were participants who supposed that introversion is preferable (Sanitioso et al., 1990; Sanitioso and Niedenthal, 2006).

Murray and Holmes (1993) asked undergraduates in dating relationships to report the amount of conflict they had with their partner while deciding on joint activities. Participants in the experimental condition then read a bogus psychological article that argued that the development of intimacy in a relationship depended on people's willingness to express disagreement. Thus, experimental participants who had reported that they and their partner experienced little conflict now learned, much to their surprise, that low conflict was actually bad for a relationship. A control condition contained participants who had also reported low conflict with their partners, but who did not read the bogus article.

How did experimental participants deal with their new understanding that conflict was desirable? Many altered their views of their partner's past behaviors. When asked to assess their relationships on a number of dimensions, experimental participants were more likely than controls to endorse items such as "My partner clearly expresses his/her needs even when he/she knows that these needs conflict with my needs." In short, they discovered evidence that their relationship was appropriately conflict-ridden.

Baumeister and his colleagues (Baumeister et al., 1990, 1993; Stillwell and Baumeister, 1997) have studied how people who anger someone else (perpetrators) remember a dispute compared to individuals who are provoked (victims). Generally, perpetrators regard their behavior as less harmful and more justifiable than victims do. Along the same lines, young children recall disputes with their siblings in a manner that tends to absolve them of blame. They remember more harmful actions by their siblings than by themselves and portray their own actions as justifiable and their siblings' behavior as arbitrary and incomprehensible (Ross et al., 1999).

Studies of mood regulation provide further evidence of motivated remembering. Several theorists have suggested that individuals who are feeling dejected may attempt to improve their moods by selectively retrieving pleasant memories (Clark and Isen, 1982; Isen, 1987; Singer and Salovey, 1988). For example, Parrott and Sabini (1990) found that participants experiencing negative moods were more likely to recall pleasant events from their lives than were participants experiencing positive moods. Subsequent researchers suggested that certain personality traits may predispose individuals to alleviate negative affect by engaging in mood-incongruent recall (Smith and Petty, 1995; Boden and Baumeister, 1997; McFarland and Buehler, 1997). McFarland and Buehler found that only individuals who are especially inclined to focus on their feelings recruited more pleasant memories after a negative mood induction than after a neutral mood induction.

The research on motivation and recall might seem to imply that people can readily create a preferred past. If a woman wants to believe that she is shy, she can recall introverted behaviors. If the same person prefers to believe that she is outgoing, then she can readily recall extraverted behaviors. George Herbert Mead (1964) argued that memory is indeed this malleable and compared people's recollections to "escape fancies . . . in which we rebuild the world according to our hearts' desires" (pp. 348–349).

More recent research suggests that there are limits to people's ability to recall pasts consistent with their heart's desires. People's autobiographical memory includes more general memories as well as specific episodic memories (Conway and Playdell-Pearce, 2000; Klein et al., 2001, 2002). These general memories are summaries of repeated behaviors and events (e.g., going to nightclubs) and include personality traits (e.g., 'I am an introvert'). A person who arrives at an experiment with the generalized memory that she is an introvert is unlikely to discover suddenly that she is outgoing, even if she learns that extraversion is highly desirable (Sanitioso et al., 1990). Her remembering is constrained in two interrelated ways. She possesses a generalized belief that she is an introvert, and her stock of accessible episodic memories likely reflects her generalized belief. A woman who believes strongly that she is shy should be more able to access introverted behaviors, regardless of the experimenter's claims regarding the desirability of the trait.

Constraints on the effect of preferences on memory are clearly evident in research that assesses recall accuracy. Consider, for example, a study of university freshmen and sophomores' recollections of their grades over all 4 years of high school (Bahrick, 1998; Bahrick et al., 1996). Overall, their recall was quite good: Participants recalled 71% of their grades accurately. In short, students did not rewrite history to create a past in which they received straight As. Nonetheless, the errors they did make were systematic. Of the errors in recall, 81% were inflations of the actual grades (Bahrick, 1998). Also, participants' errors reflected their general academic ability. Students with high grade point averages recalled more of their Bs as As than did students in the lowest grade point average quartile. Thus outstanding students were more likely than mediocre students to infer a grade of A on those relatively few occasions that they misremembered their performance.

Studies of mood recall also provide evidence of both accuracy and bias. Retrospective reports of mood are accurate, in that recollections are correlated with earlier online reports of mood (e.g., Feldman Barrett, 1997) but biased by the rememberers' personality and beliefs about emotional experiences (Feldman Barrett, 1997; Robinson and Clore, 2002; Christensen et al., 2003).

Some theorists (e.g., Bahrick, 1998) associate schema-consistent errors with memory reconstruction and accurate recall with reproductive memory. Neither of these claims is necessarily true. Memory can be schema consistent because it is selective rather than reconstructive. For example, a person who is motivated to believe that she is outgoing may accurately retrieve episodes from her memory store (reproductive memory) but selectively retrieve memories that imply extroversion rather than introversion. As well, accurate recall can reflect memory reconstruction rather than the direct retrieval of information from memory. Suppose, for example, that some participants in the Bahrick et al. (1996) study believe that they are outstanding students. Also suppose that they cannot readily recall the grades that they received in several courses. These students might infer that they received high grades in these courses, because they view themselves as good students. If their academic self-assessment is reasonably valid, then they will be accurate in inferring high grades.

As Bartlett and others (e.g., Neisser, 1967) have argued, most autobiographical recall is probably a combination of reconstruction and reproductive remembering. The degree to which reconstruction or reproduction dominate will depend on a variety of factors, including the strength of encoding of the original events, the length of the time period between the event and the recall, the motivation to remember accurately, and the accessibility of relevant cognitive schemata (e.g., beliefs about of one's academic ability, personality, etc.) to guide recall.

## 2.47.4 Perceiving Change

We have argued that people are often cognitive conservatives who underestimate the degree to which their past feelings and beliefs differ from their present judgments. But people commonly perceive change in themselves on other dimensions, especially ability- and personality-related attributes on which improvement is possible. They also see changes in the world around them. Next, we review research showing that people are particularly inclined to see themselves as improving and the world as getting worse.

### 2.47.4.1 The Perception of Self-Improvement

In his autobiography, Arthur Koestler (1961) remarked that people are critical of their adolescent past self: "The gauche adolescent, the foolish young man that one has been, appears so grotesque in retrospect and so detached from one's own identity that one automatically treats him with amused derision. It is a callous betrayal, yet one cannot help being a traitor to one's past" (Koestler, 1961: p. 96). Wilson and Ross (2000, 2001) obtained research support for Koestler's observation but found that retrospective criticism of past selves extends well beyond adolescent selves. Across various samples (e.g., university students, middle-aged individuals, celebrity interviews) and in a variety of dimensions, people viewed themselves as steadily improving (Wilson and Ross, 2000, 2001). Moreover, people rated themselves as having improved more since a particular time in the past when that point was manipulated to seem long ago rather than recent (Wilson and Ross, 2001).

This perception of improvement is due, in part, to a retrospective tendency to find fault with earlier selves. The self that seems impressive today appears less remarkable in retrospect. Ironically, the tendency to disparage earlier selves seems to reflect concerns for self-enhancement (Ross and Wilson, 2000, 2001). People who are motivated to evaluate themselves favorably (e.g., those with high self-esteem) are particularly inclined to recall an inferior past self. Also, people do not see the same steady improvement in their peers that they see in themselves. By criticizing their own earlier selves, people can view their current self favorably by contrast.

Most of the studies of perceived self-improvement involve younger people. Would people in their 60s and 70s be more likely to see themselves as declining physically and cognitively? The answer is a qualified yes (McFarland et al., 1992; Ross and Wilson, 2001). Older people do view themselves as declining, but at a much slower rate than their peers (Ross and Wilson, 2002). When people cannot use retrospective comparisons to feel good about their current selves, they apparently engage in downward social comparisons to accomplish the same end.

If people are concerned with self-enhancement, why do they not simply praise their present selves rather than derogating past selves? There are advantages to deflating the past rather than inflating the present. If people continually boosted their current selves, their present self-regard might become so overstated as to be inconsistent with objective indicators (Baumeister, 1989). Appropriate judgments and choices depend on an accurate view of one's strengths and weaknesses. By derogating the past, individuals create an impression of improvement without greatly misrepresenting their present strengths and weaknesses.

Researchers have examined perceived improvement in a number of different contexts. Karney and his associates examined people's retrospective evaluations of satisfaction with their marriage (Karney and Coombs, 2000; Karney and Frye, 2002). Spouses underestimated their past contentment and often recalled it as lower than their present satisfaction. Although marital satisfaction decreased over the early years of marriage, individuals created the illusion of improvement by underestimating their former satisfaction levels. Studying prospective and retrospective trajectories of newlyweds' relationship satisfaction, Karney and Frye (2002) showed that this perception of improvement is linked to other indicants of relationship success. Spouses' retrospective reports of increases in relationship satisfaction predicted optimism about their relationship's future, independent of any actual change in satisfaction. In contrast, absolute levels of relationship satisfaction were unrelated to expectations. By derogating earlier aspects of themselves and their relationships, people can make their current state seem superior by comparison and foster optimism about the future.

People can also use retrospective reevaluation to detect a silver lining in their personal tragedies. McFarland and Alvaro (2000) asked individuals who had experienced a tragedy to evaluate what they were like prior to the episode. Some participants were reminded of the disturbing episode before completing the evaluation, and others were not reminded. Participants who were reminded provided lower evaluations of their earlier, pretrauma selves. In addition, people were more critical of former selves after being reminded of severely rather than mildly disturbing experiences. Individuals may reduce the negative impact of a trauma by focusing on how it led to growth or positive outcomes for the self.

Retrospective overestimation of change is especially likely when people experience a circumstance that they expect to produce change on certain dimensions, but that in reality has minimal impact on those qualities. Self-help programs are a context in which people's hopes of change are likely to be disappointed. Participants tend to suppose that self-help programs are beneficial, but formal evaluations that include placebo control conditions typically show the programs to be of little value (Polivy and Herman, 1983; Ross and Conway, 1986). Conway and Ross (1984) studied the relation between memory and expectations for change in the context of a study-skills program. They asked university students to evaluate their study skills and then randomly assigned half of them to a study-skills program that lasted several weeks and the remaining half to a control condition. Although participants in the treatment program expected to improve their grades, their program, like most other study-skills courses, was ineffective. At the conclusion of the course, participants in the treatment and control conditions were asked to recall their original ratings of their study skills. They were reminded that the researcher had their initial ratings and would assess the accuracy of their recall. Participants who took the course remembered their preprogram ratings as being worse than they had reported initially. In contrast, control participants, who had not received the program, exhibited no systematic bias in recall. The biased recollections of participants in the study skills course would support their belief that the program had improved their skills. More generally, a tendency to revise the past in order to claim personal improvement may explain why many individuals report that they benefit from ineffective therapies and self-improvement programs (Conway and Ross, 1984).

## 2.47.5 Perceiving Change in Society

### 2.47.5.1 Mistaking Change in Self for Change in the World

Although people tend to see themselves as improving, they regard their society as deteriorating. Moral standards are weakening, crime rates are rocketing, and the quality of popular music and films is declining (Eibach et al., 2003). This view of societal deterioration can be found in most cultures and eras: "Virtually every culture past or present has believed that men and women are not up to the standards of their parents and forbears" (Herman, 1997: p. 13). There are a host of plausible explanations for the perceived decline (Eibach et al., 2003; Ross, 1989), but Eibach and his colleagues tested a particularly intriguing one: Change in the self is mistaken for change in the world. According Eibach et al. (2003), when people experience life changes their concerns and interests shift. For example, new parents are more sensitive to possible dangers to children, including crimes. In the face of an actual decline in crime rates, new parents are more likely to perceive crime rates as increasing than are respondents who did not become parents during that interval (Eibach et al., 2003). Similarly, dieters perceive an increase in advertising for unhealthy foods in the previous decade, relative to nondieters (Eibach et al., 2003).

Why are the perceived social changes so often negative? Eibach et al. (2003) provide a number of possible answers to this question. For example, they quote Herman (1997), who notes that as older people's cognitive and physical abilities decline with age, they might confuse their own diminishing powers with decline in the world. Also, older people's greater familiarity with the social mores, films, and music of their youth might enhance their appreciation of the good old days.

#### 2.47.5.2 Group Status and the Perception of Social Change

Eibach and his associates have conducted other research on how different groups in society, especially the haves and have-nots, evaluate progress toward social equality. Generally, privileged groups see more progress than disadvantaged groups do. Men report that the income gap between men and women has declined more in the previous decade than women do; White Americans view the conditions for Blacks as improving more over the previous few years than Blacks do (Eibach and Keegan, 2006). Eibach and Ehrlinger (2006) suggest that advantaged and disadvantaged groups use different reference points to evaluate change. White respondents compare the treatment of Blacks in the past to the treatment of Blacks in the present and report progress. Black respondents compare their current outcomes to the outcomes they should receive (equality with Whites) and report that they still have a long way to go. Both groups are right: a half full glass is also half empty.

Why do more privileged and less privileged groups select different reference points? One answer is that members of the more privileged group are concerned about losing their advantages, and so are especially sensitive to how each group's status has changed over time. In contrast, members of less privileged groups are primarily interested in achieving equality; therefore they focus on the gap between where they are and where they need to be to attain equality (Eibach and Keegan, 2006).

## 2.47.6 Subjective Time and Point of View

Although most studies have concerned the content of autobiographical memory, researchers have examined two additional properties of memory with social psychological implications: People's feelings of temporal proximity to past events and their visual perspective on the remembered events.

### 2.47.6.1 Subjective Time

The subjective experience of time is related to clock and calendar time – last week feels farther away than yesterday – but it is not the same thing (James, 1950; Brown et al., 1985; Block, 1989; Wilson and Ross, 2003). Of particular interest here is that differences in the evaluative implications of past episodes influence people's feelings of proximity to those events (Ross and Wilson, 2000, 2002). To protect their current self-regard, people are motivated to feel farther from past failings than from achievements. In one study (Ross and Wilson, 2002), university students were asked to remember the course in the previous semester in which they received either their best or worst grade. After reporting their grade, participants indicated whether the course 'felt' recent or far away. Participants felt farther away from a course in which they obtained a relatively low grade, even though the actual passage of time did not differ in the two conditions. Subsequent research indicated that this asymmetry reveals both a tendency to pull favorable outcomes forward in subjective time and push inauspicious outcomes backward (Ross and Wilson, 2002), though the latter effect may be somewhat stronger.

Meichenbaum (2006a,b) examined the relation of the subjective experience of time to psychological disorders such as posttraumatic stress disorder (PTSD). According to Meichenbaum, these disorders reflect a flawed self-narrative. A self-narrative is the internal autobiography people construct to make sense of the life they have lived so far.

Meichenbaum suggests that the trauma memories of individuals with PTSD are stuck in the present. Individuals with persistent PTSD engage in internal conversations about ongoing threats, ruminate on the negative impact of the trauma, and actively try to suppress thoughts and emotions related to the trauma. The trauma takes center stage and is characterized as the most important theme in the life story.

To address the effects of PTSD, Meichenbaum advises therapists to help patients reframe their traumatic memories into historical narratives that have a distinct beginning, middle, and end. Patients with PTSD should incorporate traumatic memories into the self-narrative in such a way that the events are seen as a small part of the life story, rather than an ongoing theme. Meichenbaum also suggests that therapists emphasize the distinction between present and past and position the traumatic memory firmly in the past.

### 2.47.6.2 Point of View

Nigro and Neisser (1983) reported that individuals recall events from either a first-person or a third-person visual perspective. When people adopt a first person perspective, they view the event through their own eyes. When people assume a third-person point of view, they view the event as an outside observer who is watching the actions of the past self. The fundamental attribute of a third-person memory is that individuals can see themselves in the recollection.

Like subjective time, point of view is a variable that relates to 'how' people remember, rather than 'what' they remember. Moreover, like subjective time, point of view is associated with actual temporal distance, memory content, and self-concept. Older memories are more likely to be viewed from a third-person point of view (Nigro and Neisser, 1983). Memory perspective is flexible, however, and the content of the memory also affects the perspective adopted (Nigro and Neisser, 1983). For example, participants were more likely to use a first-person perspective when they focused on the emotional content of a memory, rather than its objective circumstances (Nigro and Neisser, 1983).

Libby and Eibach (2002; Libby et al., 2005) related the visual perspective of autobiographical memories to the self-concept. Individuals were more likely to invoke a first-person perspective when recalling actions consistent with their current self-concept. For example, participants who were induced to feel religious (by means of a biased questionnaire) were highly likely to recall a religious memory from a first-person perspective. Participants who were encouraged to feel irreligious were significantly more likely to report that they viewed a religious memory from a third-person perspective (Libby and Eibach, 2002). In another study (Libby et al., 2005), participants were randomly assigned to recall the same episode from either a first-person or third-person perspective. Participants who invoked a third-person perspective reported that they had changed more since the time of the episode. A third-person perspective seems to operate as a distancing mechanism, leading individuals to perceive that a past self is a different person than the current self.

Some clinicians have advocated use of the third-person perspective in therapy. Lawrence (1990) suggested that a patient speaking in the third person is able to adopt a more detached perspective on memories. Lawrence claimed that, as a result, third-person analysis yields less guilt and fewer defensive justifications. Similar to pushing events back in subjective time, the use of a third-person perspective involves reducing the psychological threat of negative experiences through distancing, rather than through forgetting or denial.

## 2.47.7 Memory in a Social Context

### 2.47.7.1 Collaborative Memory

Although psychologists generally study remembering as a solitary cognitive activity, everyday remembering is frequently collaborative. For example, spouses depend on each other's memories as they try to recall phone numbers or names (Wegner et al., 1991). Intuitively, it seems likely that collaboration would improve recall, and research confirms this belief: Two people, remembering together, recall more than either individual would recall alone (e.g., Vollrath et al., 1989; Weldon, 2001).

There are two obvious reasons why collaboration might improve memory. First, group memory might be better simply because two individuals are remembering rather than one. Alternatively, collaboration might bring forth memories that would not arise during solitary remembering. If such synergy occurs, two individuals would remember more together than they would if they pooled their individual recollections. To clarify this distinction, consider two spouses independently remembering a shopping list. On his own, the man remembers items a, b, c, and d; meanwhile, his wife remembers a, b, e, and f. Alone, they each remember four items. If they pooled their individual recollections, they would together recall six nonredundant items (a, b, c, d, e, f). What if, instead of recalling the shopping list separately, they had recalled it together? Collaboration provides the opportunity for cross-cuing: The recollections of one person can offer cues that help another person remember information (Meudell et al., 1995). It seems plausible, then, that collaborative recall would generally exceed the sum of individual recollections provided by group members.

To examine whether collaboration produces better memory than pooled individual recollections, researchers include three conditions: individuals remembering alone, individuals remembering together, and nominal group recall. Nominal groups are groups in name only. Participants remembering alone are coupled, often randomly, and their recall is pooled. The recall score of a nominal group is the total amount of nonredundant information in the pooled recall. When these procedures are followed, the findings are consistent: Nominal group recall exceeds collaborative recall, which in turn surpasses individual memory (e.g., Basden et al., 1997; Weldon and Bellinger, 1997; Finlay et al., 2000; Weldon, 2001; Ross et al., 2004).

Labeled collaborative inhibition (Weldon and Bellinger, 1997), the finding that nominal recall outstrips collaborative recall has been obtained in dyads of strangers, friends, and married couples, and in elderly couples as well as college students. Although collaborative inhibition sometimes declines in well-acquainted groups, it is not reversed. Collaborating friends or spouses recall no more information than nominal groups, and they usually recall less (Andersson and Ronnberg, 1995; Johansson et al., 2000; Gould et al., 2002; Ross et al., 2004). Evidently, the cross-cuing that occurs during collaboration produces inadequate retrieval cues and interference rather than emergent memories (Meudell et al., 1995; Finlay et al., 2000). While listening to someone else's recollections, group members might forget their own memories or be prevented from trying to remember (Diehl and Stroebe, 1987). Also, idiosyncratic, self-generated retrieval cues are often better triggers for one's own memories than cues provided by another person (Basden et al., 1977; Meudell et al., 1995; Andersson et al., 2006). To the extent that collaboration inhibits self-generated retrieval cues, recall is likely to suffer.

So should spouses or work colleagues collaborate when trying to remember information in everyday settings, for example, the items in a list? The answer is yes for three reasons. First, collaborative recall is better than individual recall, even if it is not superior to pooled nominal group recall. Second, over time well-acquainted groups develop integrated systems of memory storage and retrieval for some everyday memory tasks (Wegner, 1986). They learn to divide the labor on memory tasks based on personal expertise (e.g., the travel agent spouse remembers to book summer vacations) and gender-role stereotypes (e.g., the man remembers when the car needs an oil change). Because of this division, there is no reason for spouses to try to remember everything. As long as they know what type of information their partners know, they can call on them when needed.

Finally, collaboration is useful because it can help reduce mistakes in memory even when it does not increase the amount of true memory recalled. A measure of mistakes, or false positives, is omitted in many studies of collaborative recall because the frequency of errors is low in the types of memory tasks typically used in this research (Ross et al., 2004). Using everyday memory tasks in which false memories were quite common, Ross et al. (2004) found that collaborative groups of older adults reported fewer errors in free recall than did nominal groups or individuals recalling alone. A recent study shows that collaboration produces a similar reduction in errors of younger (under age 40) participants (Ross et al., unpublished data).

Why might collaboration reduce memory errors? Any particular error is often unique to an individual, reflecting his or her knowledge, beliefs, and associative linkages between items in long-term memory (Ross et al., 2004). When errors are idiosyncratic, a rememberer's partner can exercise a kind of quality control by inspecting the memory, assessing its accuracy, and expunging false recall.

A reduction in false recall could be especially important for older people, who tend to recall more false memories than their younger counterparts (Jacoby and Rhodes, 2006). Relative to younger adults, older individuals are more likely to be misled by false information, more prone to source memory errors, and more confident of the accuracy of their false memories (Hashtroudi et al., 1989; Jacoby, 1999; Karpel et al., 2001; McCabe and Smith, 2002; Kelley and Sahakyan, 2003; Jacoby et al., 2005). There is not much research on techniques that might help older people reduce such errors. Collaboration has the advantage of being a readily available strategy in everyday life.

### 2.47.7.2 Controlling and Transmitting Memories

The research discussed in the preceding section on collaborative memory features two individuals remembering together at the same time. But memory is often collaborative in another sense. Memories are transmitted from person to person and from generation to generation. Much of what we remember we have learned from others rather than experienced directly. This type of remembering is evident in people's knowledge of the history and origins of their countries. As with individual memory, prior events or beliefs that contradict current ideas and values are sometimes erased from the history or altered so as to be consistent with present understandings (Goody and Watt, 1968; Ong, 1982). For example, when the British arrived in Ghana in the early part of the twentieth century, they found that the state of Gonja was divided into seven territories, each ruled by its own chief (Goody and Watt, 1968). When British authorities asked them to explain their system, the Gonja revealed that the founder of their state, Ndewura Jakpa, had fathered seven sons. Jakpa divided the land so that each son ruled one territory. Shortly after the British arrived, two of the seven states in Gonja disappeared as a result of changes in boundaries. Sixty years later, oral historians again recorded the myths of state. In the updated version, Ndewura Jakpa had only five sons; the Gonja made no mention of the founders of the two territories that had vanished from the scene.

In literate societies, individuals also revise history, especially in response to changing knowledge, goals, and political regimes (Greenwald, 1980). People interpret the past in terms of the present, and therefore "every generation rewrites its history" (Mead, 1964: p. 351). Some of the revisions involve efforts to improve the past. Stories of atrocities and wrongs committed by compatriots are often excluded from a nation's history textbooks and from popular culture (Hein and Selden, 2000). As Blight (2001) remarked with respect to memory of the American Civil War, "deflections and evasions, careful remembering and necessary forgetting, and embittered and irreconcilable versions of experience are all the stuff of historical memory" (Blight, 2001: p. 5).

We do not have to look to history to find archival evidence of people's efforts to improve the past. We can look at our own discipline, psychology. Research findings constitute the core of scientific psychology. Are past results described accurately in secondary sources, such as review articles and book chapters of the sort you are reading? Not always. When writing about past research, psychologists sometimes describe the results or procedures in ways that magnify the strength of the findings (Berkowitz, 1971; Loftus, 1974; Harris, 1979; Vicente and Brewer, 1993), as well as allow their theoretical preferences to guide their summaries and interpretations of past research (Berkowitz, 1971; Harris, 1979; Vicente and Brewer, 1993). Comparable distortions occur in the literature of other sciences (Vicente and Brewer, 1993).

It is also not difficult to find evidence of distortions in the media that could contribute to distortions in memory. The media play a role in communicating the words of famous individuals to society at large and therefore in producing memories of their statements. Misquotations in newspapers and other print media provide intriguing examples of historical revision (Keyes, 1992). For example, baseball manager Leo Durocher is credited with saying "Nice guys finish last." He really said, "The nice guys are all over there. In seventh place." The quote became punchier and pithier with repeated retelling. A second notable misquotation is associated with the comedian W. C. Fields. Fields is renowned for saying, "Any man who hates dogs and children can't be all bad." Fields did not say it. Leo Rosten said it about Fields when he introduced the comedian at a banquet. Keyes (1992) provided many other examples of quotations that change or are ascribed to the wrong person over time. Keyes was able to trace the source of the various quotations because he had access to documentary records.

Ordinary people do not write textbooks or journal articles or get quoted in the media all that often. But they do transmit information and memories across generations through socialization, stories, and teaching. Sometimes this information is transmitted precisely and remembered verbatim. For example, children memorize the times tables and the spelling of words, while anatomy students memorize the names and locations of brain structures. In these cases, approximations are not good enough. Even though the words are very similar, you cannot write golf if you mean gulf. In most contexts, however, children and adults are not required to recall or transmit a verbatim memory. Daily remembering typically involves recalling the meaningful gist of episodes rather than exquisite detail. Moreover, as information is transmitted from individual to individual, it changes. People adjust their reports of their memories in response to their listeners' status, age, interests, knowledge, and attitudes (Brown and

Levinson, 1978; Higgins and Rholes, 1978; Cansler and Stiles, 1981; DePaulo and Coleman, 1986; Schlenker and Weigold, 1992; Kashima, 2000; Thompson et al., 2000; Lyons and Kashima, 2003). The recipients of the information then take ownership of it by making it more consistent with their current beliefs and knowledge (Bartlett, 1932).

The study of rumors provides an intriguing example of how information is constructed and transmitted. Rumors often emerge when information is scarce but people feel a need to know (Allport and Postman, 1947). Consider, for example, rumors that occurred after Hurricane Katrina struck the Gulf Coast region of the United States (Rosenblatt and Rainey, 2005). The hurricane destroyed lines of communication and the associated ability to obtain direct news reports from the Gulf Coast. Most news reports were based, at best, on secondhand accounts. News agencies reported grossly exaggerated stories. In the first few days after the hurricane struck, news reports implied that the city had descended into chaos: Senseless looting was prevalent, snipers were randomly shooting people from rooftops, and gangs were roving the streets in murderous rampages. Most of these rumors were either exaggerations or completely false (Rosenblatt and Rainey, 2005).

Bartlett (1932) attempted to capture this process of rumor transmission with his method of serial reproduction. In Bartlett's research, the first participant in a chain read a fairly obscure and confusing passage (e.g., 'The War of the Ghosts') and recalled the passage after a 15-min delay. A second person read the first person's account and recalled it; a third person read the second person's account, and so on. Bartlett found that verbatim recall of the passage was rare. Participants commonly omitted unusual elements and added connections to make sense of the material. Bartlett took these findings as evidence for a reconstructive view of memory. It is also likely that the process of communication influenced recall of the story. To be clear and comprehensible, participants might alter the information that they transmit.

Along the same lines, Allport and Postman (1947) had the first participant in a six- or seven-person chain view a picture. The first person served as an "eyewitness" and was the only person in the chain to see the picture. The initial person described the picture (while viewing it) to a second person. This second person then transmitted what he or she remembered to a third person and so forth. Participants were told to listen carefully and transmit what they heard as "exactly as possible" (Allport and Postman, 1947: p. 66).

In contrast to Bartlett, who used obscure stories as stimuli in his studies, Allport and Postman used pictures that were not difficult to understand. The pictures contained everyday scenes such as people seated on a subway. Nonetheless, Allport and Postman obtained results similar to Bartlett's. They found that descriptions of the pictures were leveled and sharpened as recall moved along the chain. Leveling involves reducing the amount of detail, and sharpening refers to emphasizing just a few core elements. As rumors are transmitted, they change from more elaborate stories (e.g., desperate residents of New Orleans breaking into stores seeking supplies) to a core theme (e.g., senseless looting).

Allport and Postman (1947) used several pictures, but their most famous scene portrayed a Black and White man having a confrontation on a subway train. In the original scene, the White man held a knife. Early in the chains, participants accurately recalled that the White man possessed the knife. As the description of the picture was passed along the chains, however, the knife sometimes ended up in the hands of the Black man. The stereotype of aggressive Black men apparently influenced memory further down the chain. Similar to Barlett, Allport and Postman did not provide detailed descriptions of their findings. It is unclear in how many chains the knife changed hands.

Recent media reporting of world events may have replicated this finding. Many have argued that the news reports of senseless looting in New Orleans reflect similar racial stereotyping (Rosenblatt and Rainey, 2005). News reports portrayed Black Americans breaking into stores looking for necessary supplies and, occasionally, expensive consumer items (Rosenblatt and Rainey, 2005). Often incidents of people stealing expensive products such as plasma televisions were emphasized more than incidents of people appropriating diapers, toothbrushes, and canned goods (Rosenblatt and Rainey, 2005). Negative aspects of the Black stereotype likely contributed to how events were reported in the media and remembered by a non-Black audience.

Gilovich (1987; Study 1) applied the method of serial reproduction to person perception. The first person in the chain watched a videotape of a male or female student describing transgressions they had committed, along with mitigating circumstances that helped explain their actions. Participants then evaluated the target on several dimensions (e.g., generous/selfish) and described what they had seen on the videotape to another person. They were told to provide a description that would permit a listener "to determine what this person did and what this person was like" (Gilovich, 1987: p. 63). The second-generation person evaluated the target after hearing the description. Interestingly, second-generation participants evaluated the transgressor more negatively than did the first people in the chain. This difference arose because first-generation participants were more likely to take mitigating circumstances into account. In leveling and sharpening their report, however, first-generation participants underemphasized mitigating circumstances; as a result, such conditions had less of an impact on the judgments of second-generation participants.

The Gilovich study has intriguing practical implications. Because the public rarely has direct exposure to world events, public opinion is influenced by how events are depicted in the media. And the leveling and sharpening that occurs in the process of reporting is likely to affect public opinion. There is evidence, for example, that media reports affect judgments of the criminal justice system. Public opinion in Canada and elsewhere often evaluates criminal sentences as too light (Roberts and Doob, 1990). In examining this phenomenon, Roberts and Doob found that media reports of criminal trials are leveled and sharpened. Journalists often omit mitigating circumstances that judges take into account during sentencing. In one study conducted by Roberts and Doob (1990), individuals who read actual court documents supported a lighter sentencing decision than did those who read a newspaper description of the sentencing decision.

## 2.47.8 Creating Memories

The issues that we have discussed concerning the transmission of memories come into focus in media portrayals of historical figures. Novelists, dramatists, and screenwriters sometimes deliberately blur the line between historical truth and fiction. They may sometimes do this for political reasons; for example, Shakespeare tailored the facts in his histories to suit the preferences of the Tudor monarchs of his day. Authors may also rewrite history to increase dramatic tension and maintain an audience's interest. In his play *Amadeus*, Peter Shaffer's depiction of the characters of Mozart and Salieri, and of Salieri's possible complicity in Mozart's death, is effective drama but questionable history. For many members of the audience, Shaffer's account may provide the primary source of information on Mozart's life story.

Presumably most people attend films or live theater to be entertained rather than to obtain a history lesson. When the tale is set in an historical context, however, they may believe that they have received both. Audiences who are unaware of alternative accounts may accept such stories as authentic. In this manner, the media help shape people's collective memories.

The revision of history to accomplish particular objectives is not limited to professional writers, the media, or scientists. As we have emphasized in this chapter, it is also a hallmark of everybody's efforts to recall and communicate their pasts. In comparison to professional writers who derive their historical stories from written records, individuals may be less aware of their alterations as they use their present knowledge, beliefs, and goals to construct their own histories. In this sense, people's personal recollections are comparable to the oral traditions of nonliterate societies.

It is useful and normal for people to create pasts that satisfy their current needs. As Bartlett (1932) and Mead (1964) stressed, the past is a resource that people can use and adapt for current purposes. People can get into trouble, however, if they underestimate the fallibility of their own memories. Perhaps the lesson of social psychological research on memory is not that people should be less creative but that individuals should be aware of the degree to which they rewrite their own histories.

# 2.48 Collective Memory

**J. V. Wertsch**, Washington University in St. Louis, St. Louis, MO, USA

Collective memory is a representation of the past that is shared by members of a group such as a generation or nation-state. Instead of focusing on individual experience and memory, the study of collective memory examines social phenomena such as commemoration, history education, and mass media to understand how they give rise to shared accounts of the past. In some cases, the events in collective memory have occurred during the lifetime of members of the group, and in others they are from decades or centuries earlier, but in all instances the emphasis is on the social, cultural, and psychological processes that give rise to shared representations.

Instead of neutral knowledge, collective remembering typically involves beliefs – often strongly held – that are tied to identity, and hence they may evoke strong emotions when challenged. The fact that different groups can have quite different accounts of the past means that social identity and the politics of identity typically must be taken into account.

The concept of collective memory is often traced to writings of the French sociologist Halbwachs (1887–1945), who argued that remembering is shaped by participation in collective life and that there are as many accounts of the past as there are collectives (Halbwachs, 1992) (The two major works by Halbwachs in English – *On Collective Memory* (1992) and *The Collective Memory* (1980) – are compilations of French publications from the 1920s, 1930s, and early 1940s. He died in Buchenwald concentration camp shortly before the end of World War II.). In recent decades, related terms such as public memory (Bodnar, 1992) and cultural memory (Assmann, 2006; Lotman, 1990) have emerged alongside of collective memory and are now part of the memory industry (Klein, 2000) in the humanities and social sciences. A concern with these topics can be found in academic disciplines such as psychology (Pennebaker et al., 1997), anthropology (Cole, 2001), history (e.g., Novick, 1999), and sociology (e.g., Schuman and Rodgers, 2004), and it is also widely encountered in public discussions of issues such as the Holocaust and the Vietnam War.

Despite – or perhaps because of – the fact that collective memory is so widely discussed in the public sphere and academic disciplines, there is little agreement on its definition. In contrast to the study of individual memory, where some concurrence exists on basic constructs and methods, definitions of collective memory, let alone the methods for studying it, vary widely. Indeed investigators usually seem to be quite unaware of the work of others, even when they employ the same terms.

In an attempt to lay out a conceptual map for this field of inquiry, I shall use collective memory as a general term to discuss findings from a range of disciplines and theoretical traditions. Scholars such as Gedi and Elam (1996) object to this, viewing collective memory as a poor substitute for older terms such as political tradition and myth. For them, using the term is "an act of intrusion . . . forcing itself like a molten rock into an earlier formation . . . unavoidably obliterating fine distinctions" (Gedi and Elam, 1996: 30). The problem with such critiques is that they do not deal with the issue of how various strands of inquiry can be related to one another. Instead of assuming that these strands will remain isolated, the emphasis in what follows is on how they can be connected into a larger whole.

This review will be organized around sections concerned with: (1) collective memory as social framing, (2) collective memory in the social construction of groups, and (3) collective memory as semiotic distribution. These three topics are not so much competing perspectives on the same set of issues as different research traditions that have had little contact, each with its own theoretical and methodological starting point. The tradition concerned with memory as social framing focuses on how individuals' memories are shaped by social forces. Its main emphasis is on the influence of these social forces on individuals in a group, rather than the origin and nature of the groups themselves. The tradition concerned with the social construction of groups focuses on processes that create and maintain groups, and it tends to treat memory in an instrumental role in these processes. And the tradition concerned with collective memory as semiotic mediation draws on yet other disciplines to examine how language and other cultural tools mediate social and individual processes.

These three traditions do not line up neatly along disciplinary lines, nor do they constitute anything as coherent as schools of thought. They have, however, remained relatively self-contained and isolated lines of inquiry. This is due not so much to contradictions among them as to the fact that different communities of scholars, using different concepts and methods, are often unaware of the others' existence. However, the terms memory and collective memory are widely used across approaches, and for this reason these traditions of inquiry can be viewed as providing different answers to a basic question that guides this chapter: What makes collective memory collective?

All three traditions I shall outline are united in their acceptance of a psychological dimension of the larger picture, a point worth noting since this means they avoid the pitfalls of a strong version (Wertsch, 2002) that sometimes emerges in discussions of collective memory. Strong versions in one way or another assume the existence of memory in some sort of group mind, an assumption that is usually grounded in parallels between individual and collective processes. Such ideas – often in the form of unexamined assumption – have been criticized at least since Bartlett objected to positing a "more or less absolute likeness . . . between social groups and the human individual" thereby assuming that "whatever is attributed to the latter has been ascribed to the former" (Bartlett, 1932: 293).

Bartlett, who used the term social psychology quite strategically in the subtitle of his landmark monograph *Remembering*, rejected a strong version of collective memory (social memory in his terminology). He did so by stressing the difference between "memory *in* the group," which he embraced as the focus of his research, and "memory *of* the group" (Bartlett, 1932: 296, italics in the original), which he rejected as being a fundamentally misguided notion. In his view "Social direction and control of recall – memory within the group – are obvious; but a literal memory *of* the group cannot, at present at least, be demonstrated" (Bartlett, 1932: 298). As will be argued, the tradition of inquiry concerned with collective memory as semiotic distribution provides the clearest means for avoiding a strong version of collective memory, but all three traditions avoid the pitfalls of a strong version of collective memory in one way or another.

These traditions also share a preference for focusing on remembering as a process rather than memory as a static object or body of information. For reasons similar to those that motivated Bartlett to title his 1932 text *Remembering*, it is would be preferable to speak of collective remembering rather than collective memory. Using the former emphasizes the centrality of what Bartlett called the "effort after meaning." In the case of collective remembering, using the term furthermore highlights the active social and political processes involved, processes of contestation and conflict between visions of the past. But collective memory is a term that is so widely used in academic and popular discourse that any attempt to ban it would be futile. Hence, I shall use collective memory and collective remembering interchangeably in what follows.

## 2.48.1 Collective Memory as Social Framing

At least since the 1920s scholars have argued that remembering must be viewed as a socially framed or situated activity. When Halbwachs said that there are as many memories as groups, he often had such ideas in mind, a point that is reflected in his assertion that "it is individuals as group members who remember" (Halbwach, 1980: 48), and as already noted, Bartlett made similar claims. Both of these founders of memory studies took it as a given that individuals – but socially situated individuals – remember. As Olick (1999) has noted, Halbwachs sometimes appeared to be ambivalent on this issue, and at some points he even seemed to accept a strong version of collective memory (Wertsch, 2002). However, many passages in his writings are quite similar to what can be found in Bartlett.

The social framing of memory has continued to be an important thread of research in psychology and sociology, even shaping the study of forms of remembering that appear to be prototypically individual. This can be seen in the research on flashbulb memory. Since being introduced by Brown and Kulik

(1977), this phenomenon has been the object of widespread interest both in psychology and the broader public. Neisser (1982) defines it as "a subjectively compelling recollection of an occasion when we heard an important piece of news" (Neisser, 1982: 43). It appears to be intensely personal since the memory involved focuses on the individual's own experience of the event rather than the event itself.

Some flashbulb memories are about specific events experienced by individuals and derive from "the sundry private shocks in each person's life" (Brown and Kulik, 1977: 75) such as hearing about the death of a family member. However, most cases examined in the literature concern events that are jointly experienced, and it is in this connection that they have a collective dimension. The assassination of President John F. Kennedy in 1963 provides the classic example of this. Virtually everyone in the United States above early childhood at the time has a vivid and subjectively compelling recollection of where she was and how she heard about it. Along with other events such as the assassination of Martin Luther King, Jr., the 1986 Challenger shuttle explosion, and the terrorist attacks of September 11, 2001, such instances of flashbulb memory are widely shared in the United States.

From the very outset of flashbulb memory studies there have been attempts to address its collective dimensions. Brown and Kulik, for example, reported group differences between African Americans and White Americans in flashbulb memories for the assassinations of civil rights leaders. A tendency to view flashbulb memories as individual phenomena runs throughout the literature, however, largely because the research has focused on individuals' personal impressions and reactions rather than attention to the shared historical event. As Brown and Kulik noted, flashbulb memory is above all "memory for the *circumstances* in which one first heard the news" (Brown and Kulik, 1977: 95), vivid images of precisely where we were, what we were doing, who told us the news, and so forth, instead of memory for the historical event itself.

In more recent research, additional claims about the collective framing of flashbulb memories have been pursued. For example, in two studies of flashbulb memories for earthquakes (Er, 2003; Neisser et al., 1996), investigators found differences between groups of subjects who experienced the event directly and those who found out about it indirectly through media reports. A more elaborated account of group differences having to do with social identity can be found in a study by Berntsen and Thomsen (2005). Concerned with "the accuracy and clarity of [flashbulb memories] as a function of emotional and social factors" (Berntsen and Thomsen, 2005: 242), they examined Danes' memories for the German invasion of their country in 1940 and its liberation in 1945. Specifically, they examined differences between the memory of Danes who had ties to the resistance movement in World War II and those who did not and found that those in the first group had more vivid and accurate memories than subjects who did not.

In another study, Bohn and Berntsen (2007) examined additional aspects of the impact of group membership on flashbulb memory. In this case, the object of memory was the fall of the Berlin Wall in 1989. Germans who viewed the event either negatively or positively participated in the study. Those in the positive group rated their memories higher in terms of reliving and sensory imagery, but their memories were actually less accurate than participants in the negative group, something that Bohn and Berntsen attribute to a more "detail-oriented, bottom-up processing strategy related to negative affect" (Bohn and Bernsten, 2007: 571) for the negative group. They also note that differences in accuracy may be due to increased levels of discussing and rehearsing the event by the positive group, practices typically grounded in schema-based organization that derives from narrative retelling.

In sum, although flashbulb memories need not be about events experienced by a group, most of the cases studied to date are in fact of this sort. This has led some investigators to be concerned with how memory processes in one group may differ from those in another. Findings indicate that such differences can be complex, involving more than the amount of information recalled. This is part of the larger set of issues originally raised by Bartlett about the social framing of memory, issues that occasionally make it into psychological studies. While interesting, these issues "have not been systematically pursued" (Roediger, 2000: 155) to date.

## 2.48.2 Collective Memory in the Social Construction of Groups

In the view of Olick (1999), the sort of social framing discussed in the previous section is concerned with collect*ed*, as opposed to collect*ive*, memory since it amounts to "the aggregation of socially framed individual memories" (Olick, 1999: 333). In such cases, the social dimension enters the picture as a kind of independent variable having to do with objective facts about group membership. In some instances, this group membership is a matter of culturally salient categories such as race or political affiliation, and in others it amounts to little more than happening to be part of a group that experienced a major event together. From this perspective, group membership is viewed primarily as a predictor of individual memory performance.

In contrast, several investigators in sociology and psychology have outlined alternative proposals concerned with what Olick considers to be genuinely collective memory. A hallmark of this approach is that collective remembering involves social facts (Durkheim, 1982) and processes that cannot be reduced to individual psychological phenomena. As a student of Durkheim, whose ideas have done much to shape contemporary discussions in sociology, much of what Halbwachs (1980, 1992) argued fell under this heading. In more recent years, this point has sometimes been framed as a rejection of methodological individualism (Lukes, 1977). In the cases I shall review, however, the difference is more one of interest and emphasis than simple opposition to studies in psychology and other disciplines that focus on the individual.

One important strand of research concerned with what Olick views as genuinely collective memory concerns the social formation of groups. From this perspective the group is a product, rather than a prerequisite of shared memory. This is a line of reasoning that is often traced to the writings of the sociologist Mannheim, especially his essay "The problem of generations" (Mannheim, 1951). There he argued for the need to follow a romantic-historical, as opposed to a positivist, approach to group membership. Specifically, he argued for the need to view a generation as subjectively constructed and defined rather than a cohort determined by objective dates. From this perspective, generations are "mental and spiritual units" (Mannheim, 1951: 289) that come into being because people share historical experience and memories.

Schuman and his colleagues have explored several implications of this line of reasoning (e.g., Schuman et al., 1997; Schuman and Scott, 1989). Instead of being a reflection of group membership, these investigators view collective memory as playing a role in the construction of the mental and spiritual units of generations. The emphasis is on how a generation comes into being as its political outlook is shaped by the events its members experience, especially during the critical period of young adulthood. Thus the greatest generation (Brokaw, 2001) was fundamentally shaped by events it experienced in World War II, the Vietnam generation is haunted (McPherson, 2002) by events it experienced in the 1960s and 1970s, and so forth.

An essential part of Schuman's argument is that "adolescence and early adulthood are a stage of life uniquely open to gaining knowledge about the larger world" (Schuman et al., 1997: 47). For example, Schuman et al. (1997) conducted a survey about knowledge of past events among Americans between the ages of 18 and 80 and documented that this knowledge is dependent on the point in the life course when an event is experienced. Their results generally support the claim that knowledge for events encountered in young adulthood tends to be more extensive than for events experienced before or after this critical period.

For example, Americans who were in their early twenties when the Tet Offensive of the Vietnam War occurred demonstrated greater knowledge about it a quarter century later than both younger and older people. The curvilinear pattern of knowledge involved in this case also emerged for other events such as the Holocaust and Watergate (Schuman et al., 1997). In a few instances, Schuman et al. did not find the results they predicted, something that serves as a reminder that generations are subjectively defined cohorts rather than objective periods. For example, Schuman et al. (1997) failed to find distinctive generational effects for some aspects of the Watergate scandal, namely, John Dean's role in it, and they interpreted this to "indicate that a purely mechanical approach to cohort effects on knowledge is inadequate" (Schuman et al., 1997: 74). What may be required for events to be salient for collective memory is that they are taken to be what Pennebaker and Banasik (1997) term important turning points for American self-views.

The appearance of the term knowledge throughout these discussions raises a question about why it, rather than the term memory should be invoked. In order to make the case that memory is indeed involved, one must recognize that two functionally differentiated types of knowledge are at issue in such discussions. On the one hand, there is knowledge that may be widely shared but has little relevance to identity or self-views. As reflected in the title *1066 and All That* (Sellar and Yeatman, 1931), much of what people might have been taught about the past is not taken to be particularly relevant to their contemporary concerns.

In contrast, other aspects of knowledge about the past are central to understanding and defining who we are. Just as stories we live by (McAdams, 1993) are essential means for personal identity, certain narratives play an essential role in forming collectives such as nation-states. In these latter cases, it is not simply knowledge about the past that is involved; it is knowledge that is crucial to understanding and defining identity and creating self-views. In this connection, Zerubavel (2003) notes, "acquiring a group's memories and thereby identifying with its collective past is part of the process of acquiring any social identity, and familiarizing members with that past is a major part of communities' efforts to assimilate them" (Zerubavel, 2003: 3).

Assmann (1997) has discussed these issues under the heading of a distinction between history and memory. For him, the latter is vitally tied to contemporary discussions of identity. In its case, "The past is not simply 'received' by the present. The present is 'haunted' by the past and the past is modeled, invented, reinvented, and reconstructed by the present" (Assmann, 1997: 9).

In this respect, there are several points of possible contact between collective memory research and psychological studies of individual memory. For example, the centrality of identity in collective remembering suggests interesting parallels with the notions of a self-memory system as outlined by Conway and Williams (*See* Chapter 2.46). It also raises issues of how collective memory is related to constructs from psychology such as semantic and episodic memory. In many instances of collective remembering, the focus is clearly on an episode from the past, hence suggesting parallels with episodic memory. However, closer analysis usually reveals that some sort of more general category or abstract schema seems to be involved, suggesting parallels with semantic memory. As Balota and Coane (*See* Chapter 2.28) point out, however, the distinction between semantic and episodic memory is difficult to maintain in discussions of psychological processes, and trying to examine the psychological dimensions of collective remembering may further complicate this. It is also possible that research on grounding semantics in perceptual motor systems (*See* Chapter 2.28) may eventually provide insight into the psychological dimensions of collective remembering.

The major point to be kept in mind when engaging in such discussions is that knowledge about the past counts as collective remembering when it becomes crucial to the project of constructing group identity. A usable past is almost always crucial to such projects, and for this reason people become very attached to certain historical narratives, even going to far as to invent, reinvent, or reconstruct them to meet the needs of the present. Among other things, this points to the need to understand the emotional dimensions of collective remembering, perhaps harnessing some of the ideas of Barsalou (1999) about how knowledge is stored in perceptual symbol systems.

Claims about assimilating people into a mnemonic community (Zerubavel, 1997) beg the question of how this is done and when in the lifespan the effort might be most effective, and it is here that other fruitful connections among various traditions of memory studies can be forged. In this connection, there are obvious ties to be made between sociological studies by researchers such as Schuman et al. on critical periods in the formation of a generation and the notion of a reminiscence bump outlined in psychological studies of memory and the fact that the autobiographical memories retrieved are disproportionately from ages 15–25. Rubin et al. (1986) proposed this notion when analyzing the life span retrieval curve that has been observed in individuals above the age of 35. They collected evidence for this phenomenon by employing techniques such as presenting subjects with a word and asking them to provide the first autobiographical memory that comes to mind.

Rubin et al. (1998) report that such procedures repeatedly yield greater numbers of memories dating between the ages of 10 and 30 than for earlier or later periods in subjects' lives. Conway and Pleydall-Pearce (2000) similarly conclude that "the knowledge acquired during the reminiscence period is highly accessible and more accessible than knowledge outside this period" (Conway and Pleydall-Pearce, 2000: 19). Rubin et al. (1998) consider several explanations for why this is so and accept an account based on the novelty of experience and its effect on memory.

Building on the ideas of Erikson about identity development and on further empirical studies, Conway and Pleydell-Pearce provide another interpretation, namely that "the reminiscence bump reflects preferential retention of events from a period of consolidation of the self" (Conway and Pleydall-Pearce, 2000: 20). This involves forming long-term allegiances and friendships, developing a life story schema, and generating a life narrative. To the extent that these processes take place in the context of major historical events such as war, economic depression, or assassinations, one can expect events to have a formative role in individuals' and generations' political outlook.

Combining ideas about the reminiscence bump with the analysis of how memory functions in the social formation of collectives points to the importance that young adults' experiences have on the political outlook of generations. This is a point that has been recognized by those who wish to control this experience. In this connection Mannheim noted, "it may sometimes happen that a feeling for the unity of a generation is consciously developed into a basis for the formation of concrete groups, as in the case of the modern German Youth Movement" (Mannheim, 1951: 288).

In general, studies of memory in the social construction of groups focus on how effective such memory is in the formation of collectives. This orientation has led sociologists such as Fine (2001) to write about how reputational entrepreneurs try to shape the way that deeds are remembered as part of an effort to enhance group pride and membership. This emphasis contrasts with research on socially framed memory, which tends to be more concerned with accuracy or inaccuracy. This does not mean that those concerned with memory in the social construction of groups have no interest in accuracy, but their primary emphasis remains on which memory or which aspect of memory will be most effective in creating group identity. For example, Novick (1999) has argued that collective memory for the Holocaust in America is to a large degree motivated by a desire to reproduce Jewish identity, but at the same time there obviously remains a deep commitment to accuracy in representing the past.

Renan (1990) recognized this in his famous lecture (delivered at the Sorbonne in 1882) 'What is a nation?' where he noted that collective memory, whose core role is to enhance national identity, stands in contrast to analytic studies of history, which aspire to be maximally accurate and complete. As suggested by Assmann's assertion that the present reconstructs the past in memory, Renan believed that "Forgetting, I would even go so far as to say historical error, is a crucial factor in the creation of a nation, which is why progress in historical studies often constitutes a danger for [the principle of] nationality" (Renan, 1990: 11). From this perspective, elites such as state authorities constantly try to shape what Renan called the daily plebiscite on national identity, and collective memory is one of their main tools for doing this.

Perhaps the most forceful formulation of this point can be found in *Nineteen Eighty-Four*, where George Orwell warned, "Who controls the past controls the future; who controls the present controls the past" (Orwell, 1949: 204). While seldom stated in such stark terms, all modern states make an effort to create and maintain collective remembering that will enhance identity and loyalty. This is crucial for what the anthropologist Anderson (1991) has termed imagined communities and what the political theorist Smith (2003) calls people making. Both authors are concerned with the massive institutional resources devoted to constructing group identity. Huntington (2004) takes Anderson's notion a step further in arguing that a nation is "more specifically a remembered community, a community with an imagined history, and it is defined by its historical memory of itself" (Huntington, 2004: 115).

An essential feature of remembered communities is that more than one account of the past competes for the role of being the officially recognized memory. Bodnar (1992) has addressed these issues from the perspective of what he formulates as public memory. This involves a dialectic between the official culture promulgated by state authorities and other elites, on the one hand, and the vernacular culture of everyday life, especially of the nonelites, on the other. For example, in constructing war memorials, official culture celebrates the triumphal vision of the unified nation, whereas vernacular culture often seeks to find a way to interpret events from a perspective of the private pain experienced by those who lost a friend or family member. Bodnar notes that by including the names of individual Americans on the monument, the Vietnam War Memorial in Washington, DC, breaks with earlier practices of celebrating the official cultural view while downplaying the vernacular perspective. In this case, vernacular cultural practices that commemorate private loss and pain have become as much a part of public memory as the official culture perspective that emphasizes the nation as a whole.

Bodnar has explored the dialectic between public and vernacular culture in many other settings as well. For example, he harnesses this conceptual opposition to provide insight into why groups highlight their local and ethnic identities while participating in July Fourth parades that celebrate the unifying vision of the United States. Such analyses address a crucial issue of collective memory in the social formation of groups. Namely, they provide insight into how competing accounts of the past engage in an ongoing debate, thereby making collective remembering into something like an arena of ongoing contestation rather than a set body of received knowledge. Orwell's dictum reminds us that state authorities and other elites have a natural tendency to present the past as such received knowledge, but this is always open to challenge through processes such as those Bodnar outlines under the heading of vernacular culture.

## 2.48.3 Collective Memory as Semiotic Distribution

The third tradition of collective memory studies I shall consider provides yet another answer to the question: What makes collective memory collective? The starting point in this case is the notion of a distributed, as opposed to a strong, version of collective remembering (Wertsch, 2002). In this view, remembering is taken to be distributed in the sense that along with active individuals, it requires cultural tools such as written symbols or mnemotechnics (Yates, 1966). And what makes it collective is that members of a group share the same cultural tool kit (Bruner, 1990). All this does not mean that the tools somehow remember on their own, a claim that would amount to instrumental reductionism, but it does emphasize how extensively humans rely on semiotic means provided by their cultural, historical, and institutional contexts.

As an example of distributed memory at the individual level, consider the analysis of Hutchins (1995) of how a cockpit remembers its speed. By seeming to give cognitive instruments their own agency ("a *cockpit* remembers"), Hutchins emphasizes the importance that they can play in cognition and memory. In this particular case, he examines how a pilot can set and then check with recording devices in an airplane cockpit to keep track of information, and in the process he argues that any assignment of memory to the individual or to instrumentation alone is misguided. Instead, both human agents and the cultural tools they employ must be viewed as integral components of a memory system.

In most studies of semiotically distributed remembering, the emphasis is on how written or spoken language serves as a cultural tool. A major historical transformation in this regard came with what Donald (1991) calls the third transition in human cognitive evolution, one characterized by "the emergence of visual symbolism and external memory as major factors in cognitive architecture" (Donald, 1991: 17). The primary engine of change in this case was not within the individual, but external symbolic storage such as written texts and financial records. Donald stresses that these new forms of external symbolic storage have a transformational impact on psychological and neurological processes; they "impose search strategies, new storage strategies, new memory access routes, new options in both the control of an analysis of one's own thinking" (Donald, 1991: 19). As a contemporary example in the early twenty-first century consider the new skills and strategies that have emerged with the appearance of Google and other search engines on the Internet.

Approaching memory from the perspective of semiotic distribution raises the question of how the use of different linguistic tools gives rise to different forms of memory. Instead of being viewed as simply facilitating existing forms of memory, leaving them otherwise unchanged, such tools are assumed to shape remembering in fundamental ways. A further twist to this line of reasoning stems from the fact that the primary function of language is not to serve as a cognitive or memory tool. Instead, its primary function is communication, and the role it takes on as a tool for remembering is derivative in an important sense. Authors such as Middleton and Brown (2005) have made this point in their study of collective memory. There they argue that the language used to recount the past may depend as much on the need to be convincing or on other communicative goals as it depends on any inclination to be accurate.

A major focus in the study of how language affects remembering is narrative. Researchers from a variety of disciplines have found it useful to make a basic distinction between forms of memory that are mediated by narratives and those that are not. In the case of individual memory, for example, Pillemer (1998) distinguishes between imagistic and narrative forms of "personal event memories" (Pillemer, 1998: 7). Pillemer and White (1989) argue that imagistic memory is "present from birth and operational throughout life . . . The memories are expressed through images, behaviors, or emotions" (Pillemer and White, 1989: 326). In contrast, the narrative memory system "emerges during the preschool years . . . Event representations entering the higher-order system are actively thought about or mentally processed and thus are encoded in narrative form. . . . Memories in the higher-order system can be accessed and recounted in response to social demands" (Pillemer and White, 1989: 326).

Pillemer formulated this distinction in order to analyze developmental issues such as childhood amnesia, where the concern is how imagistic memory is eventually supplemented by remembering mediated by narratives. This does not mean, however, that the former is thought to disappear. Instead, imagistic memory is assumed to continue to exist in adulthood, a claim reflected in Brown and Kulik's account of flashbulb memory, which they speculated "is not a narrative and not even in verbal form, but represented in other, perhaps imaginal ways" (Brown and Kulik, 1977: 85).

Other discussions in the research literature on individual memory focus on distinctions between implicit and explicit memory (Roediger, 1990; Schacter, 1996) or unaware and aware uses of memory (Jacoby, 1988). An essential property of implicit memory is that it is nonconscious (Tulving and Schacter, 1990), which contrasts with explicit memory involving episodic form, which, in turn, is usually taken to involve narrative. Such narrative form is taken to be essential in organizing information and making it available to consciousness. According to Schacter (1994), "a key function of the episodic system is to bind together perceptual with other kinds of information (e.g., semantic, contextual) and thereby allow subsequent recall or recognition of multiattribute events" (Schacter, 1994: 257).

The relationship between imagistic and narrative forms of remembering is often formulated in terms of translation. For example, Pillemer provides an alternative account of repressed memories in terms of a failure of translation (Pillemer, 1998: 133). From this perspective, it is a failure to translate imagistic forms of remembering into narratives that gives rise to what others have called repression. And in the quite distinct realm of historical research, the semiotician Lotman (1990) made an analogous claim.

> Even when the historian is an observer of the events described (examples of this rare occurrence are Herodotus and Julius Caesar), the observations still have to be mentally transformed into a verbal text, since the historian writes not of what was seen but a digest of what was seen in narrative form . . . The transformation of an event into a text involves, first, narrating it in the system of a particular language, i.e., subjecting it to a previously given structural organization. (Lotman, 1990: 221)

From a psychological perspective, one of the important implications of such translation is that it makes possible reflection and control, processes that take on particular importance when dealing with traumatic experience. In a discussion of overcoming traumatic events, for example, Harber and Pennebaker (1992) report that "victims must consciously confront the memories and emotions associated with their traumatic ordeals. This confrontation is best accomplished by translating the chaotic swirl of traumatic ideation and feelings into coherent language" (Haber and Pennebaker, 1992: 360).

As in the case of research on memory in individuals, narrative form provides the basis for distinguishing between different types of collective remembering. The Egyptologist and historian Assmann (2006), for example, distinguishes between cultural memory, under which he includes nonnarrative forms such as foods and landscapes, on the one hand, and national narratives, which impose "a coherent ordering of events along a strict narrative line serving as an intellectual and emotional backbone of national identity" (Assmann, 2006: 21), on the other. This latter form of representation brings along with it tendencies toward being "mono-perspective, ethnocentric, and narcissistic" (Assmann, 2006: 21). As is the case for narratives in general, national narratives are assumed to "grasp together" (Ricouer, 1985: 44) events, characters, and motives into a coherent representation of the past, much in the way that Schacter says episodic memory binds together information.

Research on individual and collective remembering is distinguished, however, by assumptions about the source of the narratives involved. Psychological studies of episodic memory typically assume that narrative organization is generated by the individual. There is little doubt that narrative cognition (Feldman and Kalmar, 1996) is widely used in the effort after meaning that shapes collective remembering as well, but it is typically viewed as involving narrative tools that are provided by the sociocultural context in which individuals function. Again, from this perspective, what makes collective memory collective is the fact these narrative tools are shared across the members of a group.

In this account, collective remembering harnesses existing narratives in the "tool kit" that is "already 'there,' deeply entrenched in culture and language" (Bruner, 1990: 11) to make sense of the past. Of course active agents are always involved and every use of these tools is unique, even creative in some way, but this performance is viewed as harnessing items in what MacIntyre (1984) calls a society's stock of stories. One implication is that Orwell's dictum could be restated as: He who controls the present, controls 'narratives about' the past. He who controls 'narratives about' the past, controls the future.

Heated debates and memory wars provide striking illustrations of these issues. Such debates occur over commemorative monuments, holidays, museums, and history teaching. In the United States, these debates have been over how to represent the atomic bombing of Hiroshima and Nagasaki (Linenthal and Engelhardt, 1996); in India they reflect an ongoing struggle between secularists and religious parties over what narrative would be appropriate for textbooks (Thapar, 2003); and in China they may touch on Japan's collective amnesia (Chang, 1997) about the rape of Nanking in the 1930s.

In reality these concerns do not surface only in history wars; they are part of everyday life in the modern world. Forces of the everyday, unnoticed practices of banal nationalism (Billig, 1995) and the national narratives that are a part of it exist everywhere, and they sometimes come into sharp focus in encounters between collective memory communities. As an example of this, consider an interchange reported by Wertsch (2002) between an American adult and a Russian high school student (Sasha) in the late 1990s. During a visit to a history class in a high school in Moscow, the American adult posed a question to the class about the role of Soviet allies in World War II. The first reaction by Sasha and his classmates suggested that they viewed this as a sort of pedagogical – if not pedantic question to which everyone knows the answer. After making it clear that he took the exercise to be just that, Sasha replied:

> The United States made a lot of money from selling arms and other things to countries during the early years of the war, but it did not really contribute as an ally. In fact, along with Great Britain it refused to open a second front in 1942 and again in 1943. It was only after the U.S. and Britain began to think that the Soviet Union might win the war by itself and dominate post-war Europe that they became concerned enough to enter the war in earnest by opening a second front in 1944. (Wertsch, 2002: 4)

This account differs strikingly from what one finds in the United States – as well as many other places in the world. Indeed, Sasha's narrative might appear to American observers as an effort to be provocative, but in fact he produced it at time of relatively positive feelings toward the United States, and he and many, if not most Russians take what he said simply as a straightforward depiction of what occurred. Furthermore, like many Russians, he would undoubtedly have remained committed to this narrative in the face of what appears to others to be contradictory evidence.

An important fact about Sasha's account is that it is very unlikely that he arrived at it through independent research or the consideration of a range of alternatives. Instead, like most of us in such situations, he employed a standard narrative from the cultural tool kit provided by the textual tradition into which he had been socialized.

In such cases, speakers often fail to appreciate the power of narrative tools to shape what they are saying. Sasha, for example, demonstrated little awareness of the existence of the standard narrative he was using, let alone of how it might be contested. He said nothing like: "What we read in our history books is..." or "I saw in a movie that ..." or "I know that the U.S. has another account, but we believe ..." Instead, he presented his account as simply a description of what really happened, something that reveals a fundamental property of narratives in recounting the past: their transparency (Wertsch, 2002). It was as if he were looking through this narrative tool just as he would look through a clear pane of glass without recognizing that it separated him from the events being reported.

This anecdote about Sasha reflects a larger picture of Russian collective memory and how the narrative tools it employs differs from what can be found elsewhere. Consider, for example, an exercise I often conduct with American undergraduates in which they are to list the most important events of World War II. The procedure consistently yields the following most frequently mentioned items:

Attack on Pearl Harbor (December 7, 1941)
Battle of Midway (June 1942)
D-Day (June 6, 1944)
Battle of the Bulge (winter 1944–45)
Holocaust (throughout the war)
Atomic bombing of Hiroshima and Nagasaki (August 1945)

Results from surveys of Russians in Moscow as well as Novosibirsk in the late 1990s (Wertsch, 2002) provided a quite different list of most frequently chosen items:

German attack on USSR (June 22, 1941)
Battle of Moscow (winter 1941–42)
Battle of Stalingrad (winter 1942–43)
Battle of the Kursk salient (summer 1943)
Siege of Leningrad (1942–44)
Final Battle of Berlin (1945)

A striking fact about these two lists and the narratives they suggest is that there is no overlap. Many Russians know about the events on the American list, but they do not view them as central to the narrative of the war. For example, Russians are quite familiar with the episode called opening the second front in June of 1944. For them, this refers to something that was not only a second, but clearly a secondary front (there is no word for D-Day in Russian), and it is not considered a major event, let alone a turning point in World War II. Conversely, American students often know little about events typically listed by Russians. For example, the largest tank battle in history at the Kursk salient is something that has no resonance in American collective memory, but it is taken to be one of the turning points in the Russian narrative of World War II. Furthermore, it is at the center of scholarly accounts, including those of Western historians such as Overy (1997).

In contrast to such national differences in collective remembering, recent findings by Liu and colleagues (Liu et al., 2005) suggest some similarities. They report a high level of consensus when they asked subjects in six Western and six Asian countries to list the most important events and figures in history for the past 1000 years. The subjects across the groups shared a tendency to focus on the recent past and to include at the top of their list political events and wars, especially World War II. Such findings about similarities across groups led the authors of this study to conclude that "the degree of cross-cultural consensus suggests that hybridity across Eastern and Western cultures in the representation of knowledge may be underestimated" (Liu et al., 2005: 1).

In the end, these results may not contradict the picture of difference between mnemonic communities outlined in the Russian-American case because the nature of the events and the time frames involved are so different. It will only be with much more research of the sort conducted by Liu and colleagues that we will begin to gain clarity on these issues.

In the study of how narratives shape collective remembering, a useful distinction between specific narratives and schematic narrative templates (Wertsch, 2002) can be made. Specific narratives include information about concrete events, actors, times, and places. Sasha's account of the role of the Allies in World War II is an example. Schematic narrative templates, in contrast, are more abstract in nature. They are schematic in the sense outlined by Bartlett in his account of the schemas that shape remembering or by the folklorist Propp (1968) in his analysis of abstract functions in folktales. They are narrative in the sense that they are organized around basic narrative principles such as those outlined by Bruner (1990) and Ricouer (1985). And they are templates in the sense that they involve a generalized form from which several copies (i.e., specific narratives) can be generated.

Wertsch (2002) has outlined a basic Triumph over Alien Forces schematic narrative template that is often employed by Russians when talking about several episodes from their past. This is a general narrative template that is employed by people other than Russians, to be sure, but it plays a particularly important role as a national narrative in their case. Specific narratives that fit this pattern for Russians include accounts of the Mongol invasion of the thirteenth century, the Swedish invasion of Charles XII in the eighteenth century, the Napoleonic invasion of the early nineteenth century, the German attack in World War II, and even the reign of communism in the twentieth century.

The Triumph over Alien Forces schematic narrative template can be summarized as:

1. Russia is peaceful and not interfering with others.
2. Russia is viciously and wantonly attacked without provocation.
3. Russia almost loses everything in total defeat.
4. Through heroism and exceptionalism, and against all odds, Russia triumphs.

Emphasizing the importance of this basic narrative template in shaping Russians' interpretation of the past does not suggest that this interpretation is without foundation. Russia clearly has been the victim of numerous attacks in its history, and its people have undergone great suffering. But the effort after meaning in this case is shaped by the particularly Russian way the events are emplotted and contrasts with other interpretations. In particular, it has to do with how the meaning of actions and the motivation of those who carry them out are interpreted. For example, Estonians have long held that some of the actions that Russians interpret through the lens of the Triumph over Alien Forces are better understood in terms of Russia's longstanding, aggressive imperialism (Tulviste and Wertsch, 1994).

Partly because they are even more transparent than specific narratives, schematic narrative templates are often not recognized, let alone subject to reflection, criticism, and change. Evidence of their conservative nature can be found in the transition from the Soviet to post-Soviet official histories. On the surface, changes in the official collective memory of World War II found in textbooks are striking. Many of the things routinely included in post-Soviet Russian textbooks in 2005 would have landed people in prison had they written them in the Soviet Union of 1970. For example, the Communist Party was routinely feted as the moving force of history in Soviet accounts, but post-Soviet history textbooks, as well as the popular press, stress that it was the masses of Russian people, not the party, that won World War II. Indeed, some of these post-Soviet accounts go out of their way to say it was 'despite' the party and only through the heroism of the Russian people that the country won the war (Wertsch, 2002).

Another form of evidence that points to the conservative nature of this narrative template in Russian national consciousness can be found in references to Hitler as a second Napoleon. This formulation has remained constant across the radical changes in Russian accounts, and of course it also provides a reminder that the narrative tools used by one collective can be quite distinct from those used in other places. Whereas this is a familiar and widely repeated expression for Russians, it is not something that most Americans would have heard repeatedly as they grew up.

A great deal remains to be studied when it comes to understanding the degree to which collective remembering does or does not change. The line of argument developed by Wertsch (2002) suggests that specific narratives may change fairly quickly, but at the level of schematic narrative templates, there is a high level of conservatism and resistance to change.

Schuman et al. (2005) have recently presented a more elaborated picture of this issue. They examined Americans' account of Columbus over the past few decades and draw an important distinction between what happens with elite revisionists, on the one hand, and popular beliefs, on the other. They report that elite culture's attempt to revise the narrative about this figure has had an impact on what is presented in forums such as textbooks, but it has not had the impact on popular beliefs that one might expect. The endurance of Columbus's reputation and the "inertia of tradition" (Schuman et al., 2005: 3) can be understood only by differentiating elite and popular beliefs and tracing their dynamics.

## 2.48.4 Conclusion

The three traditions of inquiry on collective memory that I have outlined provide different visions of what makes collective memory collective. In many cases, however, differences stem more from disciplinary isolation rather than conceptual contradiction. Little citation of literature across the traditions occurs, and in many cases they do not even seem to know of the others' existence.

The study of the social framing of collective remembering has been conducted largely by psychologists and is viewed by sociologists such as Olick (1999) as being such a distinct approach that it should be labeled collected rather than collective memory. The concern with collective memory in the construction of social groups has surfaced largely in sociology and political science and shows only occasional signs of contact with the psychological study of memory. And studies of collective memory as semiotic distribution have been conducted primarily in disciplines such as history, semiotics, and anthropology, often with little benefit from the findings of the other two traditions.

Despite the dearth of contact among these approaches, there are several obvious points of contact to be made in building a more comprehensive picture of collective memory. For example, obvious complementarities exist between sociological studies of the role of memory in the formation of generations and psychological studies of the reminiscence bump. Other points of contact may have even more potential. For example, claims about the role of memory in the social formation of groups often imply notions of narrative tools, and for this reason, statements about remembered communities and people-making are as much about national narratives as about political processes.

It remains useful at this point, however, to recognize the differences among traditions of inquiry in the field of collective memory studies since this suggests a conceptual map of ideas and methods. In the end, the justification for such a map will be its ability to generate new ideas and insights into collective memory phenomena that are widely noted, but little understood. The field is rich enough that it will require a diverse set of constructs and methods to address the issues. One of the key issues that will undoubtedly continue to shape the discussion, however, will be how these ideas and methods fit together into some sort of integrated whole.
